LIST OF CONTRIBUTORS TO VOLUME IV.

SAMUEL W. ABBOTT, M.D.......Newton Centre, Mass.
Secretary of the Massachusetts State Board of Health, Lunacy and Charity.

J. GEORGE ADAMI, M.D......Montreal, Canada.
Professor of Pathology, McGill University Medical School; Pathologist, Royal Victoria Hospital.

ADOLF ALT, M.D....................St. Louis, Mo.
Professor of Ophthalmology, Beaumont Hospital Medical College.

EDWARD B. ANGELL, M.D......Rochester, N. Y.
Neurologist to the Rochester City Hospital.

GEORGE E. ARMSTRONG, M.D........Montreal, Canada.
Associate Professor of Clinical Surgery, McGill University Medical School; Attending Surgeon, Montreal General Hospital.

JAMES RAE ARNEILL, M.D....Ann Arbor, Mich.
Instructor in Clinical Medicine, Medical Department of the University of Michigan.

SAMUEL ASHHURST, M.D......Philadelphia, Pa.
Surgeon, Children's Hospital, Philadelphia.

JAMES B. BAIRD, M.D..............Atlanta, Ga.
Professor of Clinical Medicine, Southern Medical College; Attending Physician, Grady Hospital.

FRANK BAKER, M.D. ....Washington, D.C.
Professor of Anatomy, Georgetown University School of Medicine, Washington, D. C.; Superintendent, National Zoological Park, Smithsonian Institution.

SIMON BARUCH, M.D...........New York, N. Y.
Attending Physician, J. Hood Wright Memorial Hospital; Consulting Physician, Montefiore Home.

WALTER ARTHUR BASTEDO, Ph.G., M.D...New York, N. Y.
Formerly Instructor in Materia Medica, University and Bellevue Hospital Medical College, and Torrey Lecturer on Botany at the New York College of Pharmacy.

HENRY WALD BETTMAN, M.D..Cincinnati, Ohio.

ROBERT PAYNE BIGELOW, Ph.D..Boston, Mass.
Instructor in Biology, Massachusetts Institute of Technology.

ALEXANDER D. BLACKADER, M.D....Montreal, Canada.
Professor of Pharmacology and Therapeutics, and Lecturer on Diseases of Children, McGill University Medical School.

JOSEPH AUGUSTUS BLAKE, M.D.....New York, N. Y.
Instructor in Surgery, College of Physicians and Surgeons, Medical Department of Columbia University; Attending Surgeon, St. Luke's Hospital; Junior Surgeon, Roosevelt Hospital.

ALBERT N. BLODGETT, M.D.......Boston, Mass.

W. P. BOLLES, M.D................Roxbury, Mass.
Professor of Materia Medica and Botany, Emeritus, Massachusetts College of Pharmacy; Surgeon, Boston City Hospital.

JOHN T. BOWEN, M.D.............Boston, Mass.
Physician for Diseases of the Skin, Massachusetts General Hospital; Instructor in Dermatology, Harvard University Medical School.

MAJOR A. E. BRADLEY.....Fort Snelling, Minn.
Surgeon, United States Army.

WILLIAM NORTON BULLARD, M.D.......Boston, Mass.
Physician to the Department of Diseases of the Nervous System, Boston City Hospital; Neurologist to the Children's Hospital; Consulting Neurologist, Carney Hospital.

STRICKER COLES, M.D.........Philadelphia, Pa.
Demonstrator of Obstetrics and Lecturer on Clinical Obstetrics at the Jefferson Medical College; Assistant Obstetrician to Jefferson Maternity Hospital.

WILLIAM T. COUNCILMAN, M.D....Boston, Mass.
Shattuck Professor of Pathological Anatomy, Harvard University Medical School.

LUZERNE COVILLE, M.D...........Ithaca, N. Y.
Lecturer and Demonstrator in Anatomy, Cornell University Medical College at Ithaca.

MONTGOMERY ADAMS CROCKETT, M.D...Buffalo, N. Y.
Adjunct Professor of Obstetrics and Gynæcology, University of Buffalo Medical School; Gynæcologist to the Buffalo General and Erie County Hospitals.

JAMES KING CROOK, M.D......New York, N. Y.
Adjunct Professor of Clinical Medicine and Physical Diagnosis, New York Post-Graduate Medical School; Attending Physician, Post-Graduate Hospital.

EDWARD CURTIS, M.D......... New York, N. Y.
Emeritus Professor of Materia Medica and Therapeutics, College of Physicians and Surgeons, Columbia University.

JOHN G. CURTIS, M.D...........New York, N. Y.
Professor of Physiology, Columbia University in the City of New York.

CHARLES TOWNSHEND DADE, M.D........New York, N. Y.
Clinical Assistant, Department of Dermatology, Vanderbilt Clinic, Columbia University; Attending Dermatologist, Randall's Island Hospital.

NATHAN SMITH DAVIS, Jr., M.D.....Chicago, Ill.
Professor of the Principles and Practice of Medicine, Northwestern University Medical School; Attending Physician, Mercy Hospital and Wesley Hospital.

D. BRYSON DELAVAN, M.D.....New York, N. Y.
Professor of Laryngology, New York Polyclinic; Consulting Laryngologist, General Memorial Hospital, and the Hospital for Ruptured and Crippled.

WILLIAM S. DENNETT, M.D....New York, N. Y.
Surgeon to the New York Eye and Ear Infirmary, Department of the Eye.

GEORGE W. DOBBIN, M.D........Baltimore, Md.
Associate in Obstetrics, Johns Hopkins University; Professor of Obstetrics, College of Physicians and Surgeons, Baltimore.

MAX EINHORN, M.D ....New York, N. Y.
Professor of Medicine, New York Post-Graduate Medical School; Visiting Physician to the German Dispensary.

ERASMUS DARWIN FENNER, M.D......New Orleans, La.
Lecturer and Clinical Instructor in Diseases of Children, Tulane University of Louisiana; First Assistant Surgeon, Charity Hospital, New Orleans.

FREDERICK G. FINLEY, M.D..Montreal, Canada.
Assistant Professor of Medicine, and Associate Professor of Clinical Medicine, Medical Department, McGill University.

WILLIAM HASTY FLINT, M.D...Santa Barbara, Cal.

EDWARD MILTON FOOTE, M.D.......New York, N. Y.
Instructor in Minor Surgery, Medical Department, Columbia University; Visiting Surgeon, City Hospital.

GEORGE RYERSON FOWLER, M.D....Brooklyn, N. Y.
Professor of Surgery, New York Polyclinic; Surgeon-in-Chief, Brooklyn Hospital; Consulting Surgeon, St. Mary's Hospital.

GEORGE C. FREEBORN, M.D....New York, N. Y.
Instructor in Normal Histology, Medical Department of Columbia University.

JAMES MAGOFFIN FRENCH, M.D....Cincinnati, Ohio.
Lecturer on Theory and Practice, Medical College of Ohio, Cincinnati; Attending Physician, St. Mary's Hospital.

HENRY GRADLE, M.D.......... ....Chicago, Ill.
Professor of Ophthalmology and Otology, Northwestern University Medical School, Chicago.

JOHN GREEN, M.D.................St. Louis, Mo.
Special Professor of Ophthalmology, Medical Department of Washington University, St. Louis.

NORMAN B. GWYN, M.D........Philadelphia, Pa.
Instructor in Medicine, Medical Department, University of Pennsylvania.

JOHN B. HAMILTON, M.D.*....Washington, D. C.
Surgeon-General, United States Marine Hospital Service; Professor of Surgery, Medical Department, University of Georgetown, Washington, D. C.

GRAEME MONROE HAMMOND, M.D..New York, N. Y.
Professor of Nervous and Mental Diseases, Post-Graduate Medical School and Hospital; Attending Neurologist to City (Charity) Hospital.

HOBART AMORY HARE........Philadelphia, Pa.
Professor of Materia Medica and Therapeutics, Jefferson Medical College.

MILTON B. HARTZELL, M.D....Philadelphia, Pa.
Instructor in Dermatology, University of Pennsylvania Medical School; Dermatologist to the Methodist Hospital of Philadelphia and to the Philadelphia Hospital.

LUTHER LEONIDAS HILL, M.D......Montgomery, Ala.
Surgeon to the Hill Infirmary, Montgomery, Ala.

CURTIS C. HOWARD, M.Sc....... Columbus, Ohio.
Professor of Chemistry and Toxicology, Starling Medical College.

GEORGE THOMAS JACKSON, M.D....New York, N. Y
Instructor in Dermatology and Chief of Clinic, Medical Department, Columbia University; Consulting Dermatologist, Presbyterian Hospital and the New York Infirmary for Women and Children.

WILLIAM KEILLER, F.R.C.S. (Edin.)....Galveston, Texas.
Professor of Anatomy, Medical Department, University of Texas.

ALOYSIUS O. J. KELLY, M.D....Philadelphia, Pa.
Instructor in Clinical Medicine, University of Pennsylvania Medical School; Professor of the Theory and Practice of Medicine, University of Vermont Medical School; Pathologist to the German Hospital, Philadelphia; Physician to St. Mary's and St. Agnes' Hospitals, Philadelphia; Assistant Physician to the Hospital of the University of Pennsylvania.

GEORGE T. KEMP, Ph.D...........Champaign, Ill.
Professor of Physiology, University of Illinois.

EDWARD L. KEYES, Jr., M.D...New York, N. Y.
Assistant Demonstrator of Anatomy, Cornell University Medical College in New York City.

GEORGE MARTIN KOBER, M.D......Washington, D. C.
Professor of Hygiene and State Medicine, Georgetown University Medical School; Consulting Physician to Children's, Emergency, and University Hospitals, Washington, D. C.

WILMER KRUSEN, M.D.........Philadelphia, Pa.
Instructor in Gynæcology, Jefferson Medical College; Assistant Gynæcologist, St. Joseph's Hospital; Fellow of College of Physicians, Philadelphia.

MAJOR LOUIS A. La GARDE, U. S. Army...Washington, D. C.
Attending Surgeon, United States Soldiers' Home, Washington, D. C.

ALEXANDER LAMBERT, M.D...New York, N. Y.
Professor of Clinical Medicine and Instructor in Physical Diagnosis, Cornell University Medical College in New York City; Physician to Bellevue Hospital.

RALPH CLINTON LARRABEE, M.D..Boston, Mass.
Assistant in Histology, Harvard University Medical School; Physician to Out-Patients, Boston City Hospital.

AUGUST JEROME LARTIGAU, M.D....New York N. Y.
Tutor in Pathology, College of Physicians and Surgeons, Columbia University; Pathologist to Sloane Maternity Hospital; Assistant Pathologist to Roosevelt Hospital.

ALBERT E. LEACH...........Newtonville, Mass.
Analyst of the Massachusetts State Board of Health.

E. R. Le COUNT, M.D............... Chicago, Ill.
Assistant Professor of Pathology, Rush Medical College; Associate Attending Pathologist, Cook County Hospital; Pathologist to St. Elizabeth Hospital, Chicago.

WILLIAM M. LESZYNSKY, M.D..New York, N Y.
Consulting Neurologist to the Manhattan Eye and Ear Hospital; Neurologist to the Demilt Dispensary and the German Poliklinik.

LIST OF CONTRIBUTORS TO VOLUME IV.

ALFRED L. LOOMIS, M.D.*.....New York, N. Y.
Formerly Professor of Pathology and Practice of Medicine, Medical Department, University of the City of New York; Physician to Bellevue Hospital.

GEORGE BURGESS MAGRATH, M.D......Boston, Mass.
Assistant in Pathology, Harvard University Medical School.

FRANKLIN P. MALL, M.D.........Baltimore, Md.
Professor of Anatomy, Johns Hopkins Medical School.

FRANK BURR MALLORY, M.D......Boston, Mass.
Associate Professor of Pathology, Harvard University Medical School.

CHARLES SEDGWICK MINOT, S.D., LL.D....Boston, Mass.
Professor of Histology and Human Embryology, Harvard University Medical School.

DOUGLASS WILLIAM MONTGOMERY, M.D..San Francisco, Cal.
Professor of Diseases of the Skin, University of California Medical School.

JOHN H. MUSSER, M.D........ .Philadelphia, Pa.
Assistant Professor of Clinical Medicine, Medical Department, University of Pennsylvania; Physician to the Philadelphia and Presbyterian Hospitals.

RICHARD COLE NEWTON, M.D..Montclair, N. J.
Attending Surgeon, Montainside Hospital, Montclair.

JOHN BENJAMIN NICHOLS, M.D....Washington, D. C.
Demonstrator of Histology in the Medical Department of Columbian University, Washington; Assistant Pathologist, Garfield Hospital and Columbia University Hospital.

SAMUEL NICKLES, M.D.........Cincinnati, Ohio.
Emeritus Professor of Materia Medica and Therapeutics, Medical College of Ohio.

FREDERICK G. NOVY, Sc.D., M.D ....Ann Arbor, Mich.
Junior Professor of Hygiene and Physiological Chemistry, University of Michigan.

OLIVER T. OSBORNE, M.D.....New Haven, Conn.
Professor of Materia Medica and Therapeutics, Medical Department, Yale University.

EDWARD OSGOOD OTIS, M.D. .....Boston, Mass.
Visiting Physician, Free Home for Consumptives, Boston; Physician to the Department of Pulmonary Tuberculosis, Boston Dispensary.

WILLIAM K. OTIS, M.D...........New York, N. Y.
Attending Surgeon, St. Mark's Hospital; Consulting Surgeon, City (Charity) Hospital, New York.

ROSWELL PARK, M.D. ....Buffalo, N. Y.
Professor of Surgery, University of Buffalo Medical School; Surgeon to the Buffalo General Hospital.

WILLIAM H. PARK, M.D. ......New York, N. Y.
Associate Professor of Bacteriology and Hygiene, The University and Bellevue Hospital Medical College.

JAMES RUSSELL PARSONS, Jr., M.A.....Albany, N. Y.
Secretary of the University of the State of New York; Director of the College and High School Departments of the University.

RICHARD MILLS PEARCE, M.D....Philadelphia, Pa.
Demonstrator of Pathology, Medical Department, University of Pennsylvania.

AUSTIN PETERS, B.S., D.V.S., M.R.C.V.S..Jamaica Plain, Mass.
Chairman of the Massachusetts Cattle Commission.

W. F. R. PHILLIPS, M.D.........Washington, D. C.
United States Weather Bureau, Washington, D. C.

N. J. PONCE DE LÉON, M.D.....New York, N. Y.
Assistant Visiting Physician, Department of Diseases of Children, Dispensary of Cornell University Medical School in New York City.

JOSEPH HERSEY PRATT, M.D......Boston, Mass.
Instructor in Pathology, Harvard University Medical School; Second Assistant Visiting Pathologist, the Boston City Hospital.

LEOPOLD PUTZEL, M.D.........New York, N. Y.

DAVID RIESMAN, M.D..........Philadelphia, Pa.
Demonstrator of Pathological Histology and Morbid Anatomy, Medical Department, University of Pennsylvania.

HENRY H. RUSBY, M.D............Newark, N. J.
Professor of Botany, Physiology, and Materia Medica, New York College of Pharmacy; Professor of Materia Medica, University and Bellevue Hospital Medical College.

FRANK RUSSELL, S.M., Ph.D....Cambridge, Mass.
Instructor in Anthropology, Department of Arts and Sciences, Harvard University.

R. J. E. SCOTT, M.D...........White Plains, N. Y.
Attending Physician, Bellevue Hospital, Out-Patient Department.

WILLIAM WOTKYNS SEYMOUR, M.D......Troy, N. Y.
Formerly Professor of Gynæcology, Medical Department, University of Vermont; Surgeon to the Samaritan Hospital, Troy, N. Y.

FREDERICK C. SHATTUCK, M.D....Boston, Mass.
Jackson Professor of Clinical Medicine, Harvard University Medical School; Visiting Physician, Massachusetts General Hospital.

GEORGE B. SHATTUCK, M.D ....Boston, Mass.
Visiting Physician, The Boston City Hospital.

DANIEL KERFOOT SHUTE, M.D....Washington, D. C.
Professor of Anatomy, Medical Department, Columbian University; Professor of Neurology in the School of Graduate Studies, the same university; Ophthalmic Surgeon to the University Hospital; Visiting Physician to the National Deaf-Mute College.

BERTRAM W. SIPPY, M.D.............Chicago, Ill.
Assistant Professor of Medicine, Rush Medical College, in affiliation with the University of Chicago; Attending Physician, Cook County Hospital and Chicago Baptist Hospital.

BEAUMONT SMALL, M.D........Ottawa, Canada.
Attending Physician, St. Luke's General Hospital; Consulting Physician, The Children's Hospital; Late Examiner in Materia Medica, College of Physicians and Surgeons, Ontario.

ERNEST ELLSWORTH SMITH, M.D., Ph.D..New York, N. Y.
Pathologist, St. John's Hospital, Yonkers, N. Y.

M. ALLEN STARR, M.D..........New York, N. Y.
Professor of Diseases of the Mind and Nervous System, Medical Department, Columbia University; Consulting Physician, Presbyterian, St. Vincent's and St. Mary's Hospitals and the New York Eye and Ear Infirmary.

H. S. STEENSLAND, M.D..........SYRACUSE, N. Y.
Lecturer on Pathology, College of Medicine, Syracuse University; Pathologist to St. Joseph's Hospital, the Hospital of the Good Shepherd, and the Hospital for Women and Children.

BRIGADIER-GENERAL GEORGE M. STERNBERG. WASHINGTON, D.C.
Surgeon-General, United States Army.

LUCIEN MARCUS UNDERWOOD, PH.D......NEW YORK, N. Y.
Professor of Botany, Columbia University in the City of New York.

ALBERT VANDER VEER, PH.D., M.D.....ALBANY, N. Y.
Professor of Didactic, Abdominal and Clinical Surgery, Albany Medical College; Attending Surgeon, Albany Hospital; Consulting Surgeon, St. Peter's Hospital.

FRANK VAN FLEET, M.D.......NEW YORK, N. Y.
Professor of Diseases of the Eye, Post-Graduate Medical School and Hospital; Surgeon, Manhattan Eye and Ear Hospital.

EMMA ELIZABETH WALKER, M.D....NEW YORK, N. Y.
Clinical Assistant, Hospital for the Relief of the Ruptured and Crippled.

GEORGE LINCOLN WALTON, M.D..BOSTON, MASS.
Clinical Instructor in Diseases of the Nervous System, Harvard University Medical School; Physician, Neurological Department of the Massachusetts General Hospital.

GEORGE GRAY WARD, JR., M.D......NEW YORK, N. Y.
Adjunct Professor of Diseases of Women, New York Post-Graduate Medical School and Hospital; Instructor in Obstetrics, Cornell University Medical College in New York City.

HENRY BALDWIN WARD, PH.D...LINCOLN, NEB.
Professor of Zoology, University of Nebraska; Zoologist of the State Board of Agriculture.

ALDRED SCOTT WARTHIN, M.D....ANN ARBOR, MICH.
Assistant Professor of Pathology, Medical Department, University of Michigan.

BROOKS H. WELLS, M.D........NEW YORK, N. Y.

ROYAL WHITMAN, M.D.........NEW YORK, N. Y.
Chief of Clinic and Instructor in Orthopædic Surgery, Medical Department, Columbia University.

JAMES MACFARLANE WINFIELD, M.D...BROOKLYN, N. Y.

CHARLES F. WITHINGTON, M.D....BOSTON, MASS.
Instructor in Clinical Medicine, Harvard University Medical School.

RUDOLPH A. WITTHAUS, M.D....NEW YORK, N. Y.
Professor of Chemistry, Physics and Toxicology, Cornell University Medical College in New York City.

PHILIP ZENNER, M.D..........CINCINNATI, OHIO.
Clinical Lecturer on Diseases of the Nervous System, Medical College of Ohio.

---

* Deceased since the issue of the first edition.

A REFERENCE HANDBOOK

OF

THE MEDICAL SCIENCES.

ERGOT (*Ergota*, U. S. P., Br. P.; *Secale cornutum*, Ph. G.; *Ergot de Seigle*, Codex Med.), *Fungus Secalis; Mutterkorn;* Spurred Rye, etc., consists of the sclerotium of *Claviceps purpurea* (Fries) Tulasne, Order *Ascomycetes*, replacing the grains of rye, *Secale cereale* Linn. Our Pharmacopœia prescribes that ergot should be only moderately dried, preserved in a closed vessel, chloroformed occasionally to prevent the development of insects, and rejected as unfit for use when more than a year old. This remarkable parasite is developed in the flowers of several cultivated grains and of a considerable number of wild grasses, germinating upon the ovaries, which it aborts and finally destroys, and growing in the place of these organs like some monstrosity of the flowers themselves. It attains to a sort of maturity as the grain ripens in the fall, and in this condition remains quiescent until the following season, when, if in a suitable situation, as upon the surface of damp ground, it produces spores in time to attack the blossoming grasses and grains of the succeeding year. It is this resting-stage which constitutes the "sclerotium."

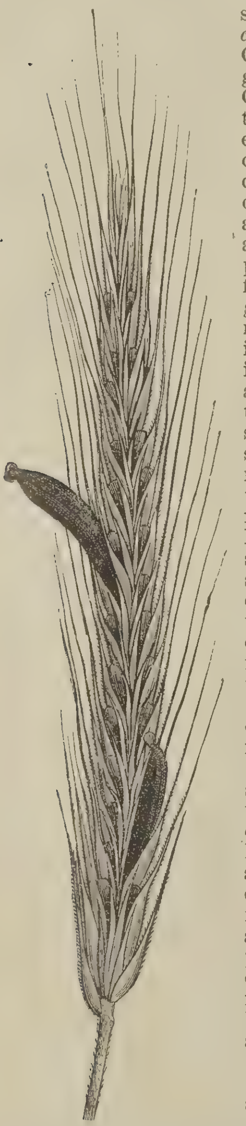

FIG. 1940.—Ear of Rye with two Ergots. Natural size. (From Luerssen.)

The first noticeable evidence of the presence of this fungus in a spikelet, say of rye or wheat, is a sticky, unpleasant-smelling, very sweet, liquid exudation from the interior of one of the flowers, which accumulates in considerable quantity, and may even drop off or run down the stem. It consists mostly of some sort of sugar, and is probably a decomposition product of the affected pistil, etc. Like similar results of the irritation of vegetable tissues by other fungi, as well as by aphides, etc., it is known as "honey dew," and designated the "honey dew of rye." It is a certain sign that ergot will follow. Ants and beetles are fond of it, flock to the ears where it is to be found, and as it contains cells capable of developing into ergot in other flowers, they assist in spreading the blight. Bees are said to avoid it. A soft, spongy or cottony, mould-like tissue, consisting of long, fine, weak filiform cells, felted together at this time, envelops and permeates the ovary; as it grows the latter becomes disorganized and disappears, and the *mycelium* of the ergot, as this structure is called, takes its place. In a short time after, a very redundant and much wrinkled layer of perpendicular cells covers the surface of the mycelium, and produces an innumerable number of minute oblong false spores (*conidia*), which are discharged into the adhesive "honey dew" just mentioned. These are capable of reproducing the plant, and are the first method of propagation. In this stage it was at one time considered to be an adult and perfect plant, and named *Sphacelia segetum* (Léveillé, 1827) (see Fig. 1941). A further development next takes place in the formation and growth of the *sclerotium.* This begins as a condensation of tissue at the base of the "sphacelium" just described, the cells of which become shorter and thicker-walled, as well as more closely packed together. The mass becomes firm and brittle as it develops, the outer surface assumes a purple-black color, and it finally grows to a long spur-like, curved, irregularly cylindrical body protruding half its length or more beyond the plumes and paleæ of the rye. The "sphacelium" atrophies as the sclerotium grows, and is carried up on the apex, as

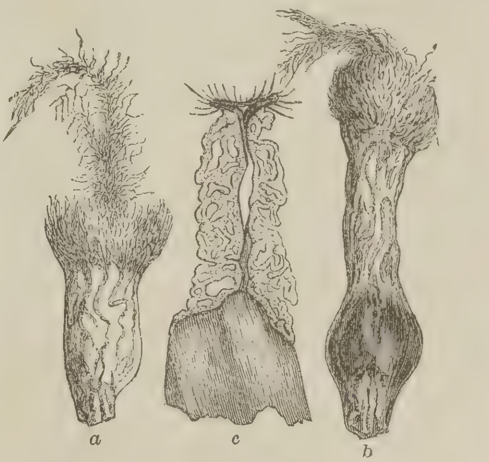

FIG. 1941.—*a*, Ovary of Rye with Commencing Growth of Claviceps in the Sphacelia Stage; *b*, the same with the parasite further developed; the hairy styles and the remains of the ovary are borne at the top of the mycelium, the commencing sclerotium or ergot is shown at the base; *c*, section of specimen a little older than *b*, and rather more magnified; the two styles and aborted ovary are seen at the top, the ruminated sphacelia in the middle portion, and the compact smooth ergot below. (Luerssen.)

are also any remains of the unfortunate pistil (see Fig. 1941). When the ergot is fully grown and gathered, scarcely any traces of either of these are to be found. At this stage ergot was also considered a distinct plant from the above, and it received separate names (*Sclerotium clavus* De Candolle, 1816, etc.). The growth of the first season terminates with the *sclerotium*, but in the early summer of the next year several minute globular heads raised upon stalks, half an inch or more in length, and looking like miniature "toadstools," grow from the sides of this organ and bear, in numerous cavities (*perithecia*), a multitude of groups of long and slender spores (see Figs. 1942 and 1943). These spores, applied to the flowers of suitable grasses, are capable of reproducing the whole series of forms described above, and complete the life history of the fungus. It is interesting to note that this stage of claviceps was also known long before its connection with the others was made out, and it was described and named by several authors (*e.g.*, *Sphæria*, *Cordiceps*, etc.).

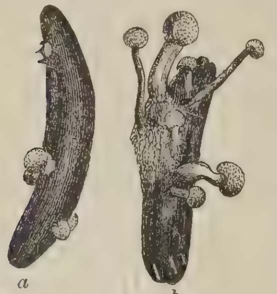

FIG. 1942.—Ergot in its Final Fructifying Stage. (Luerssen.)

The first botanist to follow the course of this plant through all its changes was M. Tulasne, who gave it its present name, and finally published his report upon it in the *Annales des Sciences Naturelles* for 1853. His investigations were so thorough, and his illustrations so fine, that but little has been added to either, so far at least as the botany of ergot is concerned.

HABITAT.—*Claviceps purpurea* is found in most temperate countries where the grains and grasses upon which it flourishes grow. It is, however, much less abundant in this country than in Europe, and there it occurs most generally in the warmer and moister countries. It is gathered in Central Europe, and especially in Spain and Central and Southern Russia. It is an incidental product of agriculture, and is sorted out from the grain at the harvest with the double purpose of collecting the ergot and of removing its baneful influence from the grain. Ergot of wheat is occasionally saved; it is shorter and thicker than that of rye, and medicinally equally good.

HISTORY.—Ergot has long been known as a blight upon grain and as a poison, but its medicinal history is comparatively modern. It appears to have been used by the peasantry, in some parts of Europe, in childbirth as much as three hundred years ago, and is mentioned by several authors of the sixteenth and seventeenth centuries in this connection; but its formal introduction into modern medicine is due to the efforts of Dr. Stearns, of New York, in the early part of the last century.

DESCRIPTION. — The above - described "*sclerotiums*," which constitute ergot, are from 1.5 to 3 cm. (½ to a little more than 1 in.) long and 3 mm. (1/8 in.) thick, oblong, tapering toward, but obtuse at both ends, triangular-cylindraceous, the sides unequally grooved; externally purple-black, nearly smooth; internally whitish, with purplish tinge or striæ, the fracture short, not sharp nor snapping; odor peculiar, disagreeable, especially upon trituration with potassium or sodium hydrate T. S.; taste oily and disagreeable. It moulds and spoils rather easily, and should be kept fresh and dry. It should not be broken or ground until needed for use. Microscopically it consists of closely entwined, elongated, thick-walled cells containing an abundance of oil drops. Of the commercial varieties, Russian and Spanish ergots are commonly preferred. Small or medium-sized grains are believed to be superior to very large ones.

COMPOSITION.—Ergot has been repeatedly examined within the past half-century, with the result of exhibiting a more and more complex composition with each successive investigation; but its active principle, if indeed there be any one substance entitled to the name, is still in doubt. One of its most abundant constituents is a *fat*, of which it contains from one-fourth to nearly one-third of its weight. This is a thick, bland, non-drying, light yellow oil consisting chiefly of olein with some palmitin and traces of glycerides of several common volatile, fatty acids. It has no therapeutic value, but is reported to be not without disagreeable action. It is recommended by Hager (as it is obtained in considerable quantity as a by-product of ergot preparations) for soaps and as a lubricant. A little *cholesterin* and *resin*, some *mycose* (sugar), several common *acids*, a fragrant *camphoraceous substance*, etc., are ingredients of no medicinal importance. In regard to the more active substances, scarcely any two chemists are agreed. *Ergotin* is a name given to various products, none of which is chemically pure. First, Bonjean's "ergotin" is prepared by treating a watery extract of ergot with alcohol, and evaporating the alcoholic solution to the consistence of a soft extract. It is a deep brown, strong-smelling, bitter substance, soluble in water and alcohol, of considerable activity and of frequent employment, but not an active principle properly so called. Wigger's ergotin was obtained by exhausting the ergot of wax, fat, etc., by means of ether, and then extracting with alcohol, evaporating the tincture, and washing with water. It is a sharp, bitter, reddish-brown powder, insoluble in water. Wenzell's *ergotine* (1864) was obtained by a more complicated process, and comes nearer the rank of a chemical compound. It is a brown, amorphous, bitter, alkaline substance, soluble in alcohol and water, but not in ether, and uniting with acids to form amorphous salts. Wenzell also separated another alkaloid, which he named *ecboline*, resembling his ergotine in most respects; on the other hand, other chemists assert that both of Wenzell's two alkaloids are practically the same, and that neither is pure. Tanret has isolated a crystalline alkaloid, which he has named *ergotinine*, soluble in ether, alcohol, and chloroform, but not in water. Its solutions rapidly decompose, and its value is not yet proved. A still more recent and very thorough analysis of ergot was made a few years ago in the laboratory of Dragendorff, with the result of separating the following, more or less well-defined, amorphous substances: 1. *Sclerotic acid*, a (yellowish-brown) hygroscopic, faintly acid, tasteless powder, obtained to the extent of from two to four per cent. 2. *Scleromucin*, a nearly related substance, two or three per cent. 3. *Sclererythrin*. 4. *Sclerojodin*, a coloring matter. 5. *Scleroanthin*. 6. *Sclerocrystalline*, etc. Sclerotic acid is an article of commerce, but not much called for. The others, excepting Bonjean's ergotin, are scarcely known excepting to the chemists who have isolated them.

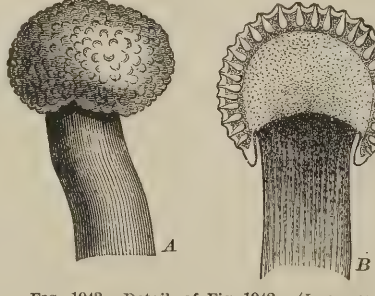

FIG. 1943.—Details of Fig. 1942. (Luerssen.)

Ergotic acid is a doubtful substance. *Ergotinic acid*, *sphacelinic acid*, and *cornutine*, described by Kobert, although none of them pure chemical compounds, are thought by Cushny most perfectly to represent the three distinct actions of the drug. Sphacelotoxin is regarded by Jacoby as the active constituent of sphacelinic acid, though this again appears resolvable into constituents, of which the most important one is called chrysotoxin.

From the foregoing it will be readily seen that ergot is not amenable to chemical assay for the determination of its quality, although, because of the highly varying action of different commercial samples, to some extent in kind as well as in degree, there are few drugs more in need of it. Under these circumstances, Houghton's method of physiological assay becomes of great interest. This consists in feeding the drug to fowls, then noting the extent and promptness of the discoloration of the comb, and finally rejecting any ergot which does not produce an effect reaching to a fixed standard. To this method various *a priori* objections have been urged by those who have not resorted to the very simple expedient of ascertaining the practical results of the method, which appear to have been the putting of an end to complaints of irregular or uncertain action.

Action.—The action of ergot and of its constituents is extremely complicated and can as yet by no means be said to be understood, though great progress has recently been made. We have now a fair knowledge of its practical effects as a drug. Our lack of knowledge relates mainly to the different effects produced by the different constituents, with the resulting disadvantage that we are unable intelligently to administer different preparations to meet special cases. The two most important effects of the drug are the prolonged contraction of the arteries, and the physiological strengthening of the natural rhythmic contractions of the uterus. Both of these effects are of complex origin, but primarily and principally due to the chrysotoxin or sphacelotoxin. In the production of the former effect, the chrysotoxin acts chiefly by stimulating the vaso-motor centre, to a lesser extent by acting directly upon the artery. At the same time, the vaso-motor centre is stimulated by the cornutine, but this stimulation is spasmodic and irritable, and is succeeded by depression, which, when the entire drug is used, may be supposed to act against the chrysotoxin, as there is often an early fall of blood pressure. This antagonism is still farther induced by the ergotinic acid, which is a direct depressor of the vaso-motor centre and of the heart, if introduced directly into the circulation. To get the full arterial effect, therefore, preparations of ergot should be given by the mouth, although the other method is preferable if we desire to secure a prompt action. In spite, however, of these antagonisms, the net effect is a powerful, prolonged contraction of all the smaller arteries, with a consequent marked increase of blood pressure, going on, *pari passu* with the administration of the drug, to dry gangrene and loss of the extremities, and to extravasation of blood into the viscera.

The effect upon the uterus is primarily due to spinal stimulation by the chrysotoxin, but there is evidently also a direct action upon its walls.

Upon the intestine, the effect of ergot is to increase peristalsis, but at the same time to diminish secretion, as is true of the secretions generally, due to diminished arterial supply.

Uses.—Ergot is chiefly employed as an ecbolic, being given in the later stages of parturition, especially to secure the complete emptying of the uterus, and to check hemorrhage. Formerly it was given at one stage earlier, to favor the expulsion of the placenta, but this practice is now generally discouraged. Against these views are still those of some excellent practitioners who recommend the early moderate use of ergot to promote labor.

Next to this use of ergot, that for checking internal hemorrhages, especially of dysentery, may be considered the most extensive. Its use has been found favorably to affect aneurisms. It is also very largely employed in the relief of headache resulting from prolonged mental activity and excitement, and whenever congestion exists. It also gives marked relief to conjunctivitis of a similar character.

Finally, it will frequently be found to do good service as an aphrodisiac, although in many cases it will fail.

Preparations and Doses.—The unofficial preparations of ergot are exceedingly numerous, and the practitioner should treat them with great conservatism, owing to the possible serious change in property resulting from slight differences in the mode of extraction. Since the cornutine and sphacelotoxin are alcohol-soluble, the ergotinic acid water-soluble, both solvents should be used in the extraction. The official fluid extract, especially if having been found to meet a satisfactory physiological test, made with diluted alcohol, and with the addition of two per cent. of acetic acid, answers every requirement. It may be given in doses of from 2 to 4 c.c. (fl. ʒ ss.–i.); the wine of fifteen-per-cent. strength may be given in doses four or five times as large; the extract ("ergotin") is considerably used in doses of 0.3 to 1 gm. (gr. v.–xv.).

ERYSIPELAS.—(Fr. *Erysipèle;* Ger. *Rothlauf*).* Definition and Etiology. By the term "erysipelas" is understood a disorder of the general system, of febrile nature, cyclic character, and varying severity, which is caused by the introduction, into the body, of a specific pathogenic germ of bacterial form. This is of the streptococcus variety, and was first described by Fehleisen, and for that reason is called by his name.†

The disease is seated upon an epithelial surface, either of the skin or of a mucous membrane. When situated upon the skin, it is characterized by a sharply defined area of redness, which gradually advances to occupy a larger surface, is accompanied by a relatively intense febrile action, and generally terminates in complete recovery, with exfoliation of the epidermis upon the surface which was the seat of the disease. One attack of the disease affords no immunity against recurrence, in the same or another locality, and it may involve the mucous membranes as well as the outer covering of the body. The accounts of some of the earlier of the known epidemics represent a much severer type of disease than the erysipelas of our day.

From a careful study of cases, as well as from experimental inoculations, the period of incubation of erysipelas has been estimated as being not less than fifteen nor more than sixty hours. A specific germ, the streptococcus of erysipelas, is found in all cases of the pure disease and is capable of transmitting the malady to healthy individuals in series. This germ is found in the lymphatic vessels of the skin and in the lymph spaces, and when the culture is pure, it is believed never to produce suppuration.‡

Infection with the streptococcus of Fehleisen produces at the point of inoculation a special inflammation of the integument, external or internal, of which the characteristic tendency is its extension peripherally, until the virulence of the micro-organism is exhausted, or the individual attacked has become immune to the disease.

At present, no difference in character or nature is recognized between erysipelas of the face (so-called "spontaneous" or "medical" erysipelas) and erysipelas following wounds ("traumatic" or "surgical" erysipelas). Contagion is the simple, inevitable, and indispensable cause of the disease.

It is always necessary that there should be a door of entrance for the microbe, and if careful search fails to discover a solution of continuity of the surface of the skin, we must still admit that such an abrasion of either the skin or the adjacent mucous membrane really exists. In certain cases it would seem that the simple absence of epidermis or epithelium is in itself sufficient to allow the entrance of the poison of erysipelas into the system. In this direction the occurrence of erysipelas in young and imperfect cicatrices from recent injuries is interesting. Warren says that it is probable that healthy skin offers a sure protection against infection from erysipelas (*op. cit.*).

---

* For the bacteriology of erysipelas consult the article on *Bacteria*, in Vol. I.

† "Die Aetiologie des Erysipels," Berlin, 1883.

‡ Petruschky (quoted by Warren) showed conclusively that a streptococcus cultivation from pus may cause erysipelas in the human subject.

The progress of erysipelas seems to depend upon the extension of the local infection by contiguous growth of the specific coccus, and not by transmission of the infection to distant parts by the circulation. The spread of the disease is usually from a distinct centre by peripheral growth. The appearance of erysipelas in regions distant from the point of original infection has been thought to indicate that the virus may be transmitted by means of the blood current, but this method of spread is not universally accepted. The constitutional disturbance—fever, etc.—accompanying the disease is probably due to the presence in the blood of the toxic products of the specific germ of the disease.

That erysipelas is a communicable disease has been proved by repeated transmission. Warren cites the former frequent conveyance of this disease in vaccination, and quotes the statements of Moreland in the Records of the "Boston Society for Medical Improvement." There is, however, a strong probability that in the former state of surgery, the poison of erysipelas was conveyed by means of hands or instruments not surgically clean, or by the contamination of dressings or other material with the virus of the disease.

The origin of erysipelas upon surfaces covered with mucous membrane is not so easily determined. In the eyes, mouth, and nose it may often be impossible to discover the wound through which entrance to the system was effected, as these mucous surfaces are extensively reflected, or are concealed to a great extent from view.

Erysipelas is comparatively rare before the age of puberty, and still more rare in old age. The associated causes of the disease may include conditions of inanition, poverty, exhaustion, overwork, previous illness, chronic poisoning, cachexia, etc. All these render the entrance of the microbe more easy by diminishing the resistance of the tissues and organs.

Certain individuals present an unusual susceptibility to erysipelas, suffering an attack whenever they are subjected to a fresh exposure. One of the physicians attached to a Paris hospital took the disease each time he had a patient with erysipelas in his service, although he employed all possible precautions against infection.

Pathological Anatomy.—Fehleisen distinguishes three zones in the erysipelatous plaque: a central field, in which the process may be receding, a circle in which the disease is still spreading, and an outer area in which the tissues are in a state of commencing congestion preceding the actual extension of the malady. On section of the tissues there is observed an abundant infiltration of the area with leucocytes, which entirely fill the field, particularly in the vicinity of the vascular channels, around the hair follicles, and in the neighborhood of the sudoriparous glands. The distinguishing characteristic of erysipelas in comparison with inflammatory œdema, is the proliferation of the fixed cells of the connective tissue, due to the specific action of the particular organism of this disease.

Symptoms and Course of the Disease.—The most common seat of erysipelas is the face, and its symptoms will be considered as observed in that location.

The invasion of the disease is accompanied by the general symptoms of septic infection, viz., malaise, headache, anorexia, dryness and a bad taste in the mouth, and occasionally vomiting. The chief symptom, however, and one which is never absent, is the initial chill, sometimes slight, but often very severe. This is sometimes repeated, but usually it consists of one prolonged rigor. The severity of the disease seems to bear some relation to the severity of the premonitory chill as regards duration and intensity. The chill is soon followed by fever of an intense character, with elevation of the temperature, often to 104° F. or even above that figure. The patient is frequently delirious. In erysipelas of the face, there are tumefaction and tenderness of the submaxillary lymphatic glands before other local symptoms of the disease are apparent. In some cases this precedes the exanthem by from one to several days. The adenopathy would seem, however, to be necessarily secondary to the local infection and its primary local processes, though the glands are possibly invaded by the micrococcus before the disease has made itself evident at the seat of invasion. The glands are sometimes painful even before there is any apparent increase in their size.

The first onset of the visible disease is in the form of an acute dermatitis, situated at the angle of the eye, at the naso-labial fold, at the nasal orifice, about the ear, or in some other location about the face or head. In a few hours a plaque of erysipelas is formed which rapidly enlarges and acquires double its first dimensions within twenty-four hours. The part affected presents a color which varies from bright scarlet to dull rose. In anæmic patients the tint is only a rosy blush. Pressure by the finger dulls it, but the color at once returns. The skin becomes tense and glistening. The temperature of the affected part is higher by from one to four degrees than that of the opposite side. There is a sensation of burning heat, and sometimes there is also considerable local pruritus. The entire plaque is elevated on account of the swelling of the skin, and its borders are sharply defined. The maximum intensity of the disease will always be found at the border of the patch, as at this point the malady is extending, while at the centre of the plaque it may be subsiding or already healed. The pain accompanying the advance of the disease is in inverse ratio to the tumefaction of the tissues; the loose structures in the vicinity of the eye allowing much swelling without great pressure, while the tense tissues upon the scalp cannot yield to pressure, and the suffering here is consequently more intense. The erysipelatous inflammation extends slowly from the periphery of the plaque, in all directions, and its advance has been compared to the spreading of a drop of oil on paper. In this way the disease may invade the greater part of the face and forehead, but it rarely extends over the surface of the chin. In a recent case seen by the writer, however, the inflammation passed from the lips to the chin on both sides of the neck, and induced great difficulty in swallowing. At the same time the face showed very marked deformity. In some instances the disease may render the patient quite unrecognizable, and breathing may be embarrassed from the swelling in the nares. The eyes may be quite closed, and the sufferings of the patient may become intense. The scalp is frequently invaded, but the disease seldom passes the line between the head and neck. The invasion of the hairy scalp is usually accompanied by severe headache and delirium, which may alternate with dulness or coma. These symptoms are thought to be of reflex character and due to irritation of the branches of the fifth pair of nerves. Nervous phenomena are much more frequently observed in alcoholic subjects.

The general character of erysipelas remains the same, though different terms have been applied to express particular features of its progress, such as "fixed," "serpiginous," "vague," "migrans," "ambulant," "phlegmonous," etc., as observed in erysipelas of the trunk, limbs, face, etc.

The variety of erysipelas which is called "phlegmonous" is characterized by the spread downward of the disease into the deeper subcutaneous tissues. The infection is much more extensive than in ordinary erysipelas, and the quality of the virus may be more virulent; the local symptoms are consequently more distinct. The fever continues high, and is often typhoidal in character. It is not long before suppuration takes place. Free incisions give vent to abundant discharge, in which may be found shreds of necrotic tissue. Large sloughs are eventually discharged. The pus burrows rapidly, to considerable distances, under the skin, which is thus dissected off from the subjacent structures. In rare cases suppuration may extend more deeply still and penetrate the intermuscular spaces. Even the periosteum and bones may become infected, and cases are recorded in which the joints have been involved and have become disorganized. In the extreme forms of this last type, large masses of tissue may become gangrenous, and at times there is emphysema of the parts from the formation of gas in the tissues, owing to the decomposition of the necrotic and sloughing tissues. The simplest case of facial erysipelas may without apparent cause assume the phlegmonous form, and be followed by the most disastrous consequences. The disease may extend to the eyelids, and orbital suppuration may occur with infection of the eye itself. Blindness is not an infrequent result of this complication. Septic meningitis may also follow erysipelas in this location.

As already stated, erysipelas occasionally involves the mucous membranes. In the faucial form of the disease there may be extension to the pharynx, and thence through the Eustachian tube to the cavity of the middle ear, whence it may pass through the drum membrane to the external auditory meatus and to the scalp. It may be traced internally as far as the lungs. Should the glottis become œdematous, as it occasionally does, the result is usually rapidly fatal. The other natural openings of the body are also occasionally the seat of this disease.

Strauss has recognized a pulmonary erysipelas. This generally occurs subsequently to an erysipelas of the face or throat, and is marked by insidious development, without chill, and by a rapid extension.

Erysipelas may also extend from the face or other point of primary attack to the digestive tube. Rendu has reported a case in which the disease was thought to have extended through the alimentary canal, and appeared at the anus, where it caused a perineal abscess. In 1887 Heidenreich published a case of erysipelas of the right thigh which had extended to the intestine by way of the anus. Ivanowski made an autopsy of a case of intestinal erysipelas which had been propagated from the perineum through the entire large intestine. To our knowledge these are all the reported observations of this complication.

Pericarditis and endocarditis have also been reported as complications of erysipelas, and the specific germ has been recovered from the blood and from the fluid in the pericardium. In this complication the path of the infection is no more clear than in rheumatic invasion of the heart or its coverings. The results depend on the amount of damage to the valves or on the other changes effected. Lesions of the kidneys are among the most frequent complications; albuminuria is generally present at some stage of the disease, but is usually transitory in character, and disappears with the recovery of the patient. Its presence or amount bears no relation to the elevation of temperature or the pulse rate. The urine often contains blood elements and epithelial and hyaline casts. Bacilli are often present in the urine; they may be due, as indicated by Professor Bouchard,* to the infectious nephritis.

Peripheral neuritis, pleurisy, and peritonitis have also been noted as complications of erysipelas.

Erysipelas in open granulating wounds often causes comparatively little disturbance. The disease sometimes appears to exert a stimulating effect upon the healing process, the part closing more rapidly than before.

There is no regularity in the temperature curve of erysipelas. Oscillations of slight extent coincide with grave forms of the disease, though there seems to be no direct relation between the degree of elevation of temperature and the extent of area comprised in the erysipelatous process. A constant elevation without irregularity usually precedes a fatal termination. The temperature may even rise after death. Usually when the progress of the disease is arrested, there is a rapid fall of temperature. This critical fall may appear at any time between the fifth and the tenth day. In severe cases the fall is usually by lysis.

Diagnosis.—The diagnosis of erysipelas may be difficult in the absence of indications of efflorescence, as in cases in which the seat of the primary infection is in the nasal fossa or in the interior of the mouth; but the high fever and the swelling and tenderness of the submaxillary glands are valuable indications of the character of the disease, and the absence of other causative agencies should lead to a suspicion of the infection even before the efflorescence is evident.

When the disease is situated upon the external surface of the body it is hardly possible to mistake it for any other malady. Erysipelas may be confounded with simple lymphangitis. The former is, however, always accompanied by inflammation of the lymphatic channels and glands. In simple lymphangitis there is swelling in the course of the lymph channels, but there is no typical inflammation of the skin with peripheral extension and central recrudescence; there are also less tumefaction of the skin and less elevation of the temperature, and the surface is not dry and glazed as in erysipelas. In lymphadenoma, and in malignant diseases, there is often induration of the glands in the vicinity, but there is absence of fever, and the course of these diseases is chronic; other signs of systemic disease, such as cachexia, emaciation, etc., are also usually unmistakable. The various forms of erythema may present some degree of resemblance to erysipelas, but this lesion is seldom confined to a single point, is not accompanied by glandular induration, and is usually disseminated over the surface of the body and limbs. Herpes zoster may simulate erysipelas to some degree, but the course of the disease will soon determine the difference. Certain drug eruptions may present appearances similar to those of erysipelas, but it is usually possible to trace their origin to the irritating substances which have produced them. Glanders presents many appearances similar to those which characterize erysipelas, when developing, but this disease is accompanied by a hard œdema, is not distinctly defined, and the skin is not so raised at its borders. At the end of a few days, the development of pustules upon the surface affected will distinguish it from erysipelas.

Prognosis.—The prognosis of erysipelas is on the whole favorable. After a few days of inflammation there is a marked tendency to resolution; and this simple fact should be borne in mind in estimating the value of any remedy. The disease varies greatly in severity, but it may be said that the danger from the disease itself is less than that which attends its complications.

If the disease attacks the mucous membrane as in the throat, it will probably be severe; if the vagina is the point of origin, as in puerperal cases, there may be great reason to fear pyæmia or septicæmia. The late Dr. Oliver Wendell Holmes was among the first to recognize the frightful conditions arising from puerperal infection, and openly laid the tremendous mortality of that disease to the introduction of erysipelas into the system of the parturient woman. "The work for which Holmes will always have a place among those who have advanced the art of healing and thus deserved well of humanity, is his demonstration of the infectiousness of puerperal fever, read before the 'Boston Society for Medical Improvement' in 1842. He was not the first to preach this doctrine, but to him belongs the credit of having forced men to listen to the truth" (*The Practitioner*, vol. lxvi., 1901, page 77). The further discussion of the relations of erysipelas to puerperal fever will doubtless be found under the latter heading, in a later volume of the present series.

The deeper-seated types of the disease, such as the phlegmonous or gangrenous, have undoubtedly a higher mortality than the cutaneous forms. In individuals enfeebled by long-standing suppuration, and in alcoholic subjects the disease may prove a formidable complication. The same may be said of a number of organic diseases, such as diabetes and Bright's disease, particularly in advanced life. For similar reasons, youth and old age are periods of life when the patient is less resistant to its influence than when in the prime of life. Erysipelas is distinguished among acute diseases for its tendency to relapse, but the relapses are usually not so serious as the initial attack. This may be due to a diminished virulence of the contagion or to the fact that the system is protected to a certain extent by the secretions of the streptococci (antitoxin?), which may increase the resistance of the body or tissues to the poison of the infection.

---

*See also a valuable reference by Salinger in Medical News, July 4th, 1891.

The ordinary duration of erysipelas varies from a few days to two or three weeks, according to the extent to which it spreads over the surface of the body. The tendency is notably toward recovery, but occasionally patients succumb from exhaustion, from the systemic poisoning caused by the toxins of the disease, or from meningitis, when the infection extends to the membranes of the brain, from the ear, the lining of the nose, or the frontal sinus.

Erysipelas of the new-born is generally acquired by infection from the navel, and usually leads to a fatal result.

The curative influence of erysipelas when it occurs in the course of other diseases has been already noticed. Chronic inflammations of the skin, particularly those of a tuberculous or syphilitic character, have been reported as benefited by an intercurrent attack of erysipelas, after resisting all other modes of treatment. Sarcoma and carcinoma have also been relieved or cured by the same influence.* Old and refractory neuralgias have often been cured or greatly relieved through the same means. In the insane, likewise, a temporary improvement has occasionally been observed.

This effect is supposed to be due to a change in the nutrition of the cells of the morbid tissues, or to a direct destructive influence upon the elements of the foreign growth by the micrococci of erysipelas. This ingenious theory needs the support of more extensive observation for its entire confirmation. At the present time one would naturally hesitate to employ so serious a measure as the voluntary infection of the system of a human being with the virus of erysipelas for a doubtful therapeutical purpose.

In like manner, the effusion of fluid within the thorax, following an acute attack of pleurisy, has been observed rapidly to diminish, and at times to undergo complete absorption, as a sequence of an invasion of the skin of the chest and trunk by erysipelas.

TREATMENT.—The treatment of erysipelas is chiefly to be directed to the complete isolation of the patient from all other sick persons, and the employment of all possible means for the establishment of good sanitary conditions about the patient. This includes scrupulous cleanliness, pure air, pure water, sunshine, and the rigid antiseptic treatment of existing wounds or other lesions. The local symptoms may be treated according to the varying requirements of the case.

The most rigid prophylaxis should be carried out; the patient should be isolated, and all possible means be employed to restrict the spread of the disease by soiled dressings, infected linen, or other articles. All these things should be burned at once.

The general treatment is the same as that commonly employed in other infectious maladies. The large number of remedies which have been recommended for erysipelas may be of service in ameliorating certain symptoms, but they are in no sense specifics for this disease. Aconitine (crystallized), in doses of 0.25 mgm. every six hours, or 0.1 mgm. every two hours, has been thought to reduce the duration of the disease and to alleviate the pain.

As regards the local treatment there are various procedures which may be used to advantage. Compresses dipped in some lotion of a cooling nature and applied to the inflamed skin usually afford considerable relief. Painting the part with tincture of iodine, with nitrate of silver, with carbolic acid in weak solution, or with corrosive sublimate in dilution of one-tenth of one per cent., has proved helpful in certain cases. Favorable results have been obtained by spraying the affected surface with a solution of corrosive sublimate in ether, in similar dilution. Under treatment of this kind the disease has apparently ceased to advance, and the inflammation has subsided in from twenty-four to forty-eight hours. Painting the borders of the affected area and the sound skin adjacent to it with contractile collodion has been a most prompt and satisfactory method of treatment in the hands of the writer, the disease seldom crossing the line of collodion; or if it has not been entirely subdued by the first application, it has generally yielded to a renewed and more extended "fencing in" by the same means.

Subcutaneous injections of carbolic acid have been highly recommended as an almost specific treatment for erysipelas, and often its use in this way has been followed by the most favorable results. The frequent application of carbolized oil relieves the sensation of burning and stiffness, and is generally very soothing in its action. White paint has been used in the same way. Frequent or sudden changes of temperature in the sick-room should be avoided, and if a "cold" is contracted it is liable to aggravate the inflammation.

When sloughing or gangrene occurs, the case must be treated according to general surgical principles—*i.e.*, by free incisions, drainage, etc.

Cool baths may be employed for the purpose of diminishing the general temperature of the body, and the internal administration of the salicylates has sometimes been of service in accomplishing the same result.

Treatment by large doses of tincture of the chloride of iron (twenty to sixty drops in water at intervals of three to six hours) was at one time highly esteemed as almost a specific in erysipelas; but its use has been almost discarded since the increased knowledge of later years as to the nature of the malady, and the introduction of antiseptic methods in its management. Many other forms of drug treatment have been abandoned for the same reason, and to the great advantage of the patient.

In the phlegmonous form of erysipelas it is important to recognize suppuration as early as possible. It is in these cases that prompt surgical interference may be productive of the best results. The tendency of the infection to spread along the spaces separating the bands of loose connective tissue must be corrected promptly, no matter how long or how numerous the incisions may have to be. Very hot and large antiseptic poultices are now indicated, and they should be often changed. The graver forms of gangrenous erysipelas with malignant œdema should be dealt with promptly and heroically by long and deep incisions. Many a life has been saved by the timely action of the surgeon.

In phlegmonous erysipelas of the face, pus often forms in the tissues of the orbital cavity, necessitating incision between the eye and the orbital margin. In scrotal erysipelas of a phlegmonous or gangrenous character, a free incision should be made through the raphé, completely dividing all the tissues involved. This incision usually results in the prompt arrest of the inflammatory process, and the wound generally heals rapidly.

During the period of convalescence the treatment should be tonic and supporting; and care should be taken to avoid chilling of the surface of the body and fatigue. So long as desquamation lasts isolation should be continued, and in private practice the patient should not be allowed to mingle with other members of the household, particularly during periods of epidemic disease, until it is tolerably certain that the micro-organisms of the disease have been completely eliminated from the system.

Cases of this disease should be visited by the surgeon after he has seen all other patients, and the hands and instruments should be thoroughly cleansed and disinfected afterward. The patient should not be considered safe from a recurrence of the disease, nor should the precautions against infection of other persons be relaxed, until the disease has entirely disappeared from every portion of the body which was at any time invaded; and the danger of a relapse or of communicating the disease to others is not entirely absent until the process of desquamation of the epidermis in the regions affected by the erysipelatous inflammation has been completed. When the skin has fully returned to its normal condition, it is advisable that the entire surface of the body should be carefully bathed in warm water, made alkaline by means of sodium bicarbonate and perceptibly impregnated with carbolic acid. A complete attire of fresh and uninfected clothing should replace the clothes previously worn. The patient may then be allowed to go at large.

---

* See the various contributions to this subject by Dr. Coley and other investigators.

One of the remoter dangers associated with erysipelas, —a danger, however, which is not of frequent occurrence —is an interference with the function of the kidneys. This complication may assume a variety of forms, and its presence as a complication of the erysipelatous process is of sufficiently grave importance to make the daily examination of the urine advisable. The renal condition often seems due not so much to the specific character of the erysipelatous infection, but rather to the action of the toxic products of the bacilli which accompany the graver forms of the disease. Should this or any other unusual complication arise in the course of erysipelas, the same rules should be observed and the same measures adopted as in other cases of similar disturbance of these important organs. The strength of the patient should be carefully husbanded, and tonic measures should be cautiously employed to support the system until the natural vigor shall have been re-established. For this purpose the diet should be carefully selected, and should consist of nutritious but unstimulating food, with the addition of some of the artificial digestive ferments if the functional ability of the alimentary organs has been seriously impaired. A very excellent addition to the ordinary diet of a weak and debilitated patient is the extract of malt in some of its more acceptable forms. Perhaps the best preparation at present for this purpose is that known as "Amê," or the Japanese extract of rice. It is of pleasant taste and possesses great nutritive power.

To overcome the debility often remaining after a prolonged attack of erysipelas, a change of scene and climate is often of great service. Excessive fatigue or prolonged bodily exertion should be prohibited, and the patient should be directed to pass a portion of each afternoon in a reclining posture, and if possible to obtain an hour's sleep in the middle of the day. In cases in which the attack of erysipelas is followed by the formation of abscesses, a sojourn at some of the watering-places, particularly at one of those whose waters are of an alterative and chalybeate character, is often of much benefit.

ERYTHEMA.—The term erythema is a general one for certain diseases of the skin in which there are evidences of hyperæmia and passive inflammation.

Erythema simply means redness, and is therefore nothing more than a symptom, and, used without a qualifying adjective, has but little definitive value.

The definition of erythema, as given by some authors, is "a localized congestion, accompanied by redness, which disappears under pressure."

Two divisions of the subject are usually made, viz., Erythema hyperæmicum and Erythema exudativum; these are again subdivided according to symptoms.

The first general division, ERYTHEMA HYPERÆMICUM or *Simple Hyperæmic Erythema*, is that form of the disease which is characterized by various-sized and various-shaped points and patches of redness, exhibiting no evidences of inflammatory exudation.

The patches readily disappear upon pressure.

The causes of the affection are numerous: heat, cold, the presence of irritating substances, as well as certain general systemic disorders.

It occurs both idiopathically and symptomatically.

The *Idiopathic Hyperæmic Erythemas* are those which are produced by cold or by heat, by traumatism, or by the application of some irritant to the surface of the body.

If the skin be exposed to any of these agents for a great length of time the condition passes from the simple hyperæmic into the exudative stage. Slight sunburn is perhaps the mildest type of hyperæmic erythema. Artificial heat may produce the same condition (*Erythema ab igne*).

Cold will also produce a certain amount of congestion (*Erythema pernio, chilblain*).

Wounds and contusions, pressure of clothing or bandages, also cause a localized erythema.

Exposing the skin to irritating substances, as mercury, iodoform, certain dye stuffs, or poison ivy can cause an erythema.

The *Treatment* for simple erythema is upon general lines. If it is caused by pressure of clothing or from the chafing of two opposing skin surfaces (Erythema intertrigo), remove the pressure and apply some soothing dusting powder.

If it has become almost eczematous in character, and the diseased area is covered with a sticky exudation, as is often the case in infantile intertrigo, Lasar's paste, calamine lotion, made with the stearate of zinc instead of the oxide, or any of the other external applications for eczema, are indicated.

If the erythema is from the external application of drugs, the treatment is obvious; remove the cause.

The *Symptomatic Erythemas* are important, because they so often simulate more serious affections. They generally occur as the result of some derangement of the digestive tract, and are more frequently seen in children or young people. They may also accompany certain systemic diseases, such as diphtheria, scarlet fever, cholera, uræmia, Bright's disease, etc.

The eruption may be found on any portion of the body, although the face seems to be the part most frequently affected. The lesions appear in various shapes; patches, spots, rings, etc., small reddish pea-sized spots called roseola, are often seen in the beginning of a syphilitic rash, smallpox, or as an accompaniment of vaccination, and in some cases of jaundice.

The persistent or fugitive flush seen in rheumatism, asthma, goitre, hemiplegia, is an erythema produced by some impairment of the central or peripheral nervous functions.

The symptomatic erythemas occur in both the hyperæmic and the exudative varieties; and, as they are more frequently observed after they have passed into the inflammatory stage, to save space they can be more conveniently discussed here, before considering the distinct group of erythema multiforme.

Erythema Diphtheriticum.—During an attack of diphtheria, especially if severe, there often occurs upon the thorax and abdomen a diffuse eruption, sometimes extending over the extremities; it may be mottled, punctate, or scarlatiniform in character. The rash usually appears on the second or third day of the disease and should be distinguished from the toxic maculo-papular erythema multiforme which appears late in the course of diphtheria.

Since the introduction of antitoxin as a therapeutic measure a form of erythema has been noted; it occurs chiefly on the trunk, making its appearance from six to twenty-four hours after the injection. This epiphenomenon is regarded by bacteriologists to be due to some idiosyncrasy of the horse from which the antitoxin is taken and not to any defect of the preparation itself. This erythema is not of any grave importance, but is a disagreeable accompaniment of the most effective therapeutic measure in the treatment of diphtheria.

Erythema Cholericum.—This is a polymorphous, maculo-papular erythema seen in some cases of cholera. The eruption first appears on the hands and feet, extending to the forearms, legs, and trunk, and finally to the face. It usually begins early or late in the disease, lasts several days, and disappears by desquamation.

The erythema of *Uræmia* is of the maculo-papular variety. The first lesions are bright red macules which rapidly change into papules, and are generally upon the extensor surfaces of the hands, forearms, and legs. The eruption may extend over the body, even involving the palms and soles; it runs its course in three or four days and subsides with flaky desquamation. When this cutaneous manifestation is seen as an accompaniment of nephritis the prognosis is grave.

In *Chronic Bright's Disease* the erythema consists of bright red macules, generally situated on the trunk, although the neck, arms, and thighs may be involved, and more rarely, the face, hands, and feet; it is accompanied by no subjective symptoms and lasts but a few days.

There is another eruption seen in Bright's disease which is papular throughout. This, I think, is the commoner form. The lesions are large, discrete papules, of a dark red color, generally springing from dry, rough, or scaly patches. The outer side of the thighs and extensor surfaces of the legs and arms are the parts involved.

Erythema Scarlatinoides.—In 1851 Hardy described a cutaneous roseola which closely resembled scarlet fever. He named it Erythema scarlatinoides. Later, Bazin reported similar cases; he applied to them the term erythema scarlatiniforme. Still later, Besnier gave the disease careful clinical and histological study, and from his researches he considered the proper name to be the one first given by Hardy.

Its close resemblance to scarlet fever makes it a disease of considerable importance.

The eruption comes on with slight constitutional disturbance and with more or less elevation of temperature; its advent may be sudden or gradual; it appears first on the chest, as a bright red punctate erythema, and from here eventually spreads over the entire body. Cases have been reported in which it appeared as a diffuse general rash. It is often accompanied by burning and itching; the duration, in either case, is short; it soon becomes pale, and in a few days passes off with little or no desquamation. If, however, the attack has been severe, the desquamation may be considerable, the epidermis shedding itself in large patches.

The disease has no specific infectious origin; it is neither contagious nor transmissible. It differs from scarlatina in the absence of the characteristic strawberry tongue and the typical throat symptoms.

Gastric and intestinal disorders seem to be the prominent causative factors. According to the reports the disease has been observed during the puerperal period and as a symptom of septicæmia. It has also been observed in typhoid fever; in which disease it usually occurs at the end of the first or at the beginning of the third week of the fever.

The external application of drugs, such as mercury or iodoform, has been known to produce the eruption.

In treating the disease such measures should be adopted as the symptoms demand.

Erythema Scarlatinoides Recidivans.—This is a variety of scarlatiniform eruption that tends to relapse, each attack clearing up with considerable desquamation. The disease has been described by the French authors, and many American dermatologists have also reported undoubted cases of this affection.

The term desquamative relapsing scarlatiniform erythema is the name by which the disease is now known. Some of the French writers consider it different from Erythema scarlatinoides because of its extremely inflammatory character, and have suggested the term Dermatitis scarlatiniformis.

The symptoms as given by Besnier are as follows: It often begins with shivering, lassitude, sore throat, headache, and elevation of temperature. When the rash is at its height the fever will suddenly cease. The eruption lasts for from four to six weeks, and is similar to that of scarlet fever.

Desquamation often begins on one part of the body while the efflorescence is present on others.

The etiological factors are numerous: it may be due to external or internal causes; it has been observed in certain diseases such as rheumatism, gonorrhœa, toxæmia, etc.; mercury, quinine, belladonna, antipyrin are among the drugs which produce this variety of erythema.

One attack predisposes to another, recurrences usually taking place at the change of seasons. While any of the foregoing factors may produce an attack, yet what induces an outbreak in one person will not in another, and attacks in the same subject may be brought about by entirely different causes.

It has been observed that each subsequent manifestation of the disease tends to become milder.

In making a diagnosis, erythema must be differentiated from scarlet fever, which disease it most closely resembles. The principal points to be remembered are: while there may be sore throat at the beginning of the attack it is not so severe as that of scarlet fever, the strawberry tongue is not present, the temperature abates during the height of the rash, the duration of the disease is more variable and prolonged, and, finally, it is non-contagious and tends to relapse.

Erythema Perstans.—This is a type of erythema which has many of the eruptive characteristics of Erythema scarlatiniforme, differing in that the rash may persist for weeks, months, or longer. The eruption is symmetrical and is attended by severe subjective symptoms, as pain and itching.

The treatment of this group of erythemas depends largely upon the cause; if it is due to some systemic disease, treat that, or if to external irritation, remove the irritant. Locally, soothing applications will be found useful.

In the perstans variety, Duhring recommends the exhibition of quinine, sodium salicylate, or ergot in full doses.

ERYTHEMA EXSUDATIVUM MULTIFORME.—The affections grouped under this general head are characterized by inflammatory changes in the skin, and are in contradistinction to the simple congestive or hyperæmic erythemas. As the name implies, the lesions are multiform, and the symptoms and etiology are varied. The French term it *Erythème polymorphe.* The general type, erythema multiforme, was clearly described by Hebra; since then the question is constantly brought up whether many of the cutaneous manifestations grouped under this head are not really distinct diseases.

It is an inflammatory affection characterized by reddish or variegated macules, papules, and pustules. The eruption occurs either discretely or in patches, with sharply defined, marginate outlines, and runs an acute course. The patches may be simply erythematous or may consist of maculo-papules, papules and vesicles, and, in some instances, of vesicles and blebs.

The lesions pass rapidly through their various evolutions: first, the erythematous patches are red and clearly defined from the surrounding skin; in a few days they begin to assume a purplish or bluish-white color, which disappears upon pressure.

The various shapes, colors, and character of the patches have given rise to the terms circinatum, annulare, papulosum, iris, marginatum, purpuricum, urticans, etc.

The eruption which fades in the centre and extends peripherally is termed circinatum. If there are a series of concentric rings formed it is called Erythema annulare.

Erythema iris is a rare manifestation of Erythema multiforme, and has been described under various names, such as Herpes iris, hydroa, Herpes circinatus, etc.

Two varieties are most frequently seen: in one the lesions are vesicular and bullous, arranged in clusters and rings; in the other they are vesicular throughout. The degree of redness is marked, assuming in most cases many hues, from which comes the term iris.

The eruption is generally located on the backs of the hands and feet, although it may invade other parts of the skin, even the mucous membranes.

Marginate erythema is simply that form in which the margin is sharply defined. The gyrate and figurate forms are those in which the patches and circles merge together and form fantastic shapes.

Papular erythema is the name given to the disease when the patches consist of papules or maculo-papules.

If the erythema is complicated with cutaneous hemorrhages it is called *Erythema multiforme purpuricum*; if with urticarial wheals, *Erythema multiforme urticans*.

Erythema multiforme attacks by preference certain regions of the body; the backs of the hands, forearms, and legs being the localities generally invaded. In some cases the face may become involved. The eruption occurs symmetrically, and the outbreak usually begins first on the hands and fingers. If it attacks the face the first lesions are seen on the forehead.

Cases have been recorded in which the eruption involved the whole cutaneous covering, beginning in the favorite locations and spreading over the entire body, finally resolving by exfoliation. The disease, in these instances, closely resembles Dermatitis exfoliativa (see Erythema scarlatiniforme).

The subjective symptoms are mild, and the patient may complain only of slight burning and itching. The systemic symptoms are variable; frequently there will be considerable eruption over the hands and feet, with no general discomfort. Again there may be a marked elevation of temperature, preceded by malaise, headache, rheumatic-like pains, sore throat and swelling of the joints.

Gastric and intestinal derangements have been noted in the severer cases.

The evolution of the disease is varied. Often erythema will be the only eruption observed throughout the whole attack, while in other cases there will be vesicles or aborted vesicles. Again the lesion may be maculo-papular. Sometimes the patch will clear in the centre and form opalescent rings. In the more serious cases there may be a diapedesis of blood in the skin. If this is great enough to form distinct purple spots, it is a question if the disease is not Purpura rheumatica, and not a true Erythema multiforme. It is now almost the universal belief that in its etiology and pathology Erythema multiforme is closely allied to the cutaneous lesions of rheumatism. Erythema multiforme is a disease of spring and autumn, although it may occur at other times of the year. Humidity or dampness seems to favor its development. Women, especially young women, are more subject to it than men.

Pathologically it is an angioneurosis, the effect being primarily upon the nerves, secondarily upon the blood-vessels. It is believed by many authorities to be of an infectious nature, although opposing theories appear to be equally well grounded in fact. Cases have been reported of nervous shock followed by an erythematous outbreak.

Microscopical examinations of the lesions show a dilatation of the vessels of the stratum corneum and some exudation of white corpuscles.

Recent observations have not been able to demonstrate the presence of emboli in the cutaneous vessels, although some pathologists claim to have found them.

The *Diagnosis* of the disease is comparatively easy, providing the multiform character and peculiar color of the lesions are borne in mind. The presence of the lesions upon the hands and feet, and the almost total absence of itching will serve to distinguish it from urticaria.

In papular eczema the papules are smaller and intensely itchy. The course and symptoms of pemphigus will aid in diagnosing it from the bullous form of erythema.

Erythema nodosum will be known from Erythema multiforme by the presence of bluish nodes on the extremities. The differential diagnosis between Erythema multiforme and Dermatitis herpetiformis is more difficult to make. Careful study, alone, makes differentiation possible. Limited space will allow only a brief outline here. Dermatitis herpetiformis is a chronic disease, and tends to relapse, each recurrence showing the herpetiform character of the lesion; Erythema multiforme is an acute disease, occurring as a rule in the spring and fall, and while in some instances the lesions may be herpetic-like, they always present more or less multiformity.

The *Treatment* of Erythema multiforme should be on general lines. At the beginning of the attack a saline purge is indicated; the diet should be light and nutritious; stimulants of all sorts should be avoided; antirheumatic remedies, such as the salicylates, appear to give the best results. In the relapsing cases quinine and iron should be used. Astringent washes, such as lead lotion, will be found useful in treating the skin lesions. If there should be itching a weak solution of carbolic acid or menthol will give relief. Some authors recommend various pastes containing a small per cent. of carbolic acid, resorcin, or salicylic acid.

In the beginning of the disease the *Prognosis* as to duration should be very guarded, for relapses may occur that would prolong the attack indefinitely. Generally the disease runs a definite course, lasting from a month to six weeks, treatment seeming to have very little influence upon it.

ERYTHEMA NODOSUM is an inflammatory disease of the skin characterized by various-sized elevated nodes of a rosy red or purplish color.

The disease is generally ushered in with some systemic disturbance; there are malaise, fever, and rheumatic-like pains of the joints.

The nodes begin as dark indurated patches, they appear suddenly and rapidly arrive at full development. Various regions of the body may be involved, although the extensor surfaces of the arms and legs are the parts usually affected. The nodes differ in size from a filbert to a large English walnut. At first they are bright red, gradually growing darker until they become purple, finally fading to a yellowish-blue tint resembling the discoloration of contusions, which has given rise to the synonym Erythema contusiforme. Throbbing and pain on pressure are characteristic symptoms; frequently the nodes become so inflamed and shiny that they are mistaken for points of suppuration. The number of the nodes vary; sometimes they are limited to two or three, then again there are four or five times as many. They appear in successive crops, each crop being accompanied by more or less systemic disturbance. Cases have been reported in which there were diarrhœa, high temperature, and vomiting.

The cause of the disease is not clearly determined, although it is most frequently met with in the anæmic and weakly; good general health does not preclude an attack. Exposure to cold in some cases seems to provoke an outbreak. Females appear to be more subject to the disease than males—the proportion being about three to one. It is more frequently seen in early middle life, although I have observed it in people over fifty years of age.

The pathology is that of an exudative inflammatory process, similar to Erythema multiforme. Some authors claim it to be an inflammation of the lymphatics; others, that the nodes are inflammatory infarcts. Many competent observers consider it to be closely allied to Purpura rheumatica. The justice of the claim that it is of infectious origin merits more than passing notice; for if the course and symptoms are closely observed it will be found that it bears a marked resemblance to some of the infectious diseases; as for instance influenza.

There seems to be no doubt that Erythema nodosum is in some way closely allied to rheumatism, for the joint and muscular pains are quite similar, and heart involvement has been noticed during a course of the cutaneous disease. It is probable that when the bacteriology of rheumatism is more fully worked out it will be found that Erythema nodosum is due to the same or a similar organism.

The microscopical findings are similar to those of Erythema multiforme. The capillaries are dilated; there is an infiltration of blood cells into the derma, and the lymphatics are filled with cells. Competent observers have failed to demonstrate free cutaneous hemorrhages in the contused areas.

In diagnosing the disease care must be taken not to mistake it for bruises; it is sometimes diagnosed as erysipelas, especially if it occurs about the face. The nodes have been cut into under the impression that they were abscesses. The number and sites of the nodes will help to distinguish it from syphilitic gumma. Giant urticaria differs from erythema in that it is never accompanied by rheumatic-like pains or by fever. The color of the lesions differs, the erythematous nodes are painful, while the wheals of urticaria are itchy. The course of the two diseases is dissimilar; erythema nodosum lasting two or three weeks, while urticaria disappears in a few days.

It might be mistaken for that rare disease Erythema induratum, but this affection runs a slow chronic course, generally terminating in ulcerations.

The distinguishing characteristics of phlebitis, lymphangitis, and Erythema multiforme should also be borne in mind.

Treatment.—The treatment is according to the symptoms. If there is much fever antipyretics are indicated. The bowels should be kept open and a simple diet should be prescribed. As regards the general therapeutics, the most reliance should be placed upon salol, salicylate of soda, or quinine; phenacetin, combined with any of the above, aids in relieving the muscular and joint pains. It is well to follow this line of treatment with liberal doses of iron and tonics, especially in weak females. External lotions of lead water and opium relieve the burning pain, or, if preferred, a ten to twenty-five per cent. ichthyol ointment can be used.

The *Prognosis* is favorable; relapses are rare.

ERYTHEMA ELEVATUM DIUTINUM.—In 1894 Crocker described a disease to which he gave this provisional name. The eruption occurs in young girls of rheumatic history, and chiefly affects the hands, lips, knees, and buttocks. The lesions are pale, purplish-red in color, and in some cases are sharply defined, in others nodular and irregular in outline. They are firm to the touch and painful when pressed upon. There are few or no subjective symptoms. Cases have been reported in which there was considerable disfigurement from the eruption, the skin being so nodular and infiltrated. The lesions tend to persist, but may undergo gradual involution. Those that do remain become as hard as cartilage. Microscopically there are evidences of inflammatory processes followed by the production of fibrous tissue. It is undoubtedly a mistake to use the term erythema in this disease, for it does not properly apply to the condition, hypertrophic changes being the chief pathological element. The proper classification will be finally decided after further study, but until then it is as well to describe the disease under this caption as elsewhere.

ERYTHEMA INDURATUM, or *Erythème induré des scrofuleux,* is a disease first described by Bazin. It is a deep-seated nodular eruption situated in the skin over the legs and fingers.

The nodes vary in size, and are round or oval in shape; as a rule they are few in number, but cases have been reported in which they became confluent. They run an indolent course: some disappear by spontaneous involution, while others suppurate or become necrosed, forming deep circular ulcers. Pain, which may be present, is not severe. Young strumous girls with feeble circulation seem to be especially subject to the disease.

In diagnosing this disorder Erythema nodosum and syphilitic gummata must be thought of. It differs from Erythema nodosum in that the lesions are more circumscribed, firmer, and of a darker color; they are more deeply situated in the skin and less tender; they run a chronic course and tend to ulcerate.

Syphilitic gummata are not bilateral, and the patient gives no evidences of other specific symptoms.

Treatment consists of change of air, tonics, and rest in bed. *James Macfarlane Winfield.*

ERYTHRASMA.—This is a cutaneous *disorder* rather than a *disease* of the skin strictly speaking, and is due to the presence and growth, *on* and *in* the superficial layers of the epidermis, of a vegetable parasite. The affection was first described by Burckhardt in 1859 and by von Bärensprung in 1862, who then named it. Later it was studied by Besnier, Balzer, Dubreuilh, Riehl, Crocker, and many others, who all agree that it is a distinct affection. It is an extremely rare though trivial affection; it produces no inconvenience and is usually only accidentally discovered. During the past six years no instance of it has been noted in the dermatological department of the Vanderbilt Clinic, New York City, where the examinations, at least amongst the male patients, in whom it is said to be most common, is of the most open kind. The parts attacked are primarily those situations of the body—such as the axillæ, the inguinal and genito-crural regions, and the cleft of the nates—where, the apposed surfaces of the skin coming in contact, warmth and moisture are most constant. To these situations the parasite may confine itself indefinitely, but sooner or later (if uninterrupted in its course) the growth spreads slowly to contiguous parts and the trunk and limbs become invaded. These parts, however, may be attacked independently. The affection first manifests itself in the form of macules of the size of a pinhead or in patches of a somewhat larger area, the lesions varying in color according to their age and location, but always presenting a sharp contrast to the color of the adjacent normal integument. The younger lesions are vividly red over their entire surface or at their borders only, where a slight elevation above the general surface, due to hyperæmia and to the presence of a scanty desquamation, may be detected by the passing finger. The larger and older patches display varying shades of color ranging from a yellowish or light brownish tinge to deep orange, they are circular or rosette-shaped, or they have very irregular outlines. Vesiculation and papulation never occur and the only subjective symptom is possibly that of itching. It is the most chronic in its course of the dermatomycoses and lasts for months or years with but little change. Males are more frequently attacked than females; no case has been noted in childhood. Riehl's youngest case was sixteen years old, the oldest fifty-eight.

The fungus to which erythrasma is due was named by von Bärensprung the Microsporon minutissimum, the chief characteristics of which are the fineness of its threads and the minuteness of its spores. A power of six hundred diameters is required to make out the organism well. The threads present an inextricably interwoven mass with the spores scattered throughout in irregular clumps.

Erythrasma is chiefly to be distinguished from chromophytosis, but the different situations usually occupied by the former, its vivid coloring, and particularly the differences observed under the microscope are features sufficiently distinctive to enable one to make a positive diagnosis when in presence of one or the other affection. From chloasma, for which it might possibly be mistaken, it may be shown to differ by the ease with which erasion removes the superficial discolored epidermis.

The following simple plan of treatment will be found all-sufficient. After a preliminary hot bath, during which vigorous friction of the affected parts with scrubbing brush and soap has been maintained, a goodly proportion of the invaded epithelium will be found to have been removed, thus allowing a saturated solution of hyposulphite of sodium in water to do its work effectively. Afterward this solution should be dabbed on twice daily until the last trace of the parasite has been removed, for, as in chromophytosis, if this be neglected, even to the extent of overlooking so small a lesion as a pinpoint-sized macule, a starting-point will be left for reinvasion. Many other remedies are used. The list includes, sulphurous acid pure or dilute, a good remedy; a ten-per-cent. ammoniated mercury ointment; and ordinary sulphur ointment of the Pharmacopœia, to be well rubbed in. None of these, however, can be compared, as regards both cleanliness and effectiveness, with the hyposulphite of sodium treatment. *Charles Townshend Dade.*

ERYTHROPHLEUM, ERYTHROPHLEINE. See *Sassy Bark.*

ERYTHROXYLON. See *Coca.*

ESCHSCHOLTZIA.—A genus (fam. *Papaveraceæ*) of ten or more species, of the western and southwestern United States and of countries lying farther southward

Medicinal properties have been credited to the *E. Californica* Cham., but this was at a time when most of the species were included under that name, so it is not now known certainly to which species (one or more) these properties were said to belong. The plants are very showy and are widely cultivated for ornamental purposes. The herb contains chelerythrine (see *Celandine*) and at least one other alkaloid, and a glucoside. The presence of a small amount of morphine has been claimed, but this is probably not justified. Mild analgesic and soporific effects are obtained from the use of the extract in doses of about 1 gm., which may be increased to three or four times this amount. *Henry H. Rusby.*

ESPERANZA MINERAL SPRINGS.—Yates County, New York.

Post-Office.—Pen Yan.

Access.—By steamers on Lake Keuka or by a trolley line between Pen Yan, which is six miles distant in one direction, and Branchport, one mile distant in the other.

The springs are located at the head of the west branch of Lake Keuka, one of the most charming and picturesque of the many series of lakes which give the name of the lake section to this part of central New York. Lake Keuka is 700 feet above the ocean level, and within a mile of the springs an elevation of 1,100 feet higher may be reached. This is the great grape-producing section of New York, and the country about the lake is dotted on every hand with vineyards. Lovely walks, drives, and bicycle paths abound on all sides. The largest of the springs flows about one thousand gallons hourly. The water, which has a temperature of 51° F., has never been examined quantitatively. A qualitative analysis shows the following ingredients: Calcium carbonate, Calcium sulphate, Calcium phosphate, Calcium chloride, Magnesium chloride, Magnesium carbonate, Magnesium sulphate, Iron oxide (trace), Sulphuretted hydrogen gas, and Carbonic acid gas.

The water, when first taken from the spring, has both the taste and the smell of sulphur, but this disappears after a few hours, and the water becomes very palatable. There is no hotel at the springs, though there are many within easy reach. Lake Keuka is well supplied not only with hotels, but with cottages, steam yachts, sailboats, etc. No systematic effort has so far been made to put the Esperanza Spring waters on the market, although large quantities have already been sold.

James K. Crook.

ESTILL SPRINGS.—Estill County, Kentucky. These springs are located 40 miles west of Irvine. We are indebted to the United States Geological Reports for the following analysis, made by Dr. Robert Peter:

One United States Gallon Contains:[*]

Solids.	Red Sulphur Springs (near saloon). Grains.	Chalybeate Spring.[†] Grains.
Sodium carbonate	1.16	....
Calcium carbonate	11.66	9.32
Magnesium carbonate	4.64	2.93
Iron carbonate	....	1.75
Sodium sulphate	9.91	.58
Potassium sulphate	5.24	.58
Calcium sulphate	....	16.32
Magnesium sulphate	.58	9.91
Sodium chloride	5.24	.58
Alumina	....	Trace.
Silica	.58	1.75
Organic matter	2.33	8.16
Total	41.34	51.88
Gases.	**Cubic inches.**	**Cubic inches.**
Sulphureted hydrogen	0.26	....
Carbonic acid	18.98	15.68

[*] Converted from parts per 1,000.
[†] Alkaline calcic chalybeate.

The waters are principally of the light sulphuretted type, with one mild ferruginous spring. Another spring in the neighborhood, termed by Walton the "Irvine" Spring, is purgative, containing about 256 grains of sulphate of magnesium to the gallon. As far as we are able to learn, the place is not at present improved as a resort.

James K. Crook.

ETHER.—In medicine and pharmacy the word *ether*, unqualified, means, as it does in common parlance, the body *ethyl oxide* $(C_2H_5)_2O$, formerly, but improperly, called *sulphuric ether*. Ether is a product of reaction between sulphuric acid and alcohol, and is obtained by distilling a mixture of these two bodies, and purifying the distillate. Under the simple title *Æther*, Ether, the United States Pharmacopœia recognizes an ether of standard purity, "composed of about ninety-six per cent., by weight, of absolute ether, . . . and about four per cent. of alcohol containing a little water." This ether corresponds to what formerly was called *Æther Fortior*, Stronger Ether, a title abbreviated in the 1890 Pharmacopœia to the simple word "Ether."

Ether is "a transparent, colorless, mobile liquid, having a characteristic odor, and a burning and sweetish taste. Specific gravity: 0.725 to 0.728 at 15° C. (59° F.); or 0.714 to 0.717 at 25° C. (77° F.). Soluble in about ten times its volume of water at 15° C. (59° F.), with slight contraction of volume. Miscible, in all proportions, with alcohol, chloroform, benzin, benzol, fixed and volatile oils. Ether boils at about 37° C. (98.6° F.), and it should, therefore, boil when a test-tube, containing some broken glass and half filled with it, is held for some time in the hand. Ether is highly volatile and inflammable. Its vapor, when mixed with air and ignited, explodes violently" (U. S. P.).

Ether tends to decompose by prolonged keeping, developing, as one product, acetic acid. For use as an anæsthetic, ether ought to be pure and of standard strength. In all cases of suspicion, therefore, the surgeon should test his sample by the following simple procedures: 1. Let soak in the ether for ten minutes a piece of pale blue litmus paper, previously moistened with water; the paper should not redden, thus showing the ether to be free from acid. 2. Pour about two teaspoonfuls of the ether upon a piece of clean blotting-paper, free from smell, and let it evaporate; as the last of the ether is dissipated, no foreign odor should be perceptible on the paper, showing absence of impurities. 3. Saturate some water with the ether, and then shake together, in a graduated test-tube, 20 c.c. of such aqueous solution of ether with an equal bulk of the ether itself. Upon standing till the two fluids separate, the layer of ether should not measure less than 19.8 c.c., thus showing an absence of undue amount of alcohol or water—in other words, that the ether is up to standard in strength.

By reason of its extreme volatility ether is best kept in hermetically sealed tins. In bottles, whether cork- or glass-stoppered, leakage by evaporation is almost certain to occur, especially during transportation. Extreme inflammability is another property of ether requiring especial precautions in handling the fluid, and a point often overlooked is that air even moderately charged with ether vapor is explosive. Hence happens every now and then the ignition of an ether inhaler during anæsthetization by the leap of fire through intervening ether-charged air from a candle, or hot cauterizing iron, several feet removed.

Ether is a conjoint local irritant and constitutional narcotic. Being of high diffusion power, it is readily absorbed by living tissues, and so speedily declares its influence. Applied in full strength to the skin, and prevented from evaporating, it quickly reddens, and in time will blister. Absorbed into the blood, ether disturbs nerve function by attacking first and more profoundly the nerve centres, and secondly, and with less intensity, the nerves themselves. Of the nerve centres, the cerebrum seems to be the most sensitive to the ether influence, the disturbance being first a conjoint excitation of the emotional and blunting of the intellectual faculties, and finally an abrogation of all mental phenomena, and unconsciousness so absolute that upon awaking there is not even that vague appreciation of the duration of the narcosis that follows ordinary sleep. Next to the cerebrum suffers the sensory tract of the spinal cord, the affection being a progressive blunting of perceptivity, and next again the motor tract, suffering first by paresis and irritation, and finally by full paralysis. Lastly, the medulla oblongata becomes involved, its sensory centres, as in the case of the cord, succumbing first and its motor centres last. Upon the nerves ether has a paralyzing power similar to what it exerts upon the centres, but the influence is so feeble as to be producible only by direct application of ether to an exposed nerve. In impregnation of the blood with ether, death of the subject by paralysis of the medulla will take place before there is any obvious impairment of conductivity on the part of the nerve trunks. Of the great functions, *heart action* is stimulated by ether, the pulse of a healthy subject rising in force and frequency, and maintaining such quickened and deepened action even through a long and full narcosis. In profound etherization, however, the heart is weakened, but the effect is always insignificant as compared with the weakening wrought by chloroform, and in death by ether the heart is still irritable. *Arterial tension* is increased at first; in part, doubtless, as a result of the increased heart action, but in part also, apparently, by vaso-motor spasm. Later in the narcosis the blood pressure falls. *Respiration* is primarily stimulated, but secondarily depressed, until in full ether narcosis the breathing becomes slow and shallow; and, in case of overdosing, respiration is the function whose failure produces death. From the experiments of Knoll it would appear that these respiratory derangements are caused by direct action of the ether upon the respiratory centres. Functions presided over by the *sympathetic* nervous system are but little disturbed by ether. The *stomach* is easily upset by ether; full doses given by swallowing are repulsive and sickening; and after ether inhalation nausea and vomiting are common occurrences, especially if the narcosis has been of considerable duration, and especially, further, if an ether of inferior quality has been used.

Clinically, the effects of ether are as follows: In administration by the *stomach*, the medicine is so offensive that enough cannot be given to produce more than a moderate grade of the peculiar ether effect. Doses of from 4 to 8 c.c. (from fl. ʒ i. to ij.) can be swallowed, dissolved in a sufficiency of iced water, with the effect of stimulating the circulation and respiration, and producing mild exhilaration. Such a draught is powerfully reviving in conditions of heart failure or of depression of the vital powers generally, and also tends to steady the nervous system and to break spasm. Given by *inhalation of the vapor*, in as concentrated condition as possible, ether produces its full effect. Such inhalation is the common method of administration for the production of ether anæsthesia, and the attendant phenomena are as follows: *Subjectively*, if the attempt be made at the very start to breathe the vapor strongly concentrated, the pungency is intolerable; spasm of the larynx occurs, and despite all willingness to be etherized, the subject involuntarily gasps for breath and fights for release. Soon, however, the mucous membrane of the larynx becomes anæsthetized by the vapor, and then inhalation can proceed without distress. Following the cessation of laryngeal irritation come an indescribable thrilling and tingling throughout the body; a sense of physical lightness and mental exhilaration; a ringing in the ears, and exaggerated appreciation of sounds — phenomena that speedily give way to a consciousness of failure of cerebral power and command. Blunting of tactile sensibility is clearly appreciable, and, in the self-experience of the writer, a sensible interval—whether real or apparent only, it is, of course, impossible to say—occurs between the willing of a motor act and its execution. With ever-progressing rapidity, now, the grasp of the centre of consciousness upon the outer world through the nerves of sense slackens, until, following a whirl of mental confusion, even the consciousness of consciousness fails, and the next act of cerebrating is the realization of an awakening from a sleep of whose duration the subject has absolutely no conception or even suspicion. In a self-administration of ether in an absolutely quiet room at night, the writer, awakening from what seemed, and was intended to be, a momentary unconsciousness only, found to his utter amazement, on glancing at the clock, that *two hours* had elapsed since the beginning of the inhalation—two hours of a coma as dreamless and blank as that attendant upon a compression of the brain. After awakening from an ether narcosis there is more or less tendency to nausea, headache, and debility and wretchedness generally. *Objectively*, the phenomena are first a rise in the frequency and force of pulse and respiration, a suffusion of the face, and a tendency to emotional excitement, varying with the temperament and disposition of the subject, exactly as in the analogous condition of alcoholic drunkenness. So while the phlegmatic or the self-contained individual may sink quietly into coma, the excitable or the ungoverned subject may be outrageously jolly, or fearful, or pugnacious, or amorous, according to natural bent. At this period the proper test will show already a decided blunting of tactile sense and impairment of co-ordinating power. Speedily, next, the emotional displays grow feeble and incoherent, sweat starts out from the brow, the saliva flows, the face congests, the pupils contract, and the muscles at once both stiffen and tremble.

And, now, testing shows tactile perception to be abolished everywhere except in parts of high natural sensitiveness, such as the eye, the "quick" of the nails, and the ano-genital region. If the inhalation continue, the muscular rigidity and trembling give way, often with striking suddenness, to a condition of absolute paralysis and relaxation. At the same time the pulse falls somewhat, the respiration becomes slow and stertorous, the pupils dilate, all outward signs of conscious existence cease, and anæsthesia is absolute even in the most sensitive parts. While this condition lasts the face sweats freely, and the saliva flows in considerable quantities. Such a condition is the extreme to which narcosis should be pushed, since it represents an abrogation of all nerve action save that of the functions of organic life, and that determining the play of the heart and lungs. If the ether be pushed further the respirations become slower and shallower, the sphincters give way, and soon thereafter breathing stops altogether—the heart, however, continuing to beat for a short time still. On withdrawing the ether, sleep may follow, more or less prolonged, according to circumstances and according to the amount of ether consumed. Retching and vomiting may come next, often taking place quite suddenly and while sleep is still profound. On awakening, the subject is generally stupid and miserable, with co-ordination still deranged, and tactile sense blunted. Occasionally, but exceptionally, emotional excitement now appears, and in such cases there is sometimes a strong erotic excitation, with vivid illusions. Deceived by such experiences, female patients have been known honestly but falsely to charge the ether-giver or the operating surgeon with the taking of improper liberties, and even with rape.

Ether narcosis is a therapeutic measure for the production of *anæsthesia*, on the one hand, and of *muscular relaxation*, on the other. And the degree of the narcosis for either purpose will vary according to the circumstances of the case. In the line of anæsthesia, if it be for the relief of existing pain, a few whiffs of ether may suffice, without the production of narcosis at all, or it may be that the pain will yield only to the general unconsciousness of full coma. If it be for the abrogation of sensation during a surgical operation, the grade of narcosis necessary will depend upon the part to be attacked. In the case of all but the highly sensitive parts already enumerated, the ether effect need not be carried farther than the stage characterized by general muscular rigidity and trembling; but for operations on the very tender regions spoken of, the narcosis must be pushed to the stage of muscular relaxation and stertorous breathing. For the purpose of affecting motility, if it be for the breaking of a cramp or spasm, a few whiffs of ether are often all-sufficient, ether being indeed quite a potent antispasmodic; but if relaxation be sought for the easier reduction of a hernia or a dislocation, full narcosis to the stage of stertorous breathing will be necessary. The actual *quantity* of ether required for narcotizing by inhalation will vary according to the inhaler used, the skill of the administrator, the respiration, the condition of the stomach, whether full or empty of food, and, also, upon the habit of the subject in the use of narcotics, and even upon idiosyncrasy. With a good inhaler; with care to prevent waste by evaporation into the room; with a subject whose susceptibility is not impaired by habitual indulgence in either ether itself or in alcoholics, whose stomach is fairly empty, and who *will and can breathe with forced inspiration and expiration,* so small a quantity as from 20 to 40 c.c. (roughly, from fl. ℥ ss. to i.), may suffice to produce full unconsciousness. But, as conditions commonly obtain, far larger amounts are required, so that it is rarely safe to provide less than half a pound for an intended anæsthesia of even ordinary duration only.

For the production of constitutional effects, ether also can be administered by rectal injection of its vapor. This method was tested experimentally so long ago as 1847 by Pirogoff, of St. Petersburg, and was revived some years ago in association with the names of Axel Yversen, of Copenhagen, and Daniel Mollière, of Lyons—a revival to be followed by a new lease of deserved oblivion. Full narcosis can be produced in this way, and without respiratory distress, and perhaps also with less gastric derangement than by inhalation; but the procedure tends dangerously to irritate the intestines. Diarrhœa and bloody dejections have repeatedly followed the practice, with resulting death in at least two instances. In another case, death ensued from rupture of the intestine at the site of an old ulcer, through overdistention by the ether vapor.

The *practical administration* of ether to the development of narcosis is a special topic, treated of in this work in the articles on *Anæsthetics* and *Chloroform, etc.*, to which, therefore, the reader is referred. For ordinary medicinal purposes, ether may be administered by inhalation or by the stomach. If given by inhalation, a very little suffices, so that it is enough to direct that a teaspoonful of ether be poured upon a crumpled handkerchief, which handkerchief is then to be held directly against the mouth and nostrils, and the fumes inhaled during a few deep inspirations. In this prescription the precautions must be enjoined, first, that in case of self-administration the subject must lie down or sit so reclining or so braced that, in the event of unconsciousness, he will not fall to the floor; and, secondly, that the whole procedure shall take place at a distance of at least six feet from any exposed flame, such as that of a candle, lamp, gaslight, or open fire. By the stomach, from one to two teaspoonfuls is the average dose, best given in from eight to ten measures of ice-cold water, sweetened, if so preferred. Ether so taken is, however, a repulsive medicine, being offensive to the taste and tending to choke, because of its pungency. But, for internal giving, the common practice is to prescribe the pharmacopœial preparation entitled *Spiritus Ætheris Compositus*, Compound Spirit of Ether, or Hoffman's anodyne. This preparation is compounded of 325 parts, by measure, of ether, 650 parts of alcohol, and 25 parts of ethereal oil. It is a colorless volatile fluid, smelling and tasting of its three powerful ingredients. It forms a milky emulsion on admixture with water. It is used as an antispasmodic and general nervine and cardiac stimulant, and is given in average dose of from half a teaspoonful to one or two such measures, in water, plain or sweetened. In the United States Pharmacopœia there is also official a preparation entitled *Spiritus Ætheris*, Spirit of Ether, a preparation consisting of 325 parts, by measure, of ether, and 675 parts of alcohol in mutual solution. This spirit may be given as an internal medicine in doses of one [illegible] teaspoonfuls, administered in a goodly quantity of iced water, plain or sweetened.

A peculiar application of ether is the driving of the fluid, in atomized spray, upon the skin for the purpose of freezing that texture by the cold developed by the evaporation of the ether—such freezing being for the sake of the anæsthesia that attends it. In this application the ether is delivered from an atomizer of good capacity, the nozzle being held about an inch and a half from the skin. The first sensation, that of cold, is followed by a severe burning feeling, which in turn is succeeded, as the skin freezes, by loss of all sensation. When so frozen the skin appears pale, shrunken, and of tallowy hue and feel, and can be cut without pain. The effect is superficial only, and if a deep incision is to be practised, the tissues beneath the skin must, after section of that covering, themselves be frozen, before cutting, by a renewed application of the spray. Freezing by ether spray is quickly done, and, if not maintained beyond a short time, is not followed by any deleterious effect. The procedure is appropriate only for brief and superficial surgical operations, and often is more painful than the knife.

Edward Curtis.

ETHIDENE DICHLORIDE.—*Ethylidene Dichloride:* $C_2H_4Cl_2$. This is an ethereal body, isomeric with and much resembling ethylene dichloride. It has been experimented with as an anæsthetic, and has been found to operate after the general manner of chloroform, including the occasional killing of a subject. It is administered similarly to chloroform.

Edward Curtis.

ETHOXY-CAFFEINE ($C_8H_9N_4O_2.OC_2H_5$) is prepared by boiling three parts of monobrom-caffeine with two parts of caustic potash in ten parts of alcohol. It forms needles which melt at 140° C., are soluble in hot alcohol or cold hydrochloric acid; slightly soluble in water and ether, being less so than caffeine, and insoluble in alkalies. It is decomposed by hot acid, and even in water dissolves easily in the presence of sodium benzoate or salicylate. Filehne found that dizziness, dimmed intellect, and headache resulted from doses of seven to ten grains. Rabbits show narcotic and diuretic effects. The presence of the *ethoxy* group seems to add distinct hypnotic qualities to the diuretic power of caffeine, and the main use of the drug is as a sedative in nervous headache or migraine. Dose, gr. i. to v. (0.06–0.3 gm.).

W. A. Bastedo.

ETHYL BROMIDE.—*Hydrobromic Ether:* C_2H_5Br. This body is a thin, colorless, very volatile ether, of a strong smell and hot taste; practically non-inflammable; sparingly soluble in water, but freely so in alcohol and ether. It is prone to spontaneous decomposition, on exposure, and should be kept in dark-colored and well-stoppered bottles, away from the light. A yellowish tinge means decomposition, and a sample so discolored is unfit for use.

Hydrobromic ether affects the human system similarly to chloroform, with the special features that sensibility is deadened early, and that narcosis comes quickly and pleasantly, but without full muscular relaxation. The latter circumstance is a drawback, since often a continuing of rigidity and even of spasms into the stage of narcosis defeats the use of the agent as an anæsthetic in surgery.

Hydrobromic ether causes fall of blood pressure, and, in overdosage, death, all after the manner of chloroform. It has been used as an anæsthetic, given by inhalation of its vapor, especially in cases in which a momentary narcosis only is needed.

It is given similarly to chloroform.

Edward Curtis.

ETHYL CHLORIDE.—*Hydrochloric Ether:* C_3H_5Cl. Ethyl chloride is prepared by the action of hydrochloric acid on alcohol, the resulting ether being condensed at a low temperature. When maintained at a temperature below 50° F. it is a colorless liquid having an alliaceous taste and smell. Its specific gravity at 32° F. is .9214. It mixes with water, about one part in fifty, and with alcohol and ether in all proportions. Its boiling point is 50° F., and above this temperature it exists as a gas. As a gas it is exceedingly inflammable, burning with a greenish flame and evolving hydrochloric acid.

Following the introduction of ether and chloroform, it was one of the many compounds suggested as suitable for general anæsthesia. Being very volatile it was easily administered and its anæsthetic action was more rapidly procured. The anæsthesia which it produced, however, proved to be very transient, and further experience as well as experimental work has shown that its action is accompanied by marked vascular and cardiac depression. Although strongly advocated by many, its employment never became general and it has now fallen into disuse.

It is now better known as a local anæsthetic. Advantage has been taken of its rapid evaporation to utilize the intense cold produced, in dental and minor surgical practice, and for the relief of the pain of superficial neuralgia. It has been used with satisfaction for the extraction of teeth, for opening abscesses, for removing ingrowing toenails, and for similar painful operations, and has been found to give instantaneous relief in facial neuralgia, intercostal neuralgia, and sciatica.

The method of utilizing this property was made simple and easy by M. Mounet, of Lyons, who suggested the storing of the compressed fluid in small capsules and tubes, by which means it may be preserved without alteration for a great length of time. When the drug was required for use the point of the capillary tube was broken off, and the opening directed downward on the part to be anæsthetized. These tubes have now been perfected by the addition of a screw cap which allows of any proportion of the contents being utilized, the remainder being preserved for future use. The heat of the hand is sufficient to raise the temperature of the fluid above its boiling point, and a stream of the rapidly volatilizing fluid issues as a spray, and may be applied to any part. The tube should be held at a distance of eight or ten inches from the part, and the surrounding tissues protected to prevent excessive and needless destruction of tissue. The surface of the skin acted upon rapidly becomes blanched and devoid of sensation, and regains its normal state upon the removal of the spray. If the application is persisted in, the vitality of the part is destroyed and necrosis is the result. During the employment of the spray care must be taken that no flame shall be in proximity, on account of the inflammability of the gas.

Beaumont Small.

ETHYL FORMATE.—*Formic Ether:* $H.COOC_2H_5$. This is the ethyl ester of formic acid, and is an ethereal liquid smelling like peach kernels. It is soluble in ten parts of water, and boils at 54° C. It is said to be of value as an antiseptic to the upper air passages.

W. A. Bastedo.

ETHYL IODIDE.—*Hydriodic Ether:* C_2H_5I. This body is a colorless ethereal fluid, non-inflammable, practically insoluble in water, but freely soluble in alcohol. It has a sharp taste and a smell simply penetrating if pure, but if impure often offensive. Ethyl iodide affects the human system after the manner of the volatile ethers generally, but is used in medicine—so far as it is used at all—either for the sake of *iodizing*, for which purpose some consider it efficacious, or for relieving oppression of breathing in pulmonary complaints. It is administered by inhalation, in dosage of fifteen drops.

Edward Curtis.

ETHYL PHENACETIN ($C_6H_4.OC_2H_5.NC_2H_5.CH_3CO$) is prepared by the action of ethyl iodide on phenacetin sodium. It is a yellow-colored oil, almost insoluble in water, readily soluble in alcohol and ether, and boiling at 350° C. As was expected, the introduction into phenacetin of an additional ethyl group has increased its hypnotic tendency, but the drug is not of sufficient value to be classed with such hypnotics as trional, chloralamide, etc.

W. A. Bastedo.

ETHYLENE BROMIDE.—$C_2H_4Br_2$. This organic compound was introduced into therapeutics as a convenient means of supplying bromine in cases in which its use is indicated for a prolonged period. The advantage claimed for it is, that it is not combined with potassium, sodium, or any basilous radicle, and its use does not disturb the digestion, the skin, or the mucous membranes, or produce any of the unpleasant effects that the older salts are liable to cause.

It is a colorless or faintly brown liquid, containing 90.9 per cent. of bromine. The odor is agreeable and taste sweetish. Its specific gravity is 2.163 at 69.8° F. Below 48° F. it becomes a solid, forming crystals. It is insoluble in water, soluble 1 in 4 of rectified spirit, and miscible in all proportions with absolute alcohol and oils.

The employment of ethylene bromide in epilepsy was recommended by Dr. J. Donath.[1] He used it in a great number of cases, and reports the details of ten cases in which he was able to watch its effects carefully. As a substitute for the bromides he found it very satisfactory, and the results, in his estimation, were much better. The cases were all of long standing and had been subjected to many forms of treatment. Under the use of the remedy the attacks became milder, shorter, and fewer in number, and in many instances assumed the character of *petit mal.* In three of the cases the convulsions were replaced by simple muscular twitchings without loss of consciousness.

The dose administered was gtt. vi. to xij. three times a day. It may be given in capsules with oil or in solution. The following preparations are recommended: (1) Ethylene bromide, gr. lxxv.; oil of almonds emulsion, ℥ iij.; oil of peppermint, gtt. ij.; dose, gtt. xxx. three times a day, in a third of a glass of milk. (2) Ethylene bromide, gr. xxiv.; rectified spirits, gr. lxxv.; oil of peppermint, gtt. ii.; dose, gtt. v. to x. three times a day. In preparing these mixtures the high specific gravity must not be forgotten, it being nearly two and a half times as heavy as water. Before using the drug Donath tested its action on himself, and found that in ordinary doses it did not produce any disturbing effects; but in large doses it was sometimes followed by nausea.

This drug must not be mistaken for ethyl bromide, which it resembles both in name and in appearance. A case is reported[2] in which such a mistake was made with fatal consequences. A written order for the anæsthetic, ethyl bromide, was sent to a druggist, who supplied ethylene bromide. Ten drachms were inhaled without producing any insensibility or anæsthesia. The administration was followed by suppression of urine and uncontrollable vomiting, which continued until the patient died, upon the following day. At the post-mortem examination there was found an hyperæmia of the meninges of the brain, also of the lungs, spleen, and kidneys. The liver was much enlarged, of a dirty-yellow color, and the cells were affected by a granular degeneration.

Beaumont Small.

ETHYLENE-DIAMINE [$C_2H_4(NH_2)_2$] is a clear, colorless liquid of specific gravity 0.970. It is readily soluble in water, has an ammoniacal odor, and strongly alkaline reaction, and dissolves albumin easily. It has been recommended for the solution of the false membrane of diphtheria, being especially useful, as its efficiency is not destroyed by antiseptics.

Ethylene-diamine-trikresol or *trikresolamine* is a solution of two per cent. each of ethylene-diamine and trikresol. It is a clear colorless liquid of alkaline reaction, becoming slightly yellow and cloudy on exposure to air. On account of this cloudiness, the manufacturers now make

---

[2] The London Lancet, January 10th, 1891.

kresamin, a twenty-five-per-cent. solution of these two chemicals from which a one- or two-per-cent. solution may be prepared when wanted (see *Kresamin*).

Ethylene-diamine silver phosphate is argentamine (see *Silver*).
W. A. Bastedo.

ETHYLENE DICHLORIDE. — *Ethene Dichloride, Dutch Liquid:* $C_2H_4Cl_2$. This body is a thin, colorless, oily fluid, smelling and tasting much like chloroform; volatile and inflammable; dissolving sparingly in water and freely in alcohol and ether. Its only medical interest lies in its attempted substitution for chloroform, as an anæsthetic which should retain the advantages of chloroform while free from its dangers. It seems to operate much like chloroform, and, according to Reichert, has little tendency to paralyze the heart. It is, however, very irritating to the throat. Administration, in mode and dose, is the same as with chloroform.
Edward Curtis.

ETHYLENE-PHENYLHYDRAZIN-SUCCINIC ACID ($C_{20}H_{22}N_4O_6$) is prepared by boiling ethylene-phenylhydrazin with succinic anhydride in alcohol. It forms crystalline needles soluble in water, and is used as an antipyretic.
W. A. Bastedo.

ETHYLIDENE CHLORIDE (CH_3CHCl_2).—Chlor-ethylidene; chloriden; ethidene bichloride; Aran's ether; Wigger's ether. This is a colorless ethereal liquid prepared by the action of chlorine on ethyl chloride. It has an agreeable fruity odor, a boiling point of 57° C. (134.6° F.), and specific gravity 1.180. It has been used as a safe and ephemeral general anæsthetic for short operations.
W. A. Bastedo.

ETIOLOGY. See *Infectious Diseases.*

EUCALYPTUS.—Blue Gum-tree. "The leaves of *Eucalyptus globulus* Labillardière (fam. *Myrtaceæ*) collected from the older parts of the tree" (U. S. P.). At the close of this article will be found some general information concerning the genus Eucalyptus. Attention is here restricted to the drug above-defined. This species occurs in the province of Victoria, Australia, and in Tasmania. It grows to a great size, but is not nearly so large as some of the other species. The exhalations from the tree, where forests of it occur, and especially from the fallen leaves, charge the atmosphere, thereby disinfecting it. This has suggested the idea of planting it in malarial regions, as about Rome, for a similar purpose, but it is doubtful if the experiment has anywhere been performed in a sufficiently thorough manner or upon a sufficiently extensive scale. It was an incorrect notion of this property of the tree which suggested its first use in medicine, that of a specific for malaria. In this direction it proved disappointing, but other important medicinal uses were found for it. The tree, when young, and the younger portions of it for some time after, bear leaves which to a great extent are wanting in the active constituent. These leaves are broadly ovate, heart-shaped at the base, little or not at all tapering at the apex, and comparatively thin. The official leaves (Fig. 1944) are 15 to 30 cm. (6 to 12 in.) long by 2 to 4 cm. ($\frac{3}{4}$ to $1\frac{1}{2}$ in.) broad, lanceolate and tapering from near the blunt base to an acute tip, strongly scythe-shaped, and very inequilateral, entire-margined, very thick, leathery, smooth, strongly glaucous, and with a short, stout, flattened and twisted petiole. Against the light they are strongly pellucid-punctate. They are highly aromatic. It is not known how leaves grown in the several countries where the tree has been introduced compare with those of native origin, but some of them are known to be very inferior, and it is certainly a conservative and wise policy to accept only those of native growth.

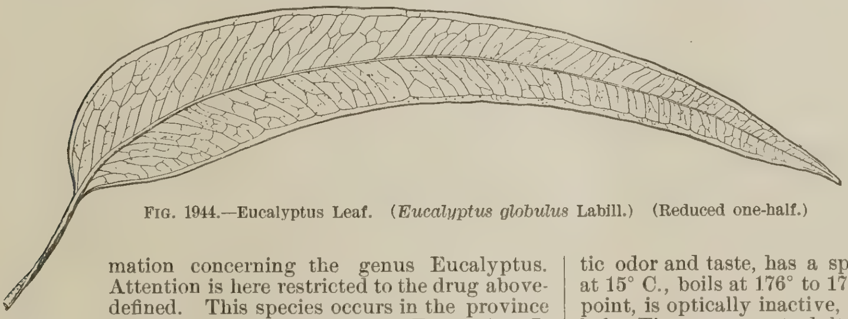

FIG. 1944.—Eucalyptus Leaf. (*Eucalyptus globulus* Labill.) (Reduced one-half.)

COMPOSITION.—Besides their active constituent, about six per cent. of volatile oil, they contain wax, resin, and tannin. The medicinal properties and uses of the drug can be best considered farther on, in connection with those of the oil and of eucalyptol.

Oil of Eucalyptus (*Oleum Eucalypti*, U. S. P.) is defined as "a volatile oil distilled from the fresh leaves of *E. globulus* Labillardière, *E. oleosa* F. von Müller, and some other species." It has a specific gravity of about 0.915 to 0.925 at 15° C., a characteristic odor and taste, and it dissolves freely in alcohol. Since the active constituent of the oil is *eucalyptol* (properly called cineol), the determination of the percentage of that constituent constitutes the proper method of valuation. For the same reason, it seems more rational for the Pharmacopœia to drop the oil from its next edition and to specify only the eucalyptol. With eucalyptol, there is pinene (from *E. globulus*) or cuminol (from *E. oleosa*), or the two oils may be mixed. Traces of several aldehydes may also be present. The optical rotation will also differ greatly in accordance with the source. The definition is faulty in that it does not specify the "other species," the oils of some of which are very distinct, even to being quite wanting in eucalyptol. The action of the oil, except for its being weaker and less regular, is that of eucalyptol. Phellandrene is its most common impurity, derived from other species of Eucalyptus.

Eucalyptol or *Cineol* ($C_{10}H_{18}O$) is defined by the Pharmacopœia as "a neutral body obtained from the volatile oil of *Eucalyptus globulus* Labillardière and of some other species of eucalyptus." The allowance of "other species" is here not objectionable as in the case of the oil, for the eucalyptol will be the same no matter what its source. It is also the active constituent of oil of cajuput and of some other Myrtaceous oils, and occurs in santonica, rosemary, peppermint, and many other oils of this and of other families. It is liquid, colorless, with a characteristic odor and taste, has a specific gravity of about 0.930 at 15° C., boils at 176° to 177° C., crystallizes at freezing point, is optically inactive, and dissolves freely in alcohol. The commonest adulterant is the oil, which at once renders it optically active.

ACTION AND USES.—The action and uses of eucalyptol and of the oil must be considered first, as that of the leaves is not quite identical. Their special property among volatile oils (see *Active Constituents of Plants*) is their antiseptic and expectorant properties. As an antiseptic, eucalyptol ranks second only to oil of cinnamon, and this property increases somewhat as the oil ages. It is not markedly irritating to the skin unless the surface is abraded or the vapor is confined, but it is markedly irritating to mucous membranes, especially to that of the stomach. As an expectorant, whether taken internally or by inhalation, it is both stimulating and antiseptic. Its antiperiodic action is very similar in kind, but also very inferior, to that of quinine. As a poison it acts as a gastro-intestinal irritant, and as a paralyzant of the vital functions, especially of the heart.

The uses of this drug are all to be regarded as local; even when given internally, it is transported in the circulation to the seat of its action. Externally, it is an excellent application to ulcers which require either disinfection or stimulation. For this purpose, a two- to five-per-cent. solution of the oil in alcohol may be employed, or a ten-per-cent. tincture of the leaves is sometimes even better, owing to the resin and tannin contained. The greatest value of eucalyptus is in the treatment of catarrhal conditions. Here the beneficial results are directly proportional to the need for stimulation and disinfection, and the reverse is true when there is already irritation or inflammation. Thus it is used topically, as well as internally, in gonorrhœa and vesical catarrh, in low forms of dyspepsia, and in respiratory catarrh. Although slightly diaphoretic, it is scarcely useful in that way. Its antiperiodic powers are feeble, but it is often of use when the case is mild, and the surroundings are not continuously infectious.

In considering the properties of the leaves, we have to regard only the percentage of oil which they contain, and the fact that the amounts of resin and tannin, and the bitter taste, are sufficient to add their effects to those of the eucalyptol.

The dose of the leaves and of their fluid extract, the only official preparation, is 2 to 8 gm., or c.c. (ʒ ss.–ij.), respectively. The oil and the eucalyptol are given in doses of from 0.3 to 2 c.c. (♏v. to xxx.).

The genus Eucalyptus contains between one hundred and twenty-five and one hundred and fifty species, almost all of Australia and Tasmania. They are for the most part large trees, rivalling in altitude the highest known, and form dense and vast forests. Their economic importance is of the highest. Their ability to withstand adverse climatic conditions permits of forestry operations where they would be otherwise impossible. Their timber is proof against the attacks of many destructive animals, and resists decay. Their astringent gums, described below, are of great importance. Many of the oils, though excluded from the uses above specified, as they contain no eucalyptol, are of importance in the arts. The trees are, moreover, highly ornamental.

(See *Honey*, *Eucalyptus*, and *Manna*, *Australian*).

Henry H. Rusby.

EUCALYPTUS GUM.—Eucalypti Gummi. A ruby-colored exudation, or so-called red gum, from the bark of *Eucalyptus rostratus* Schlecht, and some other species of eucalyptus. Sixteen species of eucalyptus have been named as yielding these gums, which are now very generally used in the place of our official malabar kino, this having become excessively scarce and high-priced. It is even true that the former is very commonly given when the latter is called for. The two are very similar indeed, this one occurring in grains or small masses, the fragments transparent and of a ruby-red or garnet-red color, somewhat tough and of a very astringent taste. When chewed, it adheres to the teeth and tinges the saliva red. Cold water dissolves from eighty to ninety per cent., forming a neutral solution, and it is almost entirely soluble in ninety-per-cent. alcohol. The properties and uses of this substance are identical with those of kino, and the dose is gr. ij.–v. *Henry H. Rusby.*

EUDERMOL, or nicotine salicylate, occurs in colorless hexagonal crystals or anhydrous needles, melting at 117.5° C., and soluble in water, alcohol, and oils. It contains fifty-four per cent. of nicotine, is non-irritant, odorless, and does not soil the clothing, and in 0.1 to 0.25 per cent. ointment is recommended in scabies, sycosis, and other parasitic skin diseases. Applied to a raw surface, it may produce symptoms of nicotine poisoning.

W. A. Bastedo.

EUGALLOL, or pyrogallol monoacetate [$C_6H_2.CH_3\text{-}CO.(OH)_3$], is a thick, brownish, transparent, syrupy material, readily soluble in water and in its own weight of acetone. It is marketed in thirty-three-per-cent. acetone solution, and when this is painted on the skin and allowed to evaporate it leaves a firm, elastic varnish. It is used in skin diseases, and Kromayer claims that when applied every day it induces an inflammation under whose influence the most stubborn psoriatic patch will disappear. He adds to its usefulness by dusting it with zinc oxide before it is dry. *W. A. Bastedo.*

EUGENOFORM is the sodium salt of eugenol-carbinol, the product of the action of formaldehyde on eugenol. It forms broad, colorless crystals, readily soluble in water, with difficulty in alcohol, and insoluble in ether. Its melting point is 160° C. The claim is made that it liberates formaldehyde in the system, and on this account Vogel recommends it as antiseptic to the gastro-intestinal tract in cholera, typhoid, etc. Its dose is 0.5–1 gm. (gr. vij.–xv.). *W. A. Bastedo.*

EUGENOL; EUGENIC ACID. See *Cloves.*

EUGENOL-ACETAMID ($C_6H_3.C_3H_5.OCH_3.OCH_2.CONH_2$) is prepared by the action of eugenol sodium on monochloracetic acid, with subsequent heating in the presence of ammonia. It forms fine needles or plates, and, according to Merck, is a local anæsthetic and antiseptic. It can be used for toothache or neuralgic pains.

W. A. Bastedo.

EUGENOL IODIDE, or iodo-eugenol ($C_6H_2I.C_3H_5.OCH_3.OH$), is obtained by the action of iodine on eugenol sodium. It is a yellowish, odorless, insoluble powder, which melts at 150° C. (302° F.), and is used as an antiseptic or as an iodoform substitute. *W. A. Bastedo.*

EUNATROL is a proprietary pill of sodium oleate coated with chocolate. Extravagant claims are made as to its value in gall stones and other biliary derangements. Dose, 1 gm. (gr. xv.) three times a day.

W. A. Bastedo.

EUNOL exists in "alpha" and "beta" modifications, made by combining eucalyptol with alpha- and beta-naphthol, respectively. These compounds are bitter, insoluble in water, and soluble in alcohol, ether, chloroform, and oils. They are antiseptic, and may be used in surgery and dermatology. *W. A. Bastedo.*

EUONYMUS; EUONYMIN. See *Wahoo.*

EUPATORIUM. See *Thoroughwort.*

EUPHORBIA PILULIFERA L.—A plant of the order *Euphorbiaceæ*, which has been recommended as a remedy for spasmodic affections and neuroses of the respiratory tract. It is indigenous to Australia, Brazil, and other Southern tropical countries. It derives its specific name from the seeds, which are held in capsules in the axils of the leaf, and when ripe are brown and hard. It is commonly known as the pill-bearing spurge. It is a very common annual herbaceous plant, and has a local reputation as a curative agent in all pulmonary troubles. Dr. Mattheson, of Queensland, was the first to call attention to its value in asthma, paroxysmal dyspnœa, whooping-cough, and other spasmodic affections. Later, it was studied by Dr. Marsset, under the direction of Dujardin-Beaumetz, and the result of his researches was published in the *Therapeutic Gazette*, February, 1885. Its action is directed to the respiratory and cardiac centres, and causes a retardation of the respiration and pulse, and when death has been produced it arises from a paralysis of these organs. It does not influence any of the other organs of the body, but when administered in excess it produces an irritant action on the gastric mucous membrane.

Its active principle is an acrid resin, which is soluble in water and dilute alcohol. Experiments on animals show that one part of the resin to one hundred of the animal, by weight, will produce a fatal result.

It has proved of service in all spasmodic affections of the bronchial tubes and lungs, in the dyspnœa of emphysema of the lungs, and in that due to cardiac affections. Dujardin-Beaumetz recommends it to be used in all cases in which iodide of potassium is used to relieve dyspnœa.

It has also been used to relieve the spasms and distress of angina pectoris, and in hay asthma as well as in coryza. In the latter diseases it rapidly checked the sneezing and other troublesome symptoms.

The dried plant is used, and its virtues are said to be best extracted by water. A decoction may be made by steeping half an ounce of the plant in two quarts of water, the dose to be three or four wineglassfuls during the day. The fluid extract is the best preparation to use, the dose being from fl. ʒ ss. to i. *Beaumont Small.*

EUPHORBIACEÆ.—(*The Spurge Family.*) One of the most important medicinal families of plants, if we consider its domestic as well as its professional uses. It contains more than two hundred genera and three thousand species, distributed over almost the entire earth, most abundant in the tropics, gradually decreasing with the temperature, and wanting in very cold regions. Their most notable property is their great power of adaptation to environment, so that some of them thrive equally well in the most arid deserts, and amidst luxuriant floras. Their economic value is great in other than medicinal directions. Two of our best rubbers are yielded respectively by the manihot and the heveas. Other manihots yield the highly important food cassava and its starch, tapioca. Some of the fruits are edible, and some of the timbers have special uses. Numerous species yield useful fixed oils, and several dye-stuffs are obtained. Medicinally, the properties depend almost entirely upon local stimulation or irritation, even the "alterative" effects probably depending ultimately upon some such depurative action. This irritating action increases in many species to the point of rendering them violent poisons, either externally or internally, or both. These irritating principles exist commonly in the milky juices with which the tissues abound, these being frequently highly caustic to the skin or other tissues. Even such violently acting juices have often been utilized as escharotics or epispastics. Among such juices we may mention those of *Hura*, *Euphorbia heterodoxa* Muell (Alvelos), and other species of this genus, *Hippomane, Toxicodendron, Ophthalmablapton*, and *Excoecaria*. The latter acts violently even by access of its smoke, and smoking the body with it is, among the Fiji, a heroic treatment for leprosy. Juices, mostly milder in their action, are used internally as irritant purges, but many of them in overdoses may prove emetico-cathartic poisons. Rarely do these purgatives consist of the extracted juice, as in *euphorbium*, but usually of the tissues containing the latex, fresh or dried, or medicinal preparations of them. Among such may be mentioned the root of *Jatropha macrorhiza* Benth., of *Stillingia*, of *Euphorbia Ipecacuanhæ* L., *E. Lathyris* L., *E. marginata* Pursh., *E. corollata* L., *E. Cyparissias* L., and other species of this genus, the spurges, the herbage of *Mercurialis*, *Tragia* sps., and *Joannesia*, and various parts of many species of *Croton* and *Phyllanthus*. Many of the latter are also used as fish poisons. In other cases, the purgative constituent is, or resides in, a fixed oil, usually of the seeds, as in croton, castor, and curcas oils. Powerful albuminous poisons usually also reside in these seeds. Occasionally, as in buxus, alkaloids occur, while a number of special or exceptional drugs, like kamala and cascarilla, will be found discussed in their proper alphabetical order. A complete enumeration of the medicinal species of the family would fill several of these pages.

Henry H. Rusby.

EUPHORBIUM, Ph. G.—An irritating and drastic gum resin, obtained from *Euphorbia resinifera* Berg (fam. *Euphorbiaceæ*). This is a large, leafless, cactus-like perennial, growing from four to six feet high, having a thick, gray, woody stem, and numerous very fleshy, quadrangular, spiny green branches. The plant is laden with a milky juice, which exudes when it is wounded, and dries readily in tears upon the surface or entangled among the spines. It is a native of the interior of Morocco.

The resin is exported from Mogador. It has been known in European commerce from a very remote period, is mentioned by numerous older medical writers, and had its place in most pharmacopœias, but its use is now nearly obsolete. It is collected by incising the stems early in the season, and collecting the hardened tears some weeks later. These are usually irregular, from the size of a hickory nut down, yellow, translucent, with a dull, waxy surface, and a brittle fracture. They often enclose or fasten spines or other portions of the plant. Frequently they are perforated. The odor is slight, unless heated, but the dust raised by gathering, sorting, or powdering it is exceedingly irritating to face and nose, so that those handling it should wear veils, or take means to avoid the dust. Flückiger's analysis of euphorbium gives it the following composition: *amorphous resin*, 38; *euphorbon*, 22; *mucilage*, 18; *malates*, 12; *inorganic ingredients*, 10. Of these, the irritating and active principle is the amorphous resin. It is soluble in alcohol.

Action and Use.—Euphorbium is a violent irritant, like cashew nuts, chrysarobin, croton oil, etc.; it is also, like the latter, an irritant drastic. Formerly it was used internally for this quality, but is now never so given. For external use as an irritant, or, more generally, diluted with other things, as a rubefacient (ointments, plasters, etc.), it is occasionally called for, and in the more obstinate chronic skin affections has some value; but the necessity which cannot better be met with other medicines must be rare. *W. P. Bolles.*

EUPHORIN.—Phenyl-urethane. Carbonate of ethyl and phenyl. This is a compound derived from aniline and is somewhat allied to acetanilid. It occurs as a white crystalline powder, with a faint aromatic odor and slight taste, almost insoluble in water, but freely soluble in weak alcohol and wines. It was introduced by Dr. Sansoni * to replace antipyrin, antifebrin, and other drugs of the same class. The dose is from gr. viiss. to xv.

It is also employed as an antiseptic powder in the treatment of ulcers and wounds. *Beaumont Small.*

EUPHTHALMIN HYDROCHLORATE ($C_{17}H_{25}NO_3$.-HCl).—The mandelic acid derivative of labile n-methyl-vinyl-diacetone-alkamine, was introduced to ophthalmology by Treutler in 1897. It is closely related to beta-eucaine, the hydrochlorate of benzoyl-vinyl-diacetone-alkamine, bearing to this the same relation as does homatropine to tropacocaine. It is a white, crystalline powder, readily soluble in water and in two parts of boiling alcohol, but separating into crystalline aggregates on addition of ether. It is anhydrous, melts at 183° C., and is not decomposed by boiling.

The salicylate ($C_{17}H_{25}NO_3.C_6H_4.OH.COOH$) is made by dissolving equal parts of euphthalmin (base) and acid salicylic in absolute ether, and recrystallizing from ether and alcohol. It melts at 115° C., and is readily soluble in water.

Experiments on animals by Vinci show a primary irritation of the nervous system in the form of restlessness, excitement, and increased reflexes, then tonic and clonic spasms, opisthotonos, exophthalmos, cyanosis, disturbed respiration, and death from general paralysis. The vaso-motor system is directly paralyzed, and blood pressure falls in spite of increased cardiac activity. Instilled into the eye in one- to ten-per-cent. solution, it produces salivation from its action on the secretory fibres of the chorda tympani; and, owing to paralysis of the nerves of the sphincter iridis, without affecting the sympathetic dilator fibres, mydriasis supervenes in fifteen to forty minutes, to disappear practically in two to eight hours, and completely in less than twenty-four hours. It also dilates the pupil when given internally.

Hinshelwood obtained the maximum dilatation from three separate drops of a five-per-cent. solution at two-minute intervals, this acting somewhat less promptly in one eye, than one-per-cent. homatropine solution in the other eye of the same patient. Euphthalmin acts more rapidly in young than in old people, causes no smarting or discomfort, weakens accommodation but little, has no appreciable effect on the conjunctival vessels or the corneal epithelium, and increases intra-ocular tension but slightly or not at all. The mydriasis is more complete in strong sunlight than that of cocaine or homatropine, yet there is such slight effect on accommodation that reading and writing are not materially interfered with. Jackson found no case in which the pupil was entirely without response to light, and noted that during the maximum effect about one-fourth of the total accommodation was lost. He prefers cocaine for ordinary ophthalmoscopic work, using euphthalmin for testing vision with strong light in cataract, or as a rapid mydriatic where iritis is suspected but still uncertain. He recommends a solution containing one per cent. each of euphthalmin and cocaine hydrochlorates. Knapp uses a ten-per-cent. solution for ordinary ophthalmoscopic examinations, stating, however, that it dilates the pupil less powerfully than atropine. Sneguiroff increased the speed of its action by a prior instillation of one per cent. holocain, this hastening the diffusion of fluids from the conjunctival sac into the anterior chamber. Some observers have used euphthalmin in glaucoma, claiming that its brief mydriasis does not allow of increased tension, yet its safety in this condition has not been proven. In glaucoma and in the aged, cocaine is a more suitable agent. As yet toxic effects from the drug have not been reported. Euphthalmin will act in one-per-cent. solution, but it requires repeated instillations to produce mydriasis.

---

* Therap. Monatsh., November, 1890.

W. A. Bastedo.

EUPYRIN.—Vanillin-ethyl-carbonate-p-phenetidin. This substance belongs to the paraphenetidin group which includes phenacetin, being a compound of paraphenetidin with vanillin. It forms pale, greenish-yellow needles of vanilla-like odor and without taste. It is freely soluble in alcohol, ether, and chloroform, but with difficulty in water. This is an antipyretic, which, according to Overbach, possesses stimulating properties, as evidenced by the sensation of well-being which follows its ingestion. It is of no use in neuralgia, but is recommended as a mild, non-toxic antipyretic, especially suitable for old people or children, or in cases of fever with great weakness. *W. A. Bastedo.*

EUQUININE, or Quinine-carbonic-ether $(CO.OC_2H_5.OC_{20}H_{23}N_2O)$, is the ethyl carbonic ester of quinine produced by the action of quinine on ethyl carbonyl chloride. It forms white needle-like crystals in fleecy masses which melt at 95° C. Its reaction is alkaline, and its taste flat with a slightly bitterish after-taste. It dissolves with difficulty in water, but readily in alcohol, ether, chloroform, and dilute acids, the acid solutions fluorescing like those of other quinine compounds. The hydrochlorate is the most soluble salt, the sulphate slightly soluble, and the tannate almost insoluble. Euquinine gives the thalleoquin reaction, but not the herapathite reaction of quinine.

Euquinine is a quinine compound which clinical reports show to possess all the valuable properties of the mother substance, without causing, in therapeutic dosage, ringing of the ears, nausea, headache, or other symptoms of cinchonism. As it is also practically tasteless, it can be administered to children with ease. It is said also to be borne well by those having an idiosyncrasy against quinine. Bernheim uses it in solution with ferric chloride for lavage in gastritis with dilatation, and as an enema in the stubborn diarrhœa of colitis. Goliner prefers it to quinine, acetanilid, antipyrin, or phenacetin in la grippe. For malaria it is best preceded by a mercurial laxative and combined with ginger or other aromatic. It is highly recommended in whooping-cough and the fevers of phthisis. The dose up to 2 or 3 gm. (gr. xxx.–xlv.) is slightly larger than that of quinine sulphate, and it can be administered in soup, gruel, milk, cocoa, or flavored syrup. *W. A. Bastedo.*

EUREKA SPRINGS.—Carroll County, Arkansas.

Post-Office.—Eureka Springs. Hotels: Crescent and Southern, and numerous smaller houses.

Access.—Viâ Eureka Springs, branch of the St. Louis and San Francisco Railroad.

The development of Eureka Springs affords a forcible object-lesson of the progress of civilization in the Western wilds of America. Where a few years ago was an uninhabited sterile mountain glen, now nestles a bright little city of more than 6,000 inhabitants, which number is greatly increased by the large floating population of visitors, tourists, business men, and invalids constantly coming and going. The city is lighted by gas and electricity, contains an electric railway system, and excellent schools, hotels, etc. The Interstate Summer Normal and Educational Assembly have erected a building with a seating capacity of five thousand persons, in which annual summer sessions are held and attended by visitors from all parts of the Union. The State District Normal School of Arkansas is also located here. The springs are sixty in number, the best known being as follows: The "Crescent," "Dairy," "Basin," "Magnetic," "Harding," "Little Eureka," "Sweet," "Grotto," "Mystic," "Oil," "Arsenic," "Cave," and "Cold" springs. The waters contain mainly carbonates of lime and magnesia, with a small proportion of sulphates and chlorides. They are not strongly mineralized, and differ but slightly from each other. The following table from the report of F. W. Clarke, Chief of Division of Chemistry, United States Geological Survey, and R. R. Riggs,* shows the proportion of solids in four of the principal springs:

	Grains per United States gallon.
Crescent Spring	5.36
Dairy Spring	6.29
Basin Spring	6.97
Magnetic Spring	10.99

The following table sent us by Dr. John D. Jordan, of Eureka Springs, shows some of the climatic advantages of the resort:

Eureka Springs.	Altitude above sea level		2,000 ft.
	Annual average precipitation		32.79 in.
	Mean temperature (Fahr.)	Spring	60.85°
		Summer	74.79°
		Autumn	58.01°
		Winter	42.08°
	Annual average		58.93°
	Relative humidity (per cent.)		58.93
	Average number of days per annum	Clear weather	209
		Fair weather	90
		Cloudy weather.	66
	Death rate per annum		10.33 per 1,000

The city is picturesquely located on the headwaters of the White River in the Ozark Mountains. A sojourn at Eureka Springs and the free use of its waters are stated to be beneficial in a wide range of affections, including rheumatism, skin, nervous, renal and bladder disorders, dyspepsia, hay fever, and general debility.

James K. Crook.

EUREKA SPRINGS.—Humboldt County, California.

Post-Office.—Eureka.

These springs are located near the town of Eureka. The waters belong to the muriated-sulphureted class, and were analyzed by Prof. W. D. Johnson in 1885, with the following result:

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	1,403.00
Sodium carbonate	10.10
Sodium bromide	14.00
Potassium sulphate	12.20
Magnesium chloride	101.00
Magnesium sulphate	211.30
Calcium carbonate	3.80
Calcium sulphate	42.50
Alumina	1.30
Silica	.95
Ferrous carbonate	.12

---

* February 15th, 1877.

Solids.	Grains.
Manganese	Trace.
Boric acid	Trace.
Iodine	Trace.
Lithium	Trace.
Total	1800.27
Carbonic acid gas	Small amount.
Sulphureted hydrogen	Saturated.

This water is now used extensively by the residents of the neighboring districts. It is also shipped to San Francisco. The action of the water is laxative and diuretic. *James K. Crook.*

EURESOL, or resorcin monoacetate [$C_6H_3(OH)_2.CH_3CO$], is a viscid, transparent mass of pleasant odor, and easily reduced to a powder. Kromayer has obtained good results in the treatment of over sixty cases of acne vulgaris, rosacea, sycosis, seborrhœa, seborrhœic eczema, etc. It is used in acetone solution as a varnish, leaving a coating on the skin when dry. *W. A. Bastedo.*

EUROBIN, or chrysarobin triacetate, is a dark powder, insoluble in water, but soluble in chloroform, acetone, ether, or acetic acid. Kromayer finds that it causes more reaction than chrysarobin on chronically inflamed skin, as in chronic eczema. He uses it in one to twenty per cent. acetone solution as a varnish. Eugallol or saligallol may be added with advantage.

W. A. Bastedo.

EUROPHEN.—This is one of the many compounds containing iodine and devoid of any disagreeable odor, that have been introduced as substitutes for iodoform. Chemically it is di-isobutylortho-cresol iodide, its formula being $\left(\begin{matrix}C_4H_9\\CH_3\end{matrix} > C_6H_3O\right)_2HI$. Its relation to cresol and iodine is much the same as that of aristol to thymol and iodine.

It is an extremely light amorphous yellow powder, being about five times as bulky as iodoform, with an aromatic odor resembling saffron. It contains 27.6 per cent. of iodine. It is insoluble in water and glycerin, soluble in alcohol up to thirty per cent., and in ether, chloroform, collodion, and fatty oils up to twenty-five per cent. It must be excluded from light and heat, as it is readily decomposed. In contact with water it is slowly decomposed, yielding free iodine.

The use of europhen is indicated in all cases in which iodoform is employed in wounds and ulcers and ulcerated surfaces, and in diseased conditions of the nasal and pharyngeal cavities of the vagina and uterus and all mucous surfaces. In various forms of skin disease it has proved beneficial, especially the acute and chronic eczemas. It is also administered internally in all stages of syphilitic disease, but is recommended as being most active in the third stage, and is thought to replace the iodide of potassium as a specific. The dose to commence with should be one-quarter of a grain, gradually to be increased to one or two grains. If it is administered too rapidly there is a danger of iodism manifesting itself. The same amount may be used hypodermically, a ten-per-cent. solution in oil being prepared for this purpose. For external use as an ointment the following has been selected as an excellent combination: Europhen, 3 parts; olive oil, 7 parts; vaseline, 60 parts; lanolin, 30 parts.

Beaumont Small.

EUSTRONGYLUS GIGAS. See *Nematodes.*

EVOLUTION.—(L. *evolutio*, an unrolling, from *evolvere*, to unroll or unfold.) The term *evolution* has been employed with various meanings:

1. It was used at first in its true etymological meaning of unrolling or unfolding to describe a supposed method of the individual development of organisms.

2. Later it was applied in a metaphorical sense to the origin of species, where it means simply continuous descent with modification, or the origin of species by the alteration of pre-existing species.

3. Finally, we have the metaphysical sense of the word when used as the designation of a system of philosophy that attempts to explain the origin of all things by continuous change. The great exponent of the evolutionary philosophy is Herbert Spencer. The central points in his philosophy are the laws of the indestructibility of matter and the conservation of energy. According to Spencer, the result of these laws is rhythmic motion, manifested everywhere from the dance of molecules to gyrations of planets, and this produces an alternation of evolution and dissolution throughout the universe. Spencer defines this evolution as "change from an indefinite, incoherent homogeneity to a definite, coherent heterogeneity, through continuous differentiations and integrations."

Metaphysics being beyond the scope of the present work, we will confine our attention to the two biological meanings of *evolution.*

Evolution in Ontogeny.—Modern embryology may be said to have begun with the work on the development of the chick which Harvey described in his "Treatise on Generation" in 1651. By means of a hand lens he was able to trace the development of the chick in a general way back to the beginning of the second day. He found that the embryo arises from the light-colored spot in the yolk, called by Fabricius the *cicatricula.* Harvey saw this dilate and become divided into circles, forming what we now call the *area embryonalis,* and this he compared to the iris of the eye and called the *oculum ovi.* At the end of the third day he discovered a fine line of red around the edge of the spot, "and nearly in its centre there appears," he says, "a leaping point of the color of blood so small that when it contracts it almost entirely escapes the eye, when it dilates it shows like the smallest spark of fire. Such is the outset of animal life which the plastic force of nature puts in motion from the most insignificant beginnings." He was unable to distinguish any other parts of the embryo until the fifth day, and he describes in a very interesting way the gradual appearance of the various organs of the embryo as he saw them from that time until the perfect chick is formed.

One of the great generalizations that Harvey made as a result of his observations is known as the theory of *epigenesis.* This is, briefly, that the embryo is built up gradually from a simple beginning by the addition of part to part in a definite order. Harvey regarded the blood as "the first engendered part . . . the source and origin of all other parts . . . which thence obtain their vital heat and become subservient to it in its duties."

It was in opposition to this theory of epigenesis that the theory of *evolution* arose.

Malpighi, working a little later than Harvey, and probably having a better microscope, found that the blood is not the "first engendered part," for he could see an outline of the embryo before the appearance of the "*punctum sanguineum.*" This small detail of observation led Malpighi to reject Harvey's whole theory of epigenesis. He asserted, instead, that the embryo as a whole is present in the egg before incubation, that it is *predelineated.* This led to a great discussion which lasted for more than a hundred years. Of course, if the whole embryo is predelineated in the egg, epigenesis is an impossibility; and development must be a process of *evolution,* an unfolding of the pre-existing embryo. The chief exponent of this theory was Bonnet, who carried it out to its logical conclusion (1762), and asserted that development is not only a process of evolution, but also that all germs have existed since the day of creation, and that each embryo contains in similar form the germs of all subsequent generations.

The theory of evolution seems, on the whole, to have prevailed as the generally accepted explanation of development until 1812, when Meckel called attention to a Latin treatise, "Theoria Generationis," published in 1759 by Caspar Frederick Wolff, as the dissertation for his doctor's degree. In this paper Wolff had traced the development of both the chick and certain flowering plants back to very simple beginnings, and he showed that the development is really an epigenesis and not an evolution. This view has been fully confirmed by the vast amount of research in embryology that has been carried out during the latter half of the nineteenth century.

The almost mediæval theory of evolution of Bonnet and his friends seems so absurd to-day that it would hardly be worth mentioning if it were not for the fact that the theory has been revived recently in a more subtle form.

To be sure the individual development of organisms, so far as we can see with the eye or with the most powerful microscopes, is clearly a process of epigenesis. But, after all, there is much that still remains invisible, and the utmost limits of our vision include only superficial manifestations of forces working within the protoplasm. May it not, then, be true that the embryo is really preformed in invisible particles within the germ-plasm? May not differentiation be in essence merely the visualization of pre-existing invisible potentialities? If we answer these questions in the affirmative, our explanation of ontogeny is as much evolution as was Bonnet's. There has been much discussion of this subject within the past ten years, but it is so intimately connected with the theories of heredity that it will be more conveniently reviewed in connection with that subject (see *Heredity*).

Organic Evolution.—Usually when one speaks of evolution one means what has been called *organic evolution*, the origin of diversity in the organic world by means of natural processes.

The opposing theory is that of *special creation*. According to this latter view, each species was established in the beginning by a miraculous act of creation. Each species is, then, a distinct and concrete phenomenon of nature. There is but one true classification which is to be discovered, not invented, by naturalists.

From the point of view of evolution, on the other hand, the great fact of nature is the diversity of organic forms, and no sharp line can be drawn between varieties, species, genera, and families. A classification is merely a convenient invention of the human mind to summarize the present state of knowledge in regard to the structure of organisms, and must change from time to time as such knowledge increases. The idea of miraculous intervention is rejected, and the effort is to discover in the organic world the same orderly working of the laws of nature that has been found to obtain in the inorganic world.

In regard to evolution, it must be borne in mind that two questions are involved: First, does the theory of evolution, as a whole, furnish a better summary of our knowledge of organisms than the theory of special creation? In other words, is evolution to be regarded as an historical fact? Second, what are the factors into which the theory of evolution may be resolved, or, how may the fact of evolution be explained as a process?

While there is much difference of opinion among naturalists in regard to the second question, the first is to-day answered by almost every man of science in the affirmative. On the other hand, there are many persons who have not paid especial attention to natural history and who still hold to the doctrine of special creation. Therefore, it may be well to give a brief summary of the evidence on which men of science base their belief in evolution as a fact.

The Evidence of Evolution.—1. In the first place, we have the *analogy of the other sciences*. For the ancients the sun, the moon, and the planets were controlled in their movements by attendant spirits. Until well into the nineteenth century the structure of the earth was explained as the result of a series of catastrophes accompanied by changes in the order of nature. But Newton showed that the movements of the planets could be described by the same formula that describes the falling of a stone, and the result of the labors of Hutton, Lyell, and their successors, has been to show that the structure of the earth may be explained as the gradual effect of forces now to be observed at work upon the earth's surface. In a similar way, in physics and chemistry the supernatural has been replaced by the natural, until the doctrine of special creation, if accepted, would remain the only exception to the general rule that all phenomena of nature are to be explained by natural laws.

When we say "explained" it must be borne in mind that, in reality, science explains nothing. What science really does is to describe phenomena by means of brief formulæ that summarize the greatest possible amount of knowledge. A "natural law" is not an object of nature, it can do nothing. It is merely a human invention to summarize man's experience of the past and his belief as to the future. When we say that a stone falls with the velocity, $v = gt$, we mean that, whenever the experiment has been tried under proper conditions, this formula has been found to describe truly the result, and we have no reason to believe that it will not always be found to be true in the future. And this is all we mean when we say that the stone falls because of the law of gravitation. In ordinary language we are said to have explained the fall of the stone, but, in fact, we do not know what gravitation is, and we know no more *why* the stone falls than we did before. The common error of deifying natural law may be avoided if we remember that a natural law is a description of a sequence of events that may be expected to occur always in the same order under the same conditions, and an event is explained, or "made plain," when referred to its proper place in this sequence.

Now the question before the naturalist is, Shall the factor of special creation be included in the formula descriptive of the diversity of form in the organic world? We have seen that in all the other sciences the supernatural factors have been rejected as superfluous, therefore from analogy it is *a priori* probable this factor should be rejected also in biological theory, including the theory of the origin of species.

2. Turning now to the results of observation, it is evident that from the doctrine of special creation it would be impossible to predict anything in regard to the *classification* of animals and plants, except that it might be supposed that species would be fairly distinct. From the theory of evolution, on the contrary, it might be expected that it would be difficult in many cases to distinguish between varieties and species on the one hand, and between species and genera on the other. Moreover, it would be expected that, to show their true affinities, in the classification the species would have to be arranged like the buds on a tree, in which the buds are the species, while the twigs, the branches, and the stem would represent their hypothetical lines of descent. These two predictions are fully verified in practice, and the theory is to that extent confirmed.

3. The classification of species leads directly to the study of their *geographical distribution*. The theory of evolution assumes that each species began with relatively few individuals in a restricted locality, from which it spread as the number of individuals increased until it reached its maximum extension. Thus far the theory of special creation might agree. But it would deny the further assumption, that each genus was at first a single species which, as it gradually extended its area of distribution, became exposed to different conditions in different parts of this area, and that, as a result of the operation of natural laws, the individuals in these different sections became changed in the course of generations so as to constitute distinct varieties and later species.

As a corollary to this theorem of evolution, we should expect that the more inclusive a group, the wider would be its range. The length of time required for the evolution of an order would probably be greater than for that of a genus, hence there would be more time for migration and, consequently, a wider range.

Another corrollary is that there should be a close relation between the affinities of the organisms in any area and the physical barriers separating it from other areas.

The study of geographical distribution confirms these predictions. It is found that, while some species have a cosmopolitan range, most species have more restricted ranges than the genera to which they belong, and the genera in turn have smaller ranges than their families and orders.

The affinities of species in any region are found, in fact, to depend more upon the position of barriers than upon the climate or other conditions. This is shown by a comparison of the productions of the Northern hemisphere with those of the more isolated areas of the Southern hemisphere. Oceanic islands, as compared to continental islands, furnish also important evidence on this point.

It must not be forgotten, however, that the facts of geographical distribution present some difficulties for the theory of evolution. But, while some of these still remain to be solved, most of them have been cleared up by a study of the past history of the earth and the geological sequence and distribution of organisms.

4. It might be expected that a study of *palæontology* would furnish the very best evidence of evolution, if it were not for the fact that the preservation of organisms as fossils depends on so many factors of chance that the odds against the preservation of any individual, or even any species, are very high, and the odds against its being both preserved and discovered by palæontologists are still higher. Nevertheless, palæontology has furnished much evidence, and, so far as it goes, it all supports the theory.

In the first place, the evidence from palæontology supplements that from the present geographical distribution by showing the geographical distribution in previous geological periods, and thus making it possible to trace the migrations of forms and to explain their present distribution. In some areas there is a marked similarity between species now living on the surface and the fossils found in the underlying deposits. In cases in which the present distribution is discontinuous to a marked degree, as in the marsupials, tapirs, and camels, it has been found that during earlier periods they occupied intermediate areas.

Direct evidence is furnished by the study of the succession of forms in geological time. In general it may be said that, the farther back we go in time, the less differentiated the forms appear. And in a few series, such as the camels and the horses, it has been possible to trace very completely the line of descent from a very generalized type to the highly differentiated forms now living. The study of such a series leaves one with very little doubt as to the fact of evolution.

5. But the fossils are not the only source of information in regard to the past history of species. Each individual may give in the course of its development an abbreviated and simplified picture of the history of its race. At least, such is the inference drawn from a large body of fact furnished by the study of *embryology*. It has been found, as a general rule, that the earlier stages in the development of any form correspond to the more generalized, lower, types of the same group. And in some cases, for example, the fishes, it has been shown that the succession of these stages of gradually increasing differentiation correspond with the succession of forms in geological time. This is exactly what would be expected on the theory of evolution. On the theory of special creation one would expect the development of the individual to take place in as direct a manner as possible, unless there is some physical necessity for the indirect methods which give the appearance of recapitulation of ancestral history. That there is no such necessity is shown by the absence of these ancestral stages in the development of many species, while they are present in related forms, and by the fact that two individuals may reach a practically identical adult structure by entirely different modes of development, as, for example, individuals developed from buds and from eggs of the same species (see article *Budding*).

6. Further evidence of the past history of a species is furnished by the presence of *vestigial organs*, organs that are arrested in development and are apparently of no use to the species in which they occur, but which are homologous with fully developed functional organs in other, usually lower, species of the same or related groups. The human body contains a great number of such vestiges. They are perfectly unintelligible on the theory of special creation, and perfectly in harmony with the theory of evolution.

7. The study of comparative anatomy affords also another line of evidence concerning evolution. This is found in the distribution of *homologous organs*. If each species has been created separately there is no reason why organs constructed on the same fundamental plan, that is homologous organs, should not be found in any number of species. But if, on the contrary, the numerous species in any great group have arisen by the diversification of a relatively simple undifferentiated type, then we would expect the species in one group to show their common origin in similarity of plan of structure, and we would expect them to differ in plan of structure from species of another group having a different origin, although their organs might be called upon to perform similar functions.

Now this is just what we do find to be the case. An internal digestive tract is a fundamental characteristic of all animals above the Protozoa, and we can regard it as probably more or less homologous in all species. But when we come to less fundamental structures, such as legs, wings, and eyes, it is found that the homologies between species are confined to their own great groups. For example, although the wing of an insect and the wing of a bird have exactly analogous functions, they are not in any degree homologous. On the other hand, the wing of a bird and the wing of a bat, while differing in detail, have the same architectural plan, which is also the same as that of the arm of man and the foreleg of a horse. Thus the fore-limb throughout the vertebrate series is homologous, although differing greatly in function. This is but one of a great many similar facts, all of which go to show that the vertebrates are derived from a common ancestral type. In the same way the eyes are homologous in all vertebrates, and are not homologous with those of any other group. Mivart thought he had found an homology in the eye of the squid. In its optical principles and general form this eye resembles that of a vertebrate very closely. But a careful examination of its mode of development and minute structure shows that it is formed upon an entirely different plan.

Looking back over these seven lines of evidence, we find that, while they present some difficulties, these are all capable of explanation from the point of view of evolution; and these lines of evidence support and supplement one another so completely that the man of science appears to be justified in accepting evolution as a fact, provided he can construct a valid theory to explain or describe the method of evolution.

History of the Theories of Evolution.—The idea of evolution appears in the speculations of the "nature philosophers" of the last decade of the eighteenth century and the first decade of the nineteenth. According to Osborn, this is largely due to the influence of the Greek philosophers. At any rate, the idea seems to have been in the air at this time, for several of these men suggested more or less independently of one another that species are not fixed things, but are subject to change, and that their present form is the result of such change. In each case, however, it was more the groping after a theory than the formation of one, and what was of scientific value was often hidden by the fanciful and absurd. The question was chiefly as to evolution as a fact, and little attempt was made to answer the question as to method, as to how evolution could be brought about.

The first consistent attempt to answer this question of method was made by Lamarck in the year 1809 in his "Philosophie Zoologique." According to Lamarck, "the systematic divisions of classes, orders, families, genera, and species, as well as their designations, are the arbitrary and artificial productions of man. The kinds or species of organisms are of unequal age, developed one after the other, and show only a relative and temporary persistence; species arise out of varieties. The difference in the conditions of life have a modifying influence on the organization, the general form, and the parts of animals, and so have the use and disuse of organs. In the first beginning only the very simplest and lowest animals and plants come into existence; those of a more complex organization only at a later period. The course of the earth's development and that of its organic inhabitants was continuous, not interrupted by violent revolutions." He not only asserted as others had done that species have developed, but he gave an answer to the question, How? It is a well-known fact that muscles and other parts that are much used grow stronger, become harder, or are modified in some way that is usually of advantage, while parts that are not used tend to dwindle. Lamarck believed that species are subject to a continued transformation by the inheritance of the results of use and disuse. As the use and disuse of organs is determined by the habits of the individual, Lamarck regarded habit as the chief cause of evolution. An animal's wish to do a certain sort of thing and his constant striving to do it resulted in a change of structure in his descendants that would render them better able to do this thing. On the face of it, it seems reasonable enough to suppose that the well-known effects of use and disuse are inherited, and that varieties and finally whole species have arisen or have suffered change in that manner. But, when Lamarck attempted to carry out this theory in detail, he ran into manifest absurdities, as, for instance, when he attributes the long neck of the giraffe to its habit of striving to reach the leaves of trees. It was perhaps as much on account of the number of such absurdities, as on account of the advance beyond its age, that this work of Lamarck's remained for a long time in obscurity, and was not even mentioned by such men as Goethe and Cuvier, although Lamarck held a high rank by reason of his other works, especially his "Histoire Naturelle des Animaux sans Vertèbres," published in 1815–22.

Another Frenchman, Etienne Geoffroy St. Hilaire, arrived at a similar theory of evolution at about the same time that Lamarck did, but he did not publish until 1828 and 1830. His theory was the same as Lamarck's, except that he laid less stress on habit and the inherited effects of use and disuse and more on changes in external conditions. His most important contribution is the idea of permanence of sports giving rise to new varieties and species. He attacked Cuvier's theory that the animal kingdom presents four great independent types of structure—radiate, articulate, molluscan, and vertebrate—and attempted to prove that the whole animal kingdom is formed upon a single structural plan. This gave rise to a dispute which culminated in the famous debates of February 22d and July 19th, 1830, in which Cuvier, with his superior knowledge of comparative anatomy, came off the victor.

From this time on for nearly thirty years the believers in special creation and the permanence of species rested assured of their position, relying on the wide knowledge and high authority of Cuvier. They little dreamed of the volcano beneath their feet. For the echoes of the famous debate of 1830 had hardly died away when Charles Darwin started on a voyage that was to have for its chief result the greatest revolution in thought of modern times.

When Darwin started on his voyage in the *Beagle* in 1831, he took with him a copy of Lyell's "Principles of Geology," and he was thus predisposed to regard the phenomena of nature as occurring in an orderly and uninterrupted sequence; moreover, there was in this book a discussion of Lamarck's theory, so that this must also have been fresh in his mind. From his autobiography (p. 82) we learn that he had been "deeply impressed by discovering in the Pampean formation great fossil animals covered with armor like that on existing armadillos; secondly, by the manner in which closely allied animals replace one another in proceeding southward on the continent; and thirdly, by the South American character of most of the productions of the Galapagos Archipelago, and more especially by the manner in which they differ slightly on each island of the group; none of the islands appearing to be very ancient in a geological sense." It seemed to him that such facts, as well as many others could be explained only by the supposition that species gradually become modified. But it seemed to him equally evident that neither the action of the surrounding condition, as Geoffroy St. Hilaire thought, nor the will of the organisms, as Lamarck supposed, could account for the innumerable cases in which organisms of every kind are beautifully adapted to their habits of life. In 1837 Darwin began to collect evidence, in the hope of obtaining some light on the subject. So far he had gone no farther than his predecessors. He had found much evidence for a theory of descent, but the question, How? still remained unanswered. In collecting facts he paid special attention to the modifications of domestic species, and soon came to the conclusion that in these cases "selection was the keystone of man's success in making useful races of animals and plants. But how selection could be applied to organisms living in a state of nature remained for some time a mystery."

In October, 1838, Darwin happened to read for amusement Thomas Robert Malthus's "Essay on the Principle of Population" (1803), and then the solution of the problem flashed upon him. Malthus quotes from Benjamin Franklin's "Observations Concerning the Increase of Mankind" (1751) the remark that "there is no bound to the prolific nature of plants or animals but what is made by their crowding and interfering with each other's means of subsistence." He applies this, as Franklin did, to mankind, and he shows, moreover, that man tends to increase in a geometrical progression, and that if it were not for checks on population, the number of human beings on the earth would be doubled at least once in every twenty-five years. And, further, while population tends to increase in geometrical ratio the food supply, according to Malthus, can be increased only at most in an arithmetical ratio. As population tends to increase faster than the food supply, the lack of food soon becomes the principal check to further increase. Darwin, from his long-continued observation of the habits of animals and plants, was well prepared to appreciate the struggle for existence which goes on everywhere as the result of this law of increase, and it struck him at once "that under these circumstances favorable variations would tend to be preserved and unfavorable ones to be destroyed. The result of this would be the formation of new species." Darwin called this the process of *natural selection.* With characteristic caution, he did not even permit himself to write out his theory for a long time, but continued searching for evidence for and against it.

In the mean time, Alfred Russell Wallace made a journey to the Malay Archipelago. Like Darwin, he was much impressed by the evidences that he found for the evolution of species. While in Borneo in February, 1855, he wrote a paper on this subject that was published in the *Annals and Magazine of Natural History* in the following September. In this paper he stated the law that, "Every species has come into existence coincident, both in space and time, with a pre-existing, closely allied species." This is the next thing to saying that every species has been evolved from a pre-existing, closely allied species. Wallace evidently hesitated to state the law in this form because he had no theory to offer as to the manner in which evolution is brought about. He brought forward the evidence from classification, from geographical distribution, palæontology, and vestigial organs; and the law that has been quoted was the final result of this paper. The question, "How?" still haunted him, however. Three years later, Mr. Wallace was at Ternate in the Moluccas and, while confined to his bed by fever, he was meditating on this problem. The "positive checks" occurred to him—war, disease, famine, and the like—described by Malthus in his "Essay on Population." He saw that these must apply to the animals as well as to man, and he thought of the much more rapid multiplication of animals, and then there suddenly flashed upon him the idea of the survival of the fittest, "that the individuals removed by these checks must be on the whole inferior to those that survive." Three days later a paper embodying this theory was written and on its way to England, addressed, strange to say, to Mr. Darwin, who had been working on this same theory for years. The immediate result was that Darwin was reluctantly persuaded to publish an abstract of his work, together with Wallace's paper, and the two appeared in the *Journal of the Proceedings of the Linnean Society* for 1858 ("Zool.," vol. iii., 1858, p. 45). In 1859 the "Origin of Species" was given to the world and gave the impetus to that great revolution in thought to which we have already referred.

We certainly cannot honor too highly the pure love of truth and devotion to science, uncontaminated by ambition for fame, which we see in these two men, and we are especially called upon to admire the loyal and ungrudging way in which Wallace attributes all the honor of the great discovery to Darwin. It is of interest to us Americans to note that the man who furnished the necessary cue to both Darwin and Wallace, Thomas Robert Malthus, received it in turn from our fellow-countryman, Benjamin Franklin.

We are indebted to Darwin for the first presentation of a theory of evolution that carried with it conviction to the scientific mind. Because it did carry conviction it was attacked with great vigor on all sides, scientific and unscientific alike. The younger generation of to-day can hardly appreciate the bitterness of the struggle between the advocates of tradition and those of the new idea.

As men of science gradually became convinced of the fact of evolution, there arose a calmer discussion as to the method. Some have held that natural selection is the sole factor; others, that it is the prime factor, but that it is supplemented by other factors; then there are the "neo-Lamarckians," who hold that, while natural selection is a factor, it is one of minor importance compared to the inheritance of acquired modifications. We will turn now to a very brief consideration of each of these factors.

Factors of Organic Evolution, Variation.—Variation may be defined as deviation from the type of the species, race, or family, or from whatever may be taken as the standard. Without variation there could be no change of type, and variation must, therefore, be at the basis of every theory of evolution.

So long as species were regarded as fixed, immutable objects of nature variations were generally disregarded. Thus, when Darwin began to collect data on the subject he found few recorded observations. While he succeeded in finding much evidence of variability in domestic races, he supposed variations of wild races to be relatively infrequent and slight in amount. Wallace was the first to point out that wild species are frequently highly variable. During the past decade a great deal of attention has been paid to variation, and a considerable amount of literature has accumulated on the subject.

It has been found that all characteristics of organisms are subject to variation. Some variations are *congenital*, that is, apparently independent of the environment; while others are *acquired modifications* due to a reaction of the organism to a definite factor in the environment.

Variations may be *abnormal*, that is, wide and infrequent departures from the type, such as the horticulturists call *sports;* or they may be *normal*, occurring in varying degrees in a majority of the individuals of the species, as, for example, variations of stature in man.

The first quantitative measurements of variation were made by J. A. Allen in 1871. Galton a little later introduced the statistical treatment of variations, and Pearson has shown how they may be subjected to accurate mathematical analysis. The subject will be treated here only so far as may be necessary for the understanding of natural selection. (For more extended treatment, see article *Variation.*)

Most persons regard "chance" as something entirely apart from law—something which cannot be predicted. But the mathematicians have shown long ago that chance is subject to strict mathematical laws. Single events cannot be predicted, it is true, but the general result can be predicted with certainty. For example, Weldon has published the results of four series of experiments in throwing dice. In each series there were 4,096 throws of 12 dice, and at each throw the number of dice having more than three points on the upper side were counted and recorded. The frequency with which 1, 2, 3, etc., dice showed more than three points was tabulated—and the results, when plotted, were found to follow very closely the theoretical curve of chance, which is described by an exact mathematical formula. Now it is found in a large number of cases that the variations in the characters of organisms which can be determined accurately—by counting, as the number of ray flowers in the daisy; or by measurement, as the length of a man's head—when tabulated and plotted occur with the frequencies predicted by the law of chance. So we may say that normal variations occur, as a rule, by chance.

This is best illustrated by an example. In the course of investigations carried on under the direction of the writer, measurements were made of the width of the angle at the apex of the shell in ninety-seven specimens of *Purpura lapillus*, a marine snail common on the New England coast. The results were tabulated as follows:

	Classes.				
Width of angle in degrees ..	60–65	65–70	70–75	75–80	80–85
Frequency	3	21	45	24	4

These results may be represented graphically by the five rectangles in Fig. 1945, where the limits of the class are represented by the width of the rectangle, and the height represents the number of individuals included, or its frequency. It will be noticed that the middle rectangle is the highest and, therefore, represents the most frequent class. This has been called the *mode*, or model class, and may be taken as representing the *type* of apical angle for the species. It will be noticed also that the classes having the least frequency are those farthest removed from the mode. By some easy mathematics one may readily obtain the general average, or arithmetical *mean*, of all the measurements, which in this case is

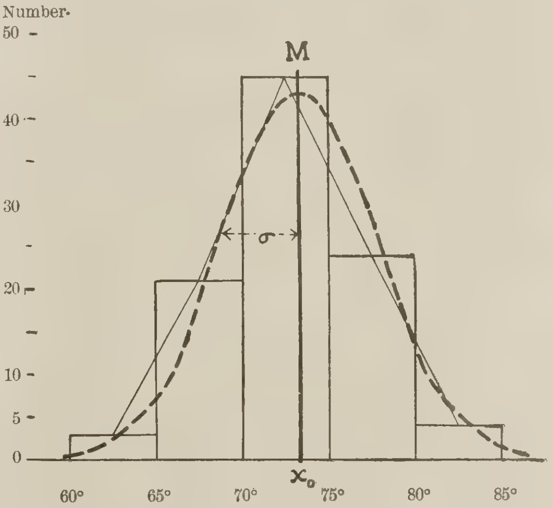

FIG. 1945.—Graphic Representation of a Series of Variations. Variation in the width of the angle at the apex of the shell in *Purpura lapillus*.

73.26°, and on the diagram (Fig. 1945) is represented by the position of the line Mx_0. The mean of any character may be taken also as the *type* for the species, and this is used much more frequently than the mode as the standard from which to measure variations. We may obtain a rough idea of the variability of a character by observing the extreme *range* of variation from the lowest to the highest value. But this cannot be done very accurately and conveys no information as to the relative frequency of the intermediate values. A better idea may be obtained by calculating what is called the *standard deviation* ($\sigma = \sqrt{\frac{\Sigma(x^2f)}{n}}$, see article *Variation*). In our example this has the value of 4.36°, and is represented at σ in the diagram. Knowing the total number of individuals measured, the mean, and the standard deviation, it is possible by the use of appropriate formulæ and tables (Davenport, "Statistical Methods") to calculate and plot the corresponding theoretical *normal curve* of chance. This is represented in the diagram by the heavy broken line. This means that if, instead of taking ninety-seven individuals and dividing them into five classes, we had taken a very large number of individuals, several thousand at least, and divided them into very many classes, we should expect to obtain a series of rectangles, the tops of which would follow the broken line; and in our diagram it will be noticed that the straight lines connecting the middle points in the tops of the rectangles follow pretty closely the theoretical curve. Thus, although only ninety-seven specimens were taken, much too few for accurate results, it is evident that the different variations in the acuteness of the apex in Purpura occur approximately with the frequency predicted by the law of chance. In calculating this curve it has been assumed that the mode and the mean coincide and that variations less than the mean and those greater than the mean occur normally with equal frequency, so that the curve is perfectly symmetrical. In many cases, however, it has been found that the frequency of variations is best represented by a curve where the mean and the mode do not coincide. In such cases the curve is asymmetrical, and is called a *skew curve.*

In other cases it has been found that there are two or more classes containing a large number of individuals with intermediate classes containing few. The curve plotted from such a series of observations would present two or more modes, as the case might be, and would be what is called a *multimodal curve.* An example of such a curve is shown in Fig. 1946, which represents the distribution of variations in the width of the leaf of the cat-tail. The data from which the curve is plotted are obtained from measurements of the widest part of the widest leaf in two hundred and fifty specimens, and are as follows:

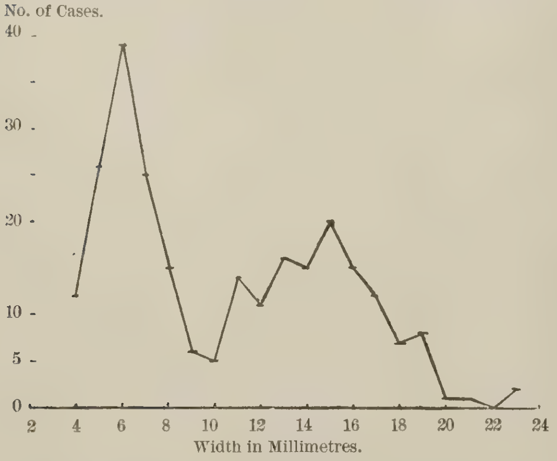

FIG. 1946.—Example of a Multimodal Curve. Variation in the width of the leaf of the cat-tail, *Typha latifolia* and *T. angustifolia.* (After Blankinship.)

CLASSES.

Width in milli-metres.	Number of cases.	Width in milli-metres.	Number of cases.	Width in milli-metres.	Number of cases.
4	12	11	14	18	7
5	26	12	11	19	8
6	**39**	13	16	20	1
7	25	14	15	21	1
8	15	**15**	**20**	22	0
9	6	16	15	23	2
10	5	17	12		

After allowing for minor irregularities, due probably to the small number of observations, there are evidently two modes, one at 6 mm. and the other at 15.

This illustrates the distinction between *individual variation* and *racial variation.* So long as the variations are distributed about a single type we have what is called individual variation, and the variability of the species in respect to the character in question is measured by its standard deviation. But where there are several modes—several types about which variations are distributed—we have what may be called racial variation, and this kind of variability is measured by the number of modes and their distance apart. Racial variability tends to divide the species into races, or sub-species. In fact, botanists divide the cat-tails into two distinct species, *Typha latifolia* L. and *T. angustifolia* L. But Blankinship has shown that these two groups grade into one another in all their characters, and this is a good example of the difficulty, often met with, of drawing a sharp line between species.

So far single variations have been treated as if they were isolated objects. As a matter of fact, they never occur as such in nature, for every individual is made up of a great many characters; and the question arises, Is there any relation between the deviation of one character and the deviations of other characters in the same individual? Such a relation is called the *correlation of variations,* and Darwin gave many interesting examples of it. Since then Galton has pointed out a method by which correlation may be studied very exactly, and the degree of correlation may be given mathematical expression. If in a number of individuals character A deviates from its mean Ma by the amount Xa, it is possible to determine what will be the average deviation Xb of the character B from its mean Mb (see article *Variation*).

While much work is still to be done in this line, enough has been accomplished to show that correlations of this kind are common among normal variations; and this is a fact of the highest importance for the theory of evolution.

Heredity.—Heredity is a special case of correlation. It is the correlation between the variations of homologous organs in individuals related by birth, especially those in the relation of parent and offspring. The facts of heredity are of equal importance with the facts of variation. For if this correlation did not exist, or, to use the common metaphor, if there were no inheritance of variations, progressive change of type, evolution, would be as impossible as if there were no variation at all.

The facts and theories of inheritance will be discussed more fully elsewhere (see articles *Heredity* and *Reversion*). Attention here will be confined to a few facts of especial importance in connection with the subject of the present article.

In the first place it may be noted that there are three chief forms of inheritance: (1) *Blended* inheritance where the character in the offspring partakes of the qualities of both parents, as in stature; (2) *exclusive* inheritance, where the character in the child is like that in one parent, but not like the other, if it differ from the first, as in the color of the eye; (3) *particulate* inheritance, where the child resembles one parent in one character and the other in another character. For example, a child may have its mother's eyes and its father's nose.

In general, all congenital characters, whether they be new acquisitions or inheritances, may be transmitted to the offspring. But it is extremely doubtful if acquired modifications are ever inherited (see p. 35). Sometimes the correlation of the offspring will be much stronger with one parent than with the other, and the parent which the offspring tends to resemble the most is then said to be *preportent.* This is often the case with sports, as in the famous Ancon breed of sheep that arose in Massachusetts in the latter part of the eighteenth century. In domestic races pure bred animals are generally prepotent over mongrels.

Heredity is *measured* in the same way that correlation is. But a complication arises owing to the fact that most individuals have two parents. In order to avoid the difficulty of measuring the correlation of three variables, the two parents are combined into one imaginary individual known as the *mid-parent.* Then it is easy to find the correlation between mid-parent and offspring.

Pearson gives the following formula for finding the mid-parent:

$$\frac{1}{2}\left(h_1 + \frac{\sigma_1}{\sigma_2}\, h_2\right) = H$$

where h_1 = value of the character in the father, h_2 = the same in mother, σ_1 = standard deviation of fathers in general, σ_2 = the same for mothers, and H = the character in the mid-parent.

It might be expected that the average offspring would be like the mid-parent. But, as a matter of fact, it is found by observation that, while some children may be exactly like the mid-parent and some more peculiar, the average of the offspring will be less peculiar, more nearly like the general average of the population, than the mid-parent, if that be possible. This is called *regression.* The amount of regression differs with different characters in different species, but in general it may be said that the offspring on the average will be about two-thirds as peculiar as the mid-parent, or one-third as either parent considered alone. This may be accounted for, perhaps, by reference to the previous ancestry. For if there be no selection or inbreeding, the number of ancestors in each generation increase as we go backward in geometrical ratio until they soon form all together a fair sample of the population as a whole. In the tenth generation back there are ten hundred and twenty-four ancestors.

On the other hand, we have the seemingly paradoxical fact of regression in the opposite sense. That is, if we take a large number of children all deviating in a certain character to a given degree from the average of the population, it will be found that the average of their mid-parents will be only one-third as peculiar. This is simply due to the fact that mediocre mid-parents are more common than peculiar ones (see Fig. 1945). From these facts Galton has derived a law of heredity, which Pearson states in the following words:

"Each parent contributes on an average one-quarter, or $(\frac{1}{2})^2$, each grandparent one-sixteenth, or $(\frac{1}{2})^4$, and so on, and that generally the occupier of each ancestral place in the *n*th degree, whatever the value of *n*, contributes $(\frac{1}{2})^{2n}$ of the heritage."

Mathematically this would be,

$$h = \tfrac{1}{2}\,\mathrm{H}_1 + \tfrac{1}{4}\,\mathrm{H}_2 + \tfrac{1}{8}\,\mathrm{H}_3 + \ldots \text{etc.},$$

a geometrical progression approaching a limit = 1, when h = the average deviation of the offspring, and H_1, H_2, H_3, etc., = the deviation in the mid-parent, mid-grandparent, mid-great-grandparent, etc. But Galton's series, $\frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \ldots \frac{1}{1024}$, etc., may not be true in all cases. So Pearson replaces these figures by symbols that may express any geometrical progression, γa, γa^2, γa^3, . . . γa^{10}, etc., in which there are two factors, one constant in each generation, γ, and one which varies in geometrical series, a, a^2, a^3, etc.* Then allowing for difference of variability, as well as differences in deviation and mean, of past generations of mid-parents, Pearson gets the following *law of ancestral* heredity:

$$h = \gamma \left\{ \frac{1}{1+\gamma,}\,\frac{\sigma}{\sigma_1}\,\mathrm{H}_1 + \frac{1}{(1+\gamma)^2}\,\frac{\sigma}{\sigma_2}\,\mathrm{H}_2 +, \ldots \right.$$
$$\left. \frac{1}{(1+\gamma)^{10}}\,\frac{\sigma}{\sigma_{10}}\,\mathrm{H}_{10} + \ldots, \text{etc.} \right\}$$

where h = average deviation of the offspring, H_1, H_2, H_3, etc. = the deviation from the means of their generation of the mid-parents, mid-grandparents, etc., σ = standard deviation, variability, of all offspring, σ_1, σ_2, σ_3, etc. = variability of the race in the generations to which the successive mid-parents belong, and γ is the *constant of heredity,* upon which all hereditary influence depends. This, in Mr. Galton's formula, would be $\gamma = 1$. But it may be found to vary in different species and in different organs.

As to the importance of the law of ancestral heredity, Pearson says: "If Darwinism be the true view of evolution, *i.e.,* if we are to describe evolution by natural selection combined with heredity, then the law which gives us definitely and concisely the type of the offspring in terms of ancestral peculiarities is at once the foundation stone of biology and the basis upon which heredity becomes an exact branch of science."

The Struggle for Existence.—With the struggle for existence we come to the first of the distinctively Darwinian factors of evolution.

Darwin's definition is as follows. He says: "I should premise that I use this term in a large and metaphorical sense, including dependence of one being on another, and including not only the life of the individual, but success in leaving progeny. Two canine animals, in a time of dearth, may be truly said to struggle with each other which shall get food and live. But a plant on the edge of a desert is said to struggle for life against the drought, though more properly it should be said to be dependent on the moisture. A plant which annually produces a thousand seeds, of which only one of an average comes to maturity, may be more truly said to struggle with the plants of the same and other kinds which already clothe the ground. The mistletoe is dependent on the apple and a few other trees, but can only in a far-fetched sense be said to struggle with these trees, for, if too many of these parasites grow on the same tree, it languishes and dies. But several seedling mistletoes growing close together on the same branch may more truly be said to struggle with each other. As the mistletoe is disseminated by birds, its existence depends on them; and it may metaphorically be said to struggle with other fruit-bearing plants, in tempting the birds to devour and thus disseminate its seeds. In these several senses, which pass into each other, I use for convenience's sake the general term struggle for existence" ("Origin of Species," 6th ed. vol. i., p. 78).

Wallace uses the term without giving a definition. In his essay of 1858 he says: "The life of wild animals is a struggle for existence. The full exertion of all their faculties and all their energies is required to preserve their own existence and provide for that of their infant offspring. The possibility of procuring food during the least favorable seasons, and of escaping the attacks of their most dangerous enemies, are the primary conditions which determine the existence both of individuals and of entire species."

---

* Then substituting, we have:

$$h = \gamma\,(a\,\mathrm{H}_1 + a^2\,\mathrm{H}_2 + a^3\,\mathrm{H}_3 + \ldots \text{etc.}).$$

Now when $\gamma\,(a + a^2 + a^3 + \ldots \text{etc.}) = 1$, then $\frac{\gamma a}{1-a} = 1$

$\therefore \gamma = \frac{1-a}{a} = \frac{1}{a} - 1. \quad \therefore \frac{1}{a} = 1 + \gamma$, and $a = \frac{1}{1+\gamma}$.

So a, a^2, a^3, . . . a^{10} . . ., etc., may be replaced in the formula by

$\frac{1}{1+\gamma}\ \frac{1}{(1+\gamma)^2} \ldots \frac{1}{(1+\gamma)^{10}} \ldots$, etc.

This term, struggle for existence, is a convenient one, and it conveys a very vivid impression as to what takes place. But it may convey a false idea unless we are careful to bear in mind the metaphorical character of the expression. It may help us to do this if we can find for this term a definition which in itself shall be free from metaphors.

Spencer has defined life as "the continuous adjustment of internal relations to external relations" ("Principles of Biology," 2d ed., vol. i., p. 99). So long as the external relations are favorable, this adjustment is made easily. When they become unfavorable it is made with difficulty, and when it becomes impossible the organism dies. Therefore we may define the struggle for existence as the tendency of organisms to preserve a continuous adjustment of internal relations to unfavorable external relations.

The meaning of this will be more clear when we consider what are these unfavorable external relations in which life becomes a struggle for existence. They may be classified under three divisions: (1) adverse physical conditions, (2) enemies, and (3) competition.

1. *The Struggle against Adverse Physical Conditions.*—Conditions that are adverse for one species may be favorable for another. Thus the polar bear is unable to live on the hot sands of the Sahara, and the polar ice fields would be equally fatal to the lion. A fish cannot live in the air, nor a bird under water. So what constitutes an unfavorable physical condition depends largely upon the constitution of the organism that meets it.

There are doubtless large numbers of individuals and species which, so long as they remain in their native habitat, never have to contend with adverse physical conditions. Such is true, for example, of the majority of dwellers in the sea, and it applies equally well to the inhabitants of many tropical lands. The islands of the Antilles with their abundant rains, and even, warm temperature, are as favorable as possible for life. The only unfavorable condition is the occasional hurricane, when the rivers "come down," as they say, in irresistible torrents and the wind tears huge trees up by the roots, while the seas dash against the shores with appalling fury. Except for these infrequent catastrophes, the processes of life are favored continually by the physical conditions on land as well as in the sea.

It is in our own temperate region, with its extremes of heat and cold and sudden changes from moisture to dryness, that the adjustment of internal relations to external relations is attended with difficulty. We see this adjustment taking place annually at the time of the falling of the leaf, when the trees prepare themselves to withstand the frosts of winter. The leaves are cut off by an ingrowth of bark. The absorption of water is suspended, and the protoplasm becomes concentrated in the cells already heavily laden with starch. The embryonic tissue is confined to a thin layer under the bark and to small areas in the buds protected by thick envelopes, often lined with down, and varnished on the outside; and the cells of other parts acquire a thick wall of cellulose which renders them incapable of further growth. Thus in the cool days of fall the trees prepare to resist the freezing of winter, and usually this is successful. But sometimes it fails.

The summer of 1879 in England was cool and damp so that the new wood was not properly matured. This was followed by an unusually severe winter, and all over the country thousands of perennial plants were killed or severely injured by freezing. In one locality every common shrub was killed to the ground (Henslow, "Frost Report," 1887). In this country it happens frequently that warm days in early spring tempt the trees to throw off their winter protection, and send forth the young shoots and flower-buds. Then comes a late frost, and all the growing parts are killed.

But extreme cold is even more disastrous to animals. Darwin says: "I estimated (chiefly from the greatly reduced numbers of nests in the spring) that the winter of 1854–55 destroyed four-fifths of the birds in my own grounds." After the great storm of February 1st, 1898, Professor Bumpus found one hundred and thirty-six sparrows lying helpless upon the ground in Providence, of which sixty-four were dead or dying.

The effects of drought upon animals as well as plants are so well known that they need not be described.

2. *Enemies.*—Darwin regards extremes of cold and drought as probably the most effective of all checks on population. But the depredations of enemies constitute a check which is even of more universal effect.

Ernest Seton Thompson says: "The life of a wild animal *always has a tragic end.*" There is hardly an animal or a plant, from the humblest protophyte to man himself, that is not subject to the attacks of other organisms. Herbivorous animals feed upon the plants, and these animals in their turn form the food of carnivorous species. Those that escape being devoured in this way, and successfully resist the effects of climate usually at last fall a prey to the inroads of bacteria or other parasites.

Plants are particularly subject to destruction in the early stages of their growth. Darwin dug and cleared a piece of ground three feet long and two feet wide, and then marked all the seedlings of the native weeds as they came up, and out of the 357 no less than 295 were destroyed, chiefly by slugs and insects ("Origin of Species," vol. i., p. 83).

Judd says: "It is not at all uncommon for a crow or blackbird to eat from 30 to 50 seeds of smartweed or bindweed, or a field sparrow 100 seeds of crab grass, at a single meal. In the stomach of Nuttall's sparrow were found 300 seeds of amaranth, and in another 300 seeds of lamb's quarters, a tree sparrow had consumed 700 seeds of pigeon grass, while a snowflake from Shrewsbury, Mass., which had been breakfasting in a garden in February, had picked up 1,000 seeds of pigweed" ("Year Book, United States Agricultural Department," 1898, p. 222). Professor Beal has estimated that in the State of Iowa the tree sparrows alone destroy annually about 1,750,000 pounds, or 875 tons of weed seeds (*l.c.*, p. 226).

These seed-eating birds are in turn preyed upon by the various hawks and owls.

In the sea, plants form the food of few species except the most minute animals. A vast majority of marine species are carnivorous, and the destruction is enormous. Brooks gives a vivid picture of this struggle ("Foundations of Zoology," pp. 220–224 and 231–233). Speaking of the inlets among coral islands he says, "Nothing could illustrate the fierceness of the struggle for food among the animals on a crowded sea-bottom more vividly than the emptiness of the water in coral sounds where the bottom is practically one enormous mouth."

3. *Effect of the Removal of Checks.*—The enormous destruction caused by these checks on population may be realized to some extent if we consider the birth rate.

It may be stated as a general rule that the birth rate in existing species is proportional to the rate of destruction. Thus the petrel, which nests on inaccessible cliffs and has few enemies, produces but one egg at a time. While the lobster, whose young are exposed to the attacks of innumerable enemies from the time they are hatched, produces from 3,000 to 90,000 eggs. (The largest number found by Herrick was 97,440, "The Lobster," p. 51.) A single carrion fly is said to produce 20,000 living maggots. These reach full size in five days, and the pupa stage lasts five days. It has been estimated that a single fly could produce in three months one hundred millions of millions of millions (Wallace, "Darwinism," p. 25). The common mosquito (*Culex pungens*) lays from 200 to 400 eggs in a bunch. These hatch in sixteen hours. Under favorable conditions the larvæ reach the pupa stage in seven or eight days. This stage lasts two days. Thus one pair of mosquitoes may produce 400 adult offspring in less than ten days. In a few days more these are ready to lay eggs in their turn.

According to Merriam, the house sparrow produces annually five or six broods of four to six each. Assuming an average of 24 young per annum, with sexes equally divided, the produce of a single pair in ten years will be 275,716,983,698 ("Agricultural Report," 1886).

The elephant is said to be the slowest breeder of all animals. Yet Darwin has estimated that if an elephant lives 100 years and produces 6 young ones, in 750 years the produce of one pair would equal 19,000,000 elephants. Man is also an extremely slow-breeding animal, yet the human population tends to double in about twenty-five years.

The power of rapid multiplication is perhaps best illustrated by the waves of life that sometimes sweep over a country. Brehm thus describes one of these waves (Brehm, "From North Pole to Equator," 1896, pp. 74–76).

In a description of the fauna of the tundra, or barren lands of northern Siberia, Brehm says: "He (the lemming), or at least his tracks, may be seen everywhere throughout the tundra. The tracks run in all directions, often through places overgrown by dwarf birches, narrow, smooth, neatly kept paths in the moss, going straight for several yards, then diverging to right or left, and only returning to the main path after many circuits. On these we may often see, in great numbers during a dry summer, a little short-tailed, hamster-like animal nimbly pattering along and soon disappearing out of sight. This is the lemming, a rodent smaller than a rat, but larger than a mouse, with a brightly but irregularly marked skin, usually brown, yellow, gray, and black. If we dissect the animal we see, not without surprise, that it consists almost entirely of skin and viscera. Its bones and muscles are fine and tender; its viscera, especially the alimentary and reproductive organs, are enormously developed. This state of things explains some phenomena of its life which were long considered unintelligible; the almost abrupt occurrence of wellnigh unlimited fertility, and the vast, apparently organized migrations of the animal. In ordinary circumstances the lemming leads a very comfortable life. Neither in summer nor in winter has he any anxiety about subsistence. In winter he devours all sorts of vegetable matter—moss-tips, lichen, and bark—in summer he lives in his burrow, in winter in a warm, thick-walled, softly-lined nest. Danger, indeed, threatens from all sides, for not only beasts and birds of prey, but even the reindeer devour hundreds and thousands of lemmings; nevertheless, they increase steadily and rapidly, until special circumstances arise when millions, which have come into existence within a few weeks, are annihilated within a few days. Spring sets in early, and a more than usually dry summer prevails in the tundra. All the young of the first litter of the various lemming females thrive, and in six weeks, at the most, these also multiply. Meantime the parents have brought forth a second and a third litter, and these in turn bring forth young. Within three months the heights and low grounds of the tundra teem with lemmings, just as our fields do with mice under similar circumstances. Whichever way we turn, we see the busy little creatures, dozens at a glance, thousands in the course of an hour. They run about on all the paths and roads; driven to extremity, they turn snarling and sharpening their teeth, on the defensive even against man, as if their countless numbers lent to each individual a defiant courage. But the countless and still increasing numbers prove their own destruction. Soon the lean tundra ceases to afford employment enough for their greedy teeth. Famine threatens, perhaps actually sets in. The anxious animals crowd together and begin their march. Hundreds join with hundreds, thousands with other thousands; the troops become swarms, the swarms armies. They travel in a definite direction, at first following old tracks, but soon striking out on new ones; in unending file, defying all computation, they hasten onward; over the cliffs they plunge into the water. Thousands fall victims to want and hunger; the army behind streams on over their corpses; hundreds of thousands are drowned in the water or are shattered at the foot of the cliffs; the remainder speed on; other hundreds and thousands fall victims to the voracity of Arctic and red foxes, wolves, and gluttons, rough-legged buzzards and ravens, owls and skuas, which have followed them; the survivors pay no heed. Where they go, how they end, none can say, but certain it is that the tundra behind them is as if dead, that a number of years pass ere the few who have remained behind, and have managed to survive, slowly multiply, and visibly re-people their native fields."

Hudson describes a similarly rapid increase of mice on the Pampas of South America, which was finally brought to a close by a drought and the increase of enemies ("Naturalist in La Plata," p. 59, *et seq.*).

This country is subject to periodic waves of locusts and chinch-bugs, which swarm at such times in hundreds of thousands and do enormous damage to crops (Webster, "The Chinch-Bug," 1898). With the introduction of irrigation and forage plants in the far West, the jack-rabbits have increased rapidly and become a pest. In California during the ten years from 1888 to 1897, 494,634 jack-rabbits were killed in "drives," and yet the total number living was not seriously diminished (Palmer, "Jack-Rabbits," 1897).

The power of rapid multiplication is also well illustrated by the effect of introducing animals and plants into a new country. If the climate be favorable, the introduced form, freed from its natural enemies, may often increase amazingly.

Many of our common weeds, like the ox-eye daisy and the so-called Russian thistle, are good examples of this. Wallace gives a number of cases ("Darwinism," p. 28) of the rapid spread of European plants introduced into South America, New Zealand, and other places.

"Columbus in his second voyage left a few black cattle at San Domingo, and these ran wild and increased so much that twenty-seven years afterward herds of from four thousand to eight thousand head were not uncommon. Cattle were afterward taken from this island to Mexico and other parts of America, and in 1587, sixty-five years after the conquest of Mexico, the Spaniards exported 64,350 hides from that country and 35,444 from San Domingo. . . . In the pampas of Buenos Ayres there were at the end of the last century, about twelve million cows and three million horses, besides great numbers in other parts of America." Similar results were obtained by setting free hogs and asses. Camels even, turned loose in Texas not many years ago, increased so rapidly as to become a nuisance.

The common European rabbit has become a pest in Australia and New Zealand. The rabbits were first liberated near Melbourne about 1864, and later in Tasmania and New Zealand. They multiplied so rapidly that in 1879 the legislature of South Australia took action for their destruction, and the matter was taken up soon after in New South Wales, Queensland, New Zealand, and Tasmania. But in spite of all efforts to destroy them, they continued to multiply. Between 1873 and 1898 New Zealand exported two hundred million rabbit skins.

Another example of the rapid increase of an introduced animal is afforded by the Indian mongoose in the West Indies. But at our very doors we have an equally good example in the house sparrow. The first successful importation was made into Brooklyn in 1852. The birds were introduced into Portland, Me., in 1854, and into Providence, R. I., in 1858, some escaping in Boston. Between 1863 and 1870 they were imported into eight cities, one lot of one thousand being sent to Philadelphia. Between 1870 and 1880 it is estimated that the range of this species had been extended by 16,000 square miles (Palmer, 1898), and it has continued to spread. Merriam estimates the rate of spreading of the sparrow as follows ("Agri. Rept.," 1886, p. 238):

	Square miles.
1870-75	500
1875-80	15,640
1880-85	500,760
During 1886	516,500
Yearly average United States and Canada	69,000

4. *Competition.*—These examples will suffice to show how rapidly animals and plants can multiply when the

first two classes of checks on population are not in operation. But this rate of multiplication cannot continue indefinitely. For, finally, food supply will become exhausted or the individuals will become so crowded as to deprive one another of the light, air, or space necessary for life. Thus the tendency of organisms to increase in geometrical ratio, if not held in check by other causes, will ultimately cause a severe competition, and this constitutes the third class of checks on population.

Competition may be between individuals of the same species, or between different species having similar habits. It is well illustrated in the forests, where each tree that reaches its full growth is, according to Pinchot, "the survivor of hundreds (or sometimes even of thousands) of seedlings."

An example where the competition of species has had a marked effect on the flora is quoted by Wallace (pp. 20–22). M. Hansten-Blangsted gives an account of the struggle between the trees in the forests of Denmark. The chief combatants are the beech and the birch, the beech being everywhere successful in its invasions. "Forests composed wholly of birch are now found only in sterile sandy tracts; everywhere else the trees are mixed, and wherever the soil is favorable, the beech rapidly drives out the birch. The latter loses its branches at the touch of the beech, and devotes all its strength to the upper part, where it towers above the beech. It may live long in this way, but it succumbs ultimately in the fight of old age, if of nothing else, for the life of the birch in Denmark is shorter than that of the beech." The superiority of the beech appears to be due to its denser shade. Nothing can live beneath it, while it grows perfectly well under the shade of the birch. The birch has been saved from total extinction only by the fact that it had possession of the Danish forests long before the beech ever reached the country, and that certain districts are unfavorable to the growth of the latter.

But we need not go to Denmark to witness a struggle of this kind. In Virginia, when a field is abandoned, trees soon spring up of all kinds, but the pines by virtue of their more rapid growth and dense shade, soon acquire the ascendancy. Many "old fields" are to be seen there where the furrows of the last crop of corn are still visible, and the ground is covered with a thick growth of young pines. Many of these die while still small, and among them may be found a few slender oaks, chestnuts, and tulip trees. If the pines are cut, or if they are allowed to grow old and fall down with decay, their place is taken at once by the longer-lived and more hardy oaks and chestnuts. So that it is a common saying in Virginia that "oaks follow pines."

Another case in point is an experiment of Darwin's. He marked out a little plot of mown turf, three by four feet, and allowed the plants to grow up freely. The result was that out of twenty species growing there nine perished ("Origin of Species," vol. i., p. 83).

Among animals the birds show especially the effect of competition. In some species each pair requires a certain area for a feeding ground, and drives off all others. The English sparrow is said to be responsible to a considerable extent for the decrease of our native birds, and according to a recent writer in *Nature* (Allchin, January 19th, 1899, p. 271), this same sparrow has had a similar effect upon the swallows and martins in England.

The efficiency of competition in checking increase is shown when the competition is lessened by an enlargement of the food supply. Most of the waves of life that have just been described are due to such an advantage rather than to protection from enemies.

In order to understand the results of these factors in the struggle for existence, it must be remembered that, as a rule, the relations of organisms to one another are highly complex; so that any change in the environment of one species is apt to effect a host of others. Thus, according to Lintner, the English sparrow protects the tussock moth (*Orgyia lincostigma*) by driving away its enemies, the robbin, oriole, and cuckoo, the only birds that can feed upon the hairy caterpillars, and thus the sparrow indirectly injures the elms and other trees ("Agric. Rept.," 1886). The classical example of this is Darwin's one of the relations of cats to the crop of clover seed. He says: "I have also found that the visits of bees are necessary for the fertilization of some kinds of clover; for instance, twenty heads of Dutch clover (*Trifolium repens*) yielded 2,290 seeds, but twenty other heads protected from bees produced not one. Humble bees alone visit red clover, as other bees cannot reach the nectar. Hence we may infer as highly probable that, if the whole genus of humble bees became extinct or very rare in England, the heartsease and red clover would become very rare, or wholly disappear. The number of humble bees in any district depends in a great degree on the number of field mice, which destroy their combs and nests; and Colonel Newman, who has long attended to the habits of humble bees, believes that 'more than two-thirds of them are thus destroyed all over England.' Now the number of mice is largely dependent, as every one knows, on the number of cats; and Colonel Newman says: 'Near villages and small towns I have found the nests of humble bees more numerous than elsewhere, which I attribute to the number of cats that destroy the mice.' Hence it is quite credible that the presence of a feline animal in large numbers in a district might determine, through the intervention first of mice and then of bees, the frequency of certain flowers in that district."

Wallace quotes an example from Sir Charles Lyell. He says: "If, by the attacks of seals or other marine foes, salmon are reduced in number, the consequence will be that otters living far inland will be deprived of food and will then destroy many young birds or quadrupeds, so that the increase of a marine animal may cause the destruction of many land animals hundreds of miles away." Another example of complexity of relations between organisms is given by Darwin: "In Staffordshire, on the estate of a relation where I had ample means of investigation, there was a large and extremely barren heath which had never been touched by the hand of man; but several hundred acres of exactly the same nature had been enclosed twenty-five years previously and planted with Scotch fir. The change in the native vegetation of the planted part of the heath was most remarkable, more than is generally seen in passing from one quite different soil to another; not only the proportional numbers of the heath plants were wholly changed, but twelve species of plants (not counting grasses and carices) flourished in the plantations which could not be found on the heath. The effect on the insects must have been still greater, for six insectivorous birds were very common in the plantations which were not to be seen on the heath; and the heath was frequented by two or three distinct insectivorous birds. Here we see how potent has been the effect of the introduction of a single tree, nothing whatever else having been done, with the exception of the land having been enclosed, so that cattle could not enter."

These examples are enough to show how very complex are the relations of organisms to one another. We see how a change in the environment of the salmon produces a change in the environment of land animals far away, and how the introduction of a single tree and the exclusion of cattle profoundly affect a host of other organisms. This gives some idea of the complexity of the phenomena to be considered in a discussion of the origin of species.

Natural Selection.—The facts of variation, inheritance, and the struggle for existence lead, as Darwin and Wallace pointed out, to the *a priori* assumption of the theory of natural selection. If individuals differ in their characteristics, and if there is a struggle for existence in which many perish, then there may be a correlation between the death rate and certain structural or physiological peculiarities, that is, we shall have a survival of the fittest, or better, an elimination of the least fit. But in order that new species may result, not only must the favorable peculiarities of the survivors be transmitted to future generations by inheritance, but other conditions must be fulfilled which we will now consider.

In the first place, as indicated in the preceding paragraph, it by no means follows that there is any necessary relation between destruction and any structural or physiological peculiarity. A flood, a tornado, a forest fire may destroy all in its path. In such a case the destruction is purely fortuitous, or non-selective. On the other hand, if a number of persons are exposed to an infection, say typhoid, to which they present different degrees of susceptibility, then those which possess those physiological characteristics that give susceptibility to the disease in the greatest degree will be those that die, and we shall have then a *selective death rate.* It may be noted in passing that a death rate which is selective in regard to one character may be fortuitous in respect to another, unless the variations of the two characters are correlated.

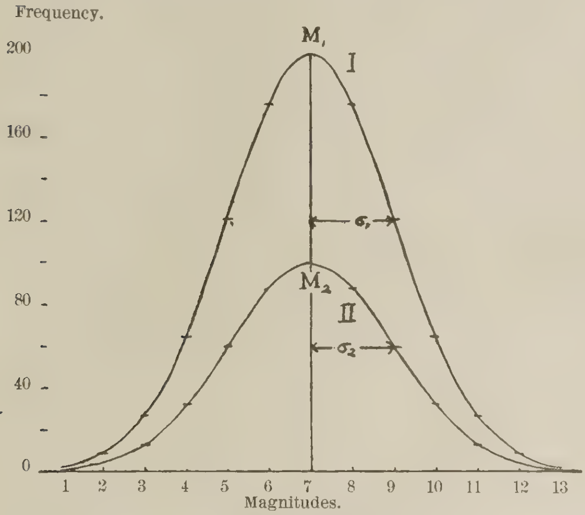

Fig. 1947.—Fortuitous Destruction of 500 in 1,000, Normal Curves. *I*, Birth curve; *II*, survival curve.

Let us consider now what the effect of these two kinds of destruction would be upon the curve of variation. Where there is no destruction, and all that are born survive, we may call the curve the *birth curve,* and its mean the *birth mean.* While the curve obtained after destruction had taken place would be the *survival curve,* and its mean, the *survival mean.* Now the effect of purely fortuitous destruction would be to give a survival curve that would be exactly like the birth curve except that it would be flatter, and the birth mean and the survival mean would coincide. Such a case is illustrated by Fig. 1947, where the upper line (*I*) may be taken to represent the birth curve of say a thousand individuals in a certain locality, and the lower line (*II*) would be the curve after a fortuitous destruction of half the number. (If percentages were used instead of absolute numbers, the curves would be exactly alike.)

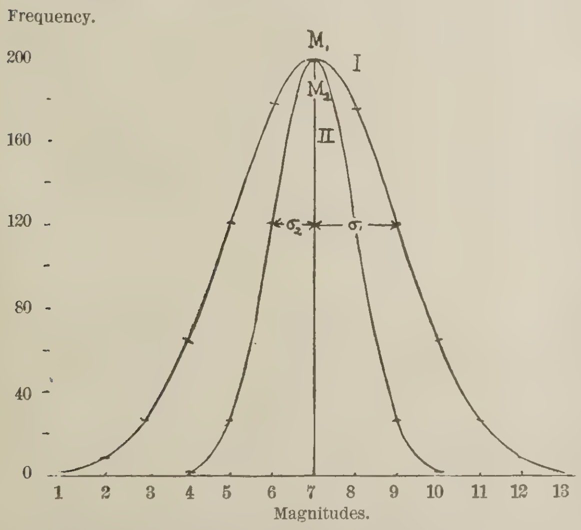

Fig. 1948.—Selective Death Rate of 500 in 1,000 when the Birth and Survival Means Coincide, Normal Curves. *I*, Birth curve; *II*, survival curve.

The effect of a selective death rate upon the birth curve would depend upon whether the cause of death is a constant factor of the environment or a new one. If it be a constant factor, it is probable that the species has become adjusted to it. In this case the most favorable variation of any character affected by this condition will be represented by the mode, and probably the mean, of the birth curve. Elimination will cause a decrease of variability, so that the survival curve will be steeper on the sides than the birth curve (Fig. 1948). But the position of the mean will not be changed, and there will be no evolution. On the contrary, the effect of natural selection here will be, if anything, to make the species more stable.

It is only when the species as a whole is not adjusted to the cause of death that we may expect natural selection to produce evolution. Then the birth mean will not coincide with the most favorable variation, and the effect of elimination will be to decrease the variability to a greater extent upon the less favorable side than on the other and thus to shift the mean, as in Fig. 1949. This is a purely imaginary example, where the most favorable value of the character measured is supposed to be 9. It will be noticed that the effect of elimination here has been to shift the mean from 7 to 7.88, that is toward 9, and the variability is decreased as shown by the smaller value of the standard deviation, σ_2, which is 1.46 instead of 2. The survival curve is also skew, while the birth curve is supposed to have been symmetrical.

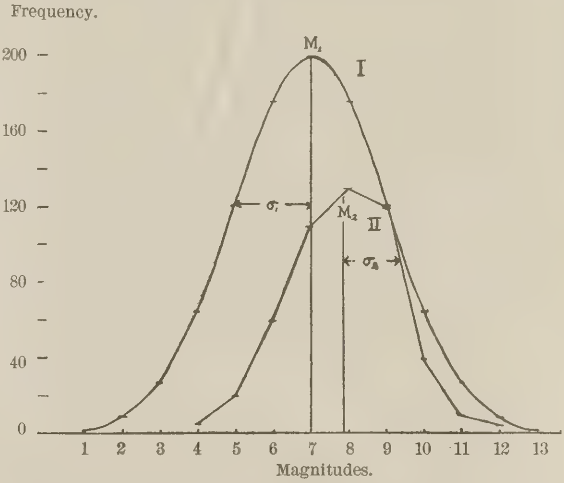

Fig. 1949.—Selective Death Rate of 500 in 1,000 where the Birth and Survival Mean do not Coincide. *I*, Birth curve, normal; *II*, survival curve, purely imaginary.

So far we have dealt with the effect of selection upon the first generation only. Of course, fortuitous destruction will have no effect upon the type or variability of the next generation, for the type and variability of the parents have remained unchanged. A selective death rate symmetrical on both sides of the birth mean will not affect the type and will have but a slight effect upon the variability, for Pearson has shown that selection for an indefinite number of generations cannot reduce the variability more than eleven per cent. But where the most favorable value of a character does not coincide with the birth mean, then there will be a change of type, the rapidity of change depending upon the severity of the selection. From the law of ancestral heredity Pearson has calculated the probable effect of perfectly rigorous artificial selection. His results are given in a table, from which it is possible to calculate the curves of six successive generations where the parents selected have a given deviation from the original mean of the population. Fig. 1950 illustrates such a case, where the mean of the population is represented by $M = 0$, the standard deviaiton is $\sigma = 1$, and the parents for each generation are supposed to have the selected character of the value $H = + 2$, or twice the standard deviation. Then the average deviation of the first, second, third, etc., generations of offspring from the original mean of the population will be represented by the distance from M to the ordinates h_1, h_2, h_3, etc. It will be seen that the regression becomes less in each generation until, in the sixth, h_6 almost coincides with H. In other words, if it were possible to make this rigorous selection, we might expect at the end of the sixth generation to obtain a new race that would breed true about a mean differing very little from the selected value.

Turning now from *a priori* considerations to observed facts, what evidence is there that natural selection has actually been a factor in evolution?

First, there is the observed fact of a selective death rate. To say that where the death rate depends upon individual peculiarities the fittest will survive in the struggle for existence, is a truism, for our only means of judging of fitness is the ability to survive. While a great deal has been written upon the subject, exact observations have only just begun to be made. It is not often easy to find a correlation between structure and the death rate. Only two instances are on record.

From measurements made by Thompson and himself in successive years, Professor Weldon came to the conclusion that in the crabs, *Carcinus mænas*, in Plymouth Harbor, England, the frontal breadth of the carapace was becoming narrower from year to year. Seeking a cause for this he found it to be probably the increase of sediment in the harbor, due to the building of a breakwater, which hinders the flow of the tides. To test this theory, he placed a number of crabs in aquaria with a considerable quantity of china clay, like the silt in the harbor, suspended in the water. A number of crabs died, and at the end of the experiment the dead crabs were separated from the living, and all were measured. It was found that the survivors had distinctly less frontal breadth than the dead crabs.

If this selective destruction is continually going on in the harbor, then the crabs protected from the action of the silt during a portion of their lives should show a greater average frontal breadth than the wild crabs of the same age. A number of crabs were kept in aquaria with clean sea-water until they moulted. When the shell was hard they were killed and compared with wild crabs of the same age. It was found, as expected, that the frontal breadth of the protected crabs was greater.

The great storm of February, 1898, enabled Bumpus to study a similar case among the house sparrows (*Passer domesticus*). During the storm in Providence 136 birds were picked up in a helpless condition. When brought into the laboratory 72 of these revived and 64 died. A number of measurements were made upon each bird of the two lots, and it was found that the mean of surviving birds differed perceptibly in many dimensions from the corresponding mean of the dead ones. Moreover, the dead birds showed a greater average deviation from the mean than the surviving ones.

In these cases single characters were studied in relation to the death rate. It would be more to the point if we could correlate the sum of the peculiarities of the individual as a whole with his chances of death, for natural selection acts upon whole individuals, not upon single characters. Pearson has demonstrated a very ingenious method of doing this for man. If there were no natural selection, the whole death rate would be non-selective, fortuitous; on the other hand, natural selection would reach its maximum efficiency when the death rate becomes wholly selective. In nature the death rate would be usually partly selective and partly non-selective, and the problem is to determine what proportion of the total death rate is selective. In Pearson's method "no attempt is made to select any particular organ, but we take pairs of individuals having some general resemblance in their whole complex of organs and characters, and correlate their fitness for surviving under practically the same conditions of life. Now pairs of relatives or members of the same family are precisely such individuals. If there were no selective death rate there would be no correlation between the ages at death of, say, brothers. On the other hand, if there were no non-selective death rate we might reasonably suppose duration of life would be determined by the law of ancestral heredity," and we should expect the correlation between the durations of life of pairs of brothers to be the same as that observed in the case of stature and other characters.

From a study of one thousand pairs of brothers recorded in the peerage Pearson found that of the total death rate eighty per cent. was selective. Comparing fathers and sons, the result was sixty-five per cent. Natural selection, then, is by no means inoperative at the present time in the human species.

The second line of evidence is one that especially meets the objections of the advocates of the theory of special creation. This is that it is impossible to find throughout the whole range of the animal and vegetable kingdoms a single structure or function developed in one species for the exclusive benefit of another.

Darwin regarded this point as of so great importance that he offered to give up his whole theory if it could be proved in a single case that a structure or instinct is developed in one species for the exclusive benefit of another. To be sure, there are innumerable cases in which the characters of one species are of use to another; but this value to the other species is purely secondary. For example, the nectar of flowers forms the daily food of bees, but this nectar is primarily of use to the plant in securing the visits of the bees, and thus providing a means for the transportation of the pollen and cross fertilization. As the result of thoughtful search Romanes was able to discover only two cases that appear to be exceptions to this rule. It is well known that the aphides (green plant lice) secrete a sweet juice that is much sought after by ants. So far as we know, this secretion is of no value to the aphid. But it has not yet been investigated suffi-

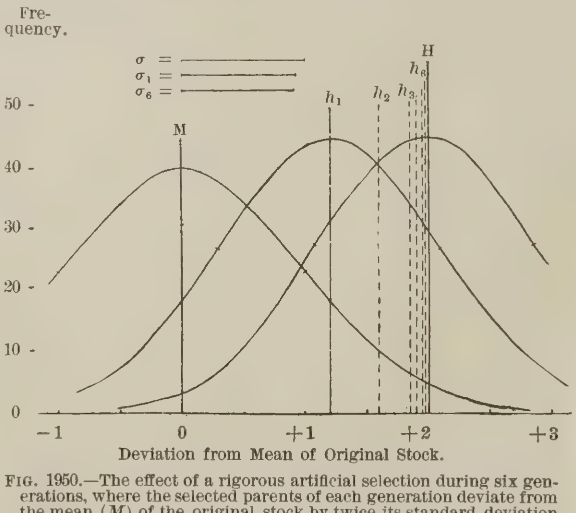

FIG. 1950.—The effect of a rigorous artificial selection during six generations, where the selected parents of each generation deviate from the mean (M) of the original stock by twice its standard deviation (H). The broken lines h_1 h_2 h_3 . . . h_6 represent the position of the means of the first, second, . . . and sixth generation of offspring. When $M = 0$ and $H = 2$, $h_1 = 1.2$, $h_2 = 1.6$, $h_3 = 1.85$, $h_4 = 1.90$, $h_5 = 1.94$, $h_6 = 1.97$. The curves of frequency are drawn for only M, h_1 and h_6, and their standard deviations are $\sigma = 1.0000$, $\sigma_1 = 0.9055$, $\sigma_6 = 0.8944$. (Data from Pearson.)

ciently to show that it is of no use. It may be a means of removing waste products of metabolism. Moreover, it seems to be rather more of a luxury than a necessity for the ants. The other case is still more remarkable. It is the production of galls upon plants as the result of the growth of an insect larva within the tissues of the plant. The gall forms a perfect home for the larva, and differs in character, not only in different plants, but it differs also according as it is produced by one species of insect or by another, each species of insect having its own peculiar form of gall. All grades are found, from simple cysts, hardly worthy to be called galls, to structures which are extremely elaborate. Here we have a structure developed by a plant apparently for the benefit of an insect. But, as pointed out by Romanes, the gall arises as a reaction on the part of the plant to a poison produced by the insect, and its first appearance was probably due to one of those accidental effects of an injurious substance upon an organism, such as Herbst discovered when he treated sea-urchin larvæ with potassium and lithium salts. The gall-forming property, being of use to the insect, would be preserved and modified by natural selection acting directly upon the insect, and the plant would be affected indirectly.

The third line of evidence is that which first attracted Darwin's attention to the principle of selection. Darwin found that in the production of domestic varieties of animals and plants artificial selection is the keynote to success. All of our domestic productions are descendants from wild species, but in many cases either the wild parent species has been exterminated, or else the domesticated descendants have been so greatly modified that it is impossible to recognize the ancestral form. The differences between artificial varieties and between them and the original form, when known, are often as great as the differences between species, or even between genera, of animals and plants in the natural state. Compare a deer hound with a King Charles spaniel, a Cochin China with a game cock, a pouter pigeon, a fan-tail, and the wild rock dove, from which Darwin showed the pigeons to be descended. Romanes calls special attention to the well-marked varieties of canary birds, and regards this as a case of unusual interest because of the shortness of time during which the evolution has taken place, the first mention of these birds that he could find being by Gesau in the sixteenth century. Among most of our domestic animals man has been selecting more or less unconsciously the individuals which best served his needs or answered to his ideal of beauty; and this has been going on since prehistoric times. In later years selection has been practised with great care and with reference to more exact ideals, and the progress made is truly wonderful.

Darwin regarded evolution as an extremely slow process, and this idea prevailed for a long time, but recently several cases of very marked change in domestic forms have come to light where the change has been comparatively rapid. The American trotting horse is a case in point. An ordinary horse runs when he wants to move rapidly, but the trotting horse prefers the trot, and will keep to that gait until he attains a speed far beyond that at which other horses would be forced to break into a gallop. The lowest limit of what is regarded as racing speed in a trotting horse is a mile in two minutes and thirty seconds. The first horse to make a mile within 2:30 was Lady Suffolk, a great-granddaughter (by three crosses) of Messenger, a thoroughbred race horse imported from England in 1788, and famous as the ancestor of almost all American trotting horses. Lady Suffolk was foaled in 1833, and made her record in 1845. From that time the speed of the fastest trotter has steadily increased, until Cresceus, foaled in 1894, made the remarkable record of 2:02¼ in 1901, beating the record made by The Abbot the previous year. But the improvement of the trotting horse is seen best when we compare the number of fast trotters at a recent date with the number several years before. In 1892 there were 116 horses with records of 2:15 or better, at the end of 1897 there were 585 horses with such records, and during 1897 109 horses entered this class, only 7 less than the total number in 1892, and many of these had no previous record.

Now is this improvement due to the selection of fortuitous congenital variations, or to some other cause? If races are changed by the inheritance of acquired characters, this process should be expected to be efficient in the case of the trotting horse. This question will be discussed later when we consider the inheritance of acquired characters as a factor of evolution. But it may be said now that, of the sixteen champion trotters from Lady Suffolk to Cresceus, Cresceus is the only one having a sire with a record below 2:30, and The Abbot is the only one that has a dam with any record at all, and it seems probable that a careful study of the pedigrees of trotting horses will fail to show that horses which have been trained have any greater power of transmitting trotting speed than horses which have not been trained. It is probable that such a study will show that that combination of instinct and structure which enables a horse to trot at a high speed has arisen as a fortuitous variation in a few individuals, and that fortunate selection and crossing of their descendants during eight or ten generations at most has produced the remarkable result that we see to-day. This is the more probable since Galton has shown that variations in speed follow the normal curve. Take the pedigree of Alix, for example. Both parents of this champion trotter were totally untrained. Her paternal grandsire has a record of 2:21¾, the others have no record. Of her grandparents only one has a record (2:21½), and of her great-grandparents again only one has a record (2:42). On the other hand, her descent is traced by more than fourteen converging lines from Messenger, the ancestor of Lady Suffolk. She is descended by four lines from imported Bellfounder, the son of a Norfolk trotter, and by four lines from Amazonia, a "natural trotter." Moreover, she counts among her ancestors the sires of three champion trotters: Dexter, 2:17¼; Goldsmith Maid, 2:14, and Maud S., 2:08¾, and if each ancestor be regarded as a separate individual at each place in which he occurs in her pedigree, it will be found that she is descended from seven sires of champions, three on the paternal side, and four on the maternal side.

But if the inheritance of acquired characters may be a factor in the development of the trotting horse, there are other cases of rapid improvement in which it cannot have entered. One of these, the cultivated cyclamen (*Cyclamen latifolium* Sibth.), is one of the spring wild flowers in Greece and Syria. It has pink flowers with a ring of darker color at the throat (W. T. T. Dyer, *Nature*, May 20th, 1897, vol. lvi., pp. 65–68). The species is said to have been first cultivated in Europe at Lille in 1731. It was probably obtained from Syria. "The Lille plant ultimately went to Ghent, and it has been asserted that all the cultivated forms in existence are descendants from this one individual." A variety with white flowers —"pure white with a bright purple button"—was described in 1768. The modern development of the plant began in 1860, and started with one of the principal growers (Messrs. Sutton) with the old "crimson and white."

The changes have been brought about entirely without resort to hybridization. But starting with the slightest deviation, even so small as the slightest difference in a cotyledon of a germinating seed, by careful self-fertilization and selection the present varieties have been produced. The changes produced have been in the size of the flower, its fragrance, color, and form of corolla. The original form has narrow, twisted, reflexed petals about an inch long. The cultivated varieties have broader, less twisted petals, and in one variety they have reached a length of three inches. This was accomplished by continuous in-breeding and selection. The old crimson and white had a crimson ring at the throat, but was otherwise an albino. From this, forms have been produced varying from pure white, on the one hand, to a uniform deep crimson, on the other. "The modern colored forms were obtained in the first instance by selecting forms in which the colored ring showed a disposition to spread into the white corolla segments. The first indication would be a scarcely perceptible streak. By selection from self-fertilized plants the streak was widened into a stripe. Continuing the process, the stripes united, and a uniformly colored flower was obtained." The colored varieties when self-fertilized come true from seed.

One of the most remarkable modifications in the form of the corolla is the spreading of the segments. Cyclamen belongs to the order *Primulaceæ*, and is distinguished from the rest of the tribe *Lysimachiæ*, to which it belongs, by the reflexed segments of the corolla. In the variety with a spreading corolla, then, we see a modification of a character which not only distinguishes the species but also the genus.

Doubling has occurred in one variety. Ordinarily doubling is due to a homœotic variation of the stamens by which they become petal-like. In this case, on the other hand, the stamens retain their proper structure, and both they and the segments of the corolla become increased in number.

The butterfly form is a case of parallel variation, it having been obtained independently by several horticulturists. In this variety the petals are partly spreading and arched, and are toothed and curled at the edges. It is interesting to note that in one case at least there is a correlation between the corolla and the leaves, for they also are toothed. This variety arose as a well-marked sport which was improved by selection.

Another example of the rapid effect of selection is the tomato. The different varieties of the edible tomato (*Lycopersicum esculentum*) differ as much, if not more, than do the other species of the genus (Bailey, "Survival of the Unlike," pp. 112–125). Colonel Waring, who introduced the Trophy tomato in 1872, gives the history of this variety, from which the best modern tomatoes have been produced. The Trophy tomato was the result of crossing and selection begun by Dr. Hand, of Baltimore County, Md., in 1850. He began by crossing the smooth "Love Apple," which was filled with juice and seeds, with the common convoluted red tomato of that period, which was so rough as to be unfit for use. It consisted practically of four or five separate fruits packed together in one, with the skin running far into the convolutions. After several years by continued in-breeding and selection he succeeded in producing a form which combined with the smooth skin of the Love Apple the solid fleshy mass of the compound red. This accomplished, he continued to select a very few specimens of the best and best flavored of the earliest fruit for the next year's seed, and thus increased the size and solidity of the fruit, until in 1870 he had produced a variety which was a mass of flesh interspersed with ten or more small seed cells, and which was the earliest, largest, smoothest, the most fleshy, and much the best flavored of all the kinds then grown. Moreover, the continued selection had resulted in a marked fixity of type, which was very different from the two- or three-celled original form.

The growth of sea-island cotton, on the islands off the coast of South Carolina and Georgia, was made possible only by the process of selection. When first introduced from the West Indies, the plants were not adapted to the climate, and seldom produced fruit. But by rigorous selection a race was produced which was well adapted to the climate, and the quality of the fibre was improved until now it is the best grown in any part of the world. That the improvement in the fibre is due to selection and not to conditions of growth is shown by the fact that when selection is relaxed the fibre deteriorates (Webber, "Year-Book Dept. Agric.," 1898, p. 358).

Many more examples might be cited to show how great the changes are that have been produced by artificial selection. Many domestic races produced in this way differ as much from each other and from the parent species as do species or even genera in nature. If artificial selection acting during only a few generations can produce so great changes, how much more effective must have been natural selection, which is probably much more rigorous and continuous, acting through countless ages.

To sum up, then, we have considered three lines of evidence that natural selection is a factor in organic evolution: 1. We have observed facts of the struggle for existence and a selective death rate. 2. We find that no organism in nature has developed any structure or function for the exclusive benefit of another species, contrary to what we might expect to find on the theory of special creation; but just what must be the case on the theory of natural selection. (This would probably be true also on any theory of evolution.) 3. We find that the analogous process of artificial selection has been the most effective means of developing in domestic races those qualities of most value to man, and therefore we infer that natural selection has been an important factor in developing in natural species those qualities of benefit to themselves.

One of the best ways of testing a theory is to attempt to apply it to concrete cases of the class of phenomena which it is supposed to explain. In the applications of the theory of natural selection we shall find the fourth and last line of evidence in favor of the theory.

The phenomena in question are in general those of *adaptation*. Many plants have especial floral structures which facilitate cross fertilization by the aid of insects, and Darwin has shown that this is of great advantage to the species. Climbing plants have peculiar structures and powers of movement that are clearly of advantage in enabling the long, slender stems to find support. Both plants and animals frequently have structures which serve to repel enemies, and many animals are provided with a protective coloring which renders them inconspicuous to their enemies or to their prey. Other animals, provided with offensive secretions or weapons, also have conspicuous warning colors which render them less liable to attack. Finally, there are inoffensive animals which resemble the offensive ones superficially in color and form, and by this mimicry probably share in their immunity from enemies.

These are examples of a large and important class of phenomena that, rejecting the theory of special creation, can be explained by only one theory of evolution, that is the theory of natural selection. Thus we see that natural selection is not merely a factor, but is perhaps the most important of all factors in organic evolution.

Passing over the objections to the theory of natural selection that arise from misunderstanding of the theory or ignorance of the facts, there are three objections that are important.

First, it is true that a great many species are distinguished by differences of form or color that are so minute that it seems impossible for them to be of selective value. Not knowing all the conditions of life, we are unable to say that such differences are not in themselves of selective value or correlated with characters of selective value. But in many cases there is no evidence of such value or correlation.

Second, one of the most marked peculiarities of species is infertility when crossed with other forms. Now it is difficult to see how infertility of any form could be produced by natural selection, except in relation to the food supply. But food supply could have nothing to do with infertility between species.

Third, a distinction must be drawn between linear evolution and divergent evolution. Linear evolution would be the gradual change of specific type by which the new species would become different from the old, but the number of species would remain the same. Divergent evolution, on the other hand, would mean the splitting of original specific types into two or more new types. Now it would be impossible for a species to become multimodal and ultimately to separate into two or more by the action of natural selection alone. For there would be nothing to prevent individuals of different types from breeding together and thus reducing them all to a common type.

These objections are valid, unless some other factor may be brought to the aid of natural selection. But selection is not the only means employed by the breeder of domestic races; then why should natural selection be supposed to be the sole factor of organic evolution?

Isolation.—When a breeder wishes to improve a race or to create a new one, he not only makes a very careful selection of his breeding stock, but he builds a fence around it and guards it against admixture with other stock. That this principle of isolation, or segregation, is of great importance as a factor of organic evolution has been pointed out, especially by Gulick and Romanes. By isolation is meant "simply the prevention of intercrossing between a separated section of a species or kind and the rest of that species or kind." Romanes regards natural selection as a prime factor of vast importance in evolution, but he believes it to be less fundamental and of more limited application than the principle of isolation. He says: "Equalled only in its importance by the two basic principles of heredity and variation, this principle of isolation constitutes the third pillar of a tripod upon which is reared the whole superstructure of organic evolution."

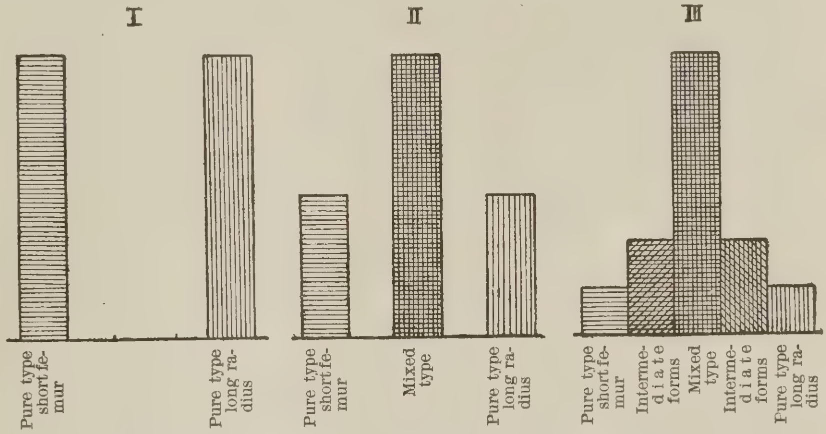

FIG. 1951.—Illustration of the Swamping Effect of Inter-crossing. *I*, First generation—selection intense, model type destroyed leaving two pure types distinctly differentiated; *II*, Second generation—random mating of the two pure types of equal fertility. Results, mixed type twice as numerous as either pure type. *III*, Third generation—random mating of the second; all individuals equally fertile. Results, mixed type six times as numerous, and intermediate forms four times as numerous, as either pure type. (Data from Pearson.)

From this point of view natural selection becomes a special case of isolation, where the individuals best fitted for their environment are isolated and prevented from crossing with inferior individuals by the death of the latter. But, as we have seen, this form of isolation can produce only linear, or monotypic, evolution, for of the two separated sections of the species only one survives. It is possible, however, that the modal type might become the least favorable, and that selection would result in the separation of two types equally fit. To borrow an illustration from Pearson, suppose a short femur and a long radius to be equally favorable and their combination in one individual so rare as to be negligible. Rigorous selection would produce two pure types, as in Fig. 1951, I. But natural selection alone is powerless to prevent the free intercrossing of these types, and the birth curve of the next generation will have the form of II in Fig. 1951. Selection will need to be repeated with equal rigor, otherwise in the third generation we shall find an approach to the normal curve with the mixed type as the mode, six times as numerous as either pure type (Fig. 1951, III). By natural selection alone, then, we should have in such a case merely periodic selection and no progress in divergent evolution. In order that the types A and B may become the foundation for two new species, some other barrier must arise between them. We must look for some other form of isolation.

Isolation may be total or it may be partial of various degrees. A more important distinction is between isolation that is "discriminate" and that which is "indiscriminate." Indiscriminate isolation allows free intercrossing of all variations, or *apogamy*; while discriminate isolation allows only individuals having some point of resemblance to breed together, or *homogamy*.

Apogamy will occur only where sections of the species contain large numbers of individuals at the time of separation. In this case there will be no change of type unless the separated sections become subjected to different conditions so that natural selection may act in a different manner.

Where the isolated section is so small as not to be a fair sample of the population, there will be a sudden change of type. That is, the mean of this section will differ somewhat from the mean of the species as a whole, and there will be a certain degree of homogamy. But this change of type may be very small, and it is very doubtful if homogamy without natural selection can produce any continuous change of type, although Gulick and Romanes have held that it can.

Geographical isolation has, without doubt, played a very important part in the differentiation of species. As we have seen, it will give rise to homogamy or apogamy, according to the number of individuals separated. But probably its most important effect has been to allow the gradual adaptation of parts of a species to different conditions, which would be impossible where free intercrossing could take place.

There are numerous forms of homogamy. "When, for example, any section of a species adopts somewhat different habits of life, or occupies a somewhat different station in the economy of nature, homogamy arises in that section." In plants differences in times of flowering, in habitat, or in the habits of insect visitors may give rise to homogamy. But, according to Romanes, aside from natural selection, the most important form of homogamy is sexual incompatibility, which he calls physiological isolation. In this form of isolation individuals having some peculiarity of the reproductive organs are prevented by this from crossing with individuals having some other peculiarity. If this sterility between different sections of the species be correlated with other peculiarities, we have what Romanes calls *physiological selection* and the formation of a new race, which is free to develop independently of the rest of the species.

This theory is based upon two principal considerations: (1) the general variability of organisms, including the reproductive organs, and (2) the fact that the character that chiefly distinguishes species from varieties is sterility between them. This sterility may be absolute, or it may result in the production of more or less sterile hybrids. Whether sterility has arisen before or after other divergent characters, it will be, in either event, an important factor in evolution. We must suppose it to have arisen gradually and to have spread until it affected a number of individuals; but it is difficult to see how this could have taken place without the aid of some other form of isolation.

The chief evidence for the theory of Physiological Selection is found in the topographical distribution of plants. Naegeli found ninety-five per cent. of allied species and a great number of allied varieties living together in the same stations separated by no barrier except sterility. And this is confirmed by the experiments of Alexis Jordan, published in 1873. He discovered in plants great numbers of varieties hitherto overlooked owing to the minuteness of the differences between them. And he found that in many hundreds of cases these varieties, in nature living side by side, would breed true to seed and be sterile *inter se.*

Sexual Selection.—Another series of special cases of isolation is furnished by the various kinds of sexual selection. This term, as recently employed by Pearson, includes all forms of *selective mating.* This is sharply contrasted with *pangamic mating,* or the mating at random of all members of the race. The forms of selective mating are classified by Pearson as follows:

1. Autogamic mating, or self-fertilization, including the fertilization of a flower by another flower on the same plant.

2. Endogamic mating, or mating within the family, brood, or clan, a very effective mode of isolation.

3. Homogamic, or assortive mating, the union of like with like, the two mates not necessarily being of the same brood.

4. Apolegamic (from *ἀπολέγω,* I pick out, refuse), or preferential mating. This is *sexual selection* in the sense in which the word was originally used by Darwin.

5. Heterogamic mating, or the union of unlikes. Darwin found many cases of this form of mating in his study of the effects of cross and self-fertilization in plants. It includes those cases in which the species is polymorphic and a union of diverse forms is prepotent over a union of similar individuals.

The theory of sexual selection in the narrower sense was devised by Darwin to account for the origin of certain secondary sexual characters in animals.

There are many species in which the individuals of one sex, usually the male, fight with one another for the possession of mates. The fur seal is an excellent example. In such cases it is obvious that those males having superior weapons and strength to use them will beget the greater number of offspring, and that these will inherit and transmit their favorable peculiarities. This might be regarded as a special form of natural selection.

But there are many species, especially among the birds, in which the contest for mates is carried on by gentler means. In these cases the males usually seem to vie with one another in an attempt to excite the sexual instincts of the females by melodious song and cries, by movements of the body, or display of bright colors. It is supposed that those males which are most attractive to the females will produce the most offspring, and thus the development of ornamental secondary sexual characters is regarded as due to selective action on the part of the females.

Of course, this theory can apply only to animals of a relatively high grade of organization, and the efficiency of this factor in evolution has been denied entirely by Wallace and others.

To enter into this controversy would require too much space. But it may be pointed out here that (1) males are frequently distinguished, not only by bright colors, but by a highly decorative color pattern, sometimes associated with a highly elaborate structure, as in the peacock, angus pheasant, bird of paradise, etc.; (2) many birds possess not only call notes, but a melodious song, often to our ears, at least, of great beauty, as the wood thrush, the wren, and the catbird; (3) and, finally, the deer family possess handsome arborescent antlers that are highly ornamental, but certainly less efficient weapons than the straight horns of the antelopes. Now these facts cannot be explained by the assumption of vigor of the male, nor by the usual process of natural selection, while they are easily explained on the theory of preferential mating.

In order that the choice of the female may be an efficient factor in evolution there must be a certain general tendency in one direction. In order to discover whether this be true or not it would be necessary to resort to careful statistical inquiry.

Pearson has pointed out the method for making such inquiries, and in the case of man he found no evidence of preferential mating in respect to stature, but he found distinct evidence of preferential mating in the matter of eye-color or of some closely allied character in the male. The general tendency is for the lighter-eyed to mate, while the dark-eyed are less frequently mated. He concludes that it cannot be doubted "that sexual selection in the form of preferential mating is not a mere hypothesis, but can be demonstrated to actually exist in the case of man."

Preferential mating would have an effect on evolution similar to that of natural selection. That is, there might be a tendency to progressive change of type, but it could not alone produce differentiation. On the other hand, it is clear that self-fertilization and endogamy would aid differentiation, and assortive mating would also have this effect, if mating of this kind takes place.

Pearson, using the method of correlation, studied the stature of one thousand pairs of husbands and wives, and the eye color of seven hundred and seventy-four pairs. And he found that, "the assortive mating is indeed so great that husband and wife have for the average of these two characters a sensibly greater degree of resemblance than that assumed on theoretical grounds to hold for first cousins and approaching the degree of resemblance found for uncle and niece."

Panmixia.—The presence of vestigial organs in vast numbers of species, and the fact that some groups entirely lack organs possessed by other related and perhaps lower groups, as, for example, the snakes, lead to the belief that in the course of evolution organs in many cases have dwindled in successive generations, and sometimes have entirely disappeared.

Perhaps the most natural explanation of these facts would be to ascribe them to the inherited effects of disuse. But this explanation is inadequate, for it will not account for the loss of parts in plants, nor for the loss of passively protective structures in animals; and it is particularly inapplicable to the cases of the loss of wings in neuter insects, for neuters produce no young, and hence there could be no inherited effect.

To meet this difficulty Weismann introduced the hypothesis of *panmixia.* This is merely random mating without selection. But, as has been pointed out by C. L. Morgan and Pearson, the only effect of panmixia would be a reduction from the survival mean to the birth mean. There would be a sudden slight change of adult type in one generation, and after that no further effect.

So it would seem that we must fall back upon Darwin's principle of natural selection and economy of growth. For example, in the case of wingless insects inhabiting small oceanic islands, it is evident that if the species were unable to become strong fliers, it were better for them not to fly at all. Because weak fliers would be apt to be blown out to sea and lost. Darwin argued also that useless organs require as much nourishment as useful ones, and in time of dearth the animal which had to find nutrition for the smallest amount of useless tissue would stand the best chance of surviving. This might account for the dwindling of useless organs, but it would not account for their complete disappearance. For it cannot be supposed that the presence or absence of a minute vestige of an organ could ever be a matter of life or death. And as no satisfactory hypothesis has been advanced to explain this, we shall have to regard it as one of the unsolved problems of evolution.

Bathmic Evolution.—Palæontologists have asserted that they find in the study of extinct animals evidence of a constitutional tendency toward variation in a definite direction. Such a change of type, due solely to something inherent in the constitution, without action of organic or inorganic environment, is called *bathmic* evolution (from *βαθμίς,* basal).

The evidence that such evolution has taken place is not very convincing. Nevertheless, supposing it to be a fact, many explanations have been offered to account for it. Mivart suggested an innate tendency, and Naegeli, a perfecting principle. But these are merely words and explain nothing. Hyatt from a study of certain fossil mollusca, ammonites, found evidence of a cycle of development of species corresponding to the cycle of individual development. He holds that there is a law of growth which compels species to pass through the stages of youth, maturity, and senescence. This may be true of the ammonites; it may be the reason that they are extinct. But it has not been shown to hold for any other group, and the law itself would need explanation.

Weismann has offered as an explanation of bathmic evolution his hypothesis of *germinal selection*. But this is a pure assumption based upon Weismann's theory of the structure of the germ plasma, which is directly contradicted by observed facts (see *Heredity*).

The first reasonable hint of a cause for bathmic evolution has been furnished by Pearson in his theory of *reproductive*, or *genetic, selection*. From the study of four thousand three hundred and ninety families in the middle and upper classes, Pearson found that variations in fertility do not follow a normal symmetrical curve, but have a very skew distribution, small families being much more numerous than large ones. The result is that twenty-five per cent. of the parents produce fifty per cent. of the children. It is clear that on the average one pair of the smaller group of more fertile parents will have as much effect on the type of the next generation as three pairs of the larger less fertile group. Therefore, if fertility be inherited, and if there be a correlation between fertility and any other character, progressive change of type may take place by a purely bathmic process, unless checked by natural selection or other cause. As to the inheritance of fertility, Pearson found from a comparison of the sizes of the families of a thousand pairs of mothers and daughters, where the marriages had lasted fifteen years or more, that there was very good evidence of such inheritance. (He obtained a coefficient of heredity of .213 with a probable error of ±.020.) Similar results were obtained by the study of one thousand pairs of paternal grandmothers and granddaughters. Here the coefficient of heredity (.112 ±.021) is about half as large as for mother and daughter, as would be expected by the law of ancestral heredity, and this is an example of the transmission of a female character through the male line with undiminished intensity. Thoroughbred horses also furnished evidence that fecundity is inherited between dam and daughter and also through the male line, fecundity being transmitted by a sire from his dam to his daughter. There is also evidence of correlation between fertility and other characters. In man, Pearson found that the more fertile women are slightly taller than the less fertile, and dark-eyed fathers and mothers are found to be more fertile than those with light eyes.

Poppies have radiating ridges on the upper part of the seed capsule, the stigmatic bands. In 4,443 capsules of Shirley poppies the range of variation was from 5 to 19 bands and the modal number was 13. Capsules with 12 to 13 bands were found to be very full of seed, while there were hardly any in capsules having very few or very many bands. Likewise in 3,212 seed capsules of *Nigella hispanica* the range of variation in the number of segments was from 2 to 20, with 8 for the modal number. Capsules with 8 segments were found to be very fertile, while those with 10, 11, and 12 segments contained hardly any seed, and those with 5 or less were practically sterile.

It is evident, then, that where the most fertile character coincides with the modal character, as in the case of the poppies and Nigella, this differential fertility, or genetic selection, will tend to preserve the stability of the race, and in order that differentiation of type may take place, this effect will have to be overcome. On the other hand, if the most fertile character differs from the modal character, as appears to be the case in the eye color of man, then there will be a progressive change, unless this is checked by preferential mating, natural selection, or some other cause. So differential fertility is to be reckoned with as a factor in evolution. It is certainly in some cases a conservative factor, and it is possible that it may become a cause of progressive change of type. But whether bathmic evolution has ever taken place by this means without the aid of other factors is another of the unsolved problems.

Inheritance of Acquired Characters.—An "acquired" character is one which arises during the life of the individual as the result of functional activity or in response to an external stimulus. The term is an unfortunate one, for to many minds the word "acquired" conveys simply the impression of newness without regard to the source of the change. To meet this difficulty C. L. Morgan has proposed to use the term *modification* in place of acquired character, and to reserve the term *variation* for changes of purely congenital origin. Moreover, it is often difficult to distinguish between modifications and variations. For example, deafness may be due to congenital malformation of the ear, or it may be due to disease. In the first case it would be a variation, in the second it would be a modification. Now Fay in his study of the inheritance of deafness often found it difficult to decide in which class a given case should be placed.

The factors of organic evolution that we have examined so far have been the great factor, natural selection, and a number of others more or less aiding and accessory to it. We have seen that natural selection is itself conditioned by three other factors: (1) variation, (2) inheritance, and (3) the struggle for existence.

Natural selection is only indirectly concerned with the origin of variations. So long as variations are of the right kind and are capable of being transmitted, natural selection, with the aid of isolation, will protect and develop them. It is evident, then, that if the purposeful, adaptive modifications of the individual that arise as the result of its reactions to the stimulus of its environment may become hereditary, they will be a great aid to natural selection. For they will insure the presence of the right kind of variation to be selected when it is needed. Darwin thought that such acquired characters are inherited, and he regarded them as an important aid to natural selection. The neo-Lamarckians, on the other hand, have taken the view that the inheritance of acquired characters is much more than an aid to natural selection; that it is itself a prime factor of organic evolution.

Now comes the school of Wallace and Weissmann, and says that the inheritance of acquired characters not only is not a prime factor in evolution, but it is not even an aid, as Darwin supposed, to natural selection. In fact, according to this school, acquired characters are not in any degree inherited. The question then is, Are acquired characters inherited, and if so, how far has this inheritance been a factor in the origin of species?

To discuss fully the subject of the inheritance of acquired characters as a factor of organic evolution would require much more space than we have at our command. But we may endeavor to present a few of the thoughts which seem to be of greatest importance in this connection.

In the first place, the neo-Lamarckian contention that the inheritance of acquired characters is the *prime factor* in evolution can be ruled out of court at once as manifestly untenable. There are a large number of structures in both plants and animals that can have developed only as the result of continued selection. Such are the cases of mimicry, both in form and color, warning colors, adaptations for cross fertilization in plants, and the like. But the most instructive examples, as pointed out by Brooks, are to be found in species having normally sterile individuals. In many species of polyps there are nutritive, offensive, or protective persons in each colony which never produce offspring; and among ants, bees, and termites, the most numerous and most active members of the community are sterile workers. These sterile individuals generally differ from the fertile males and females, presenting very beautiful modifications of both structures and instincts in adaptation to their very different functions and mode of life. Now as the worker has no offspring its acquired characters cannot be inherited. The evolution of the worker must be explained as the result of natural selection, preserving those queens that produced the workers best adapted to the needs of the species.

If such complex adaptations as the mechanism for cross fertilization in orchids, and modifications observed in the worker of the honey-bee have arisen through the action of natural selection without the aid of the inheritance of modifications, a strong presumption is raised in favor of the view that natural selection and not inheritance of acquired characters, has been the prime factor in evolution generally. This being granted, should we not return to the position taken by Darwin, that while natural selection is by far the most important factor in evolution, it has been aided by the favorable variations resulting from the inheritance of acquired adaptive modifications?

The amount and kind of evidence that is required to prove any generalization depend upon its theoretical probability. Now if we accept Darwin's view as to the inheritance of acquired characters, we must also accept his theory of heredity or some theory closely allied to it. The study of heredity, however, makes it clear that the only theory that corresponds with what is known of the origin of the germ cells and the subsequent development of the embryo utterly fails to explain the inheritance of acquired characters. If acquired characters are ever inherited, our theory of heredity must include some form of pangenesis and of preformation. But the only theory that agrees with the facts of development must include the contrary principles of continuity of the germ plasm and epigenesis. This makes the inheritance of acquired characters seem theoretically improbable, and necessitates a critical examination of the testimony in its favor. This evidence may be classified as follows:

1. Indirect evidence.

(*a*) Analogy between congenital and acquired characters.

(*b*) Apparent uselessness of nascent structures observed in fossils.

(*c*) Reflex actions.

(*d*) Instinct.

2. Direct evidence.

Reported cases of inherited effects of (*a*) use or disuse, of (*b*) climate, and of (*c*) food.

3. Experimental evidence.

(*a*) Brown-Séquard's experiments on guinea-pigs.

(*b*) Experiments of Hoffman, Carrière, and Buckman on plants.

It will be most convenient to take up this evidence in the reverse order. Beginning with the experimental evidence, Brown-Séquard's experiments were supposed to show that epilepsy induced in guinea-pigs by operation is inherited by their offspring. But Romanes repeated these experiments as carefully as possible, and his results were inconclusive.

Carrière and Buckman were able to produce change in plants increasing in successive generations, by growing them on different soils. But here the principle of selection was employed, and it is impossible to say how far the result is due to selection and how far to the inheritance of acquired characters. It is also to be remembered that food is one of the factors in the environment that may affect the germ plasm directly. It is possible, therefore, that the changes observed in the succeeding generations of plants may be due to the new constituents of the sap affecting the germ plasm directly. The new characters would not then be acquired characters in the technical sense, but true congenital variations. Moreover, these experiments are offset by a number of experiments made by careful observers especially to test the question of inheritance of acquired characters, which have given purely negative results. Fay found that when both parents are congenitally deaf, twenty-six per cent. of the children are deaf. When one parent is congenitally deaf and one has acquired deafness, the percentage of deaf children is 6.5 per cent., while where both parents have acquired deafness it is only 2.3 per cent., and this last percentage may be due to an error in determining whether the deafness is congenital or acquired.

So the experimental evidence, which should be expected to give the most conclusive answer, is after all unsatisfactory.

The direct evidence as a whole is worthless. Most of the cases have been reported by unscientific persons unskilled in exact observation. The cases in which there have been competent observers can be explained as well either as the result of selection of congenital variations or as the result of the direct effect of environment upon the germ plasm.

It is the indirect evidence that offers by far the best cases in favor of the inheritance of acquired characters. In the first place, that the effects of use and disuse of parts and the effects of external conditions, climate, food, etc., are inherited, is a matter of common belief. We know the effects of these causes upon the individual, and we know that very minute individual peculiarities frequently are inherited. It is reasonable to suppose then that peculiarities caused by external conditions are inherited with the rest. No one can claim, however, that this line of evidence offers more than a presumption in favor of the inheritance of acquired characters. A better line of indirect evidence is furnished by those adaptations which apparently could not have been of use in the early stages of their evolution, and many palæontologists believe that they find in extinct species such nascent structures and that these prove the inheritance of acquired characters to be the prime factor in evolution. This is regarded as especially true of those cases in which a high degree of co-adaptation is required. Spencer, for example, presents the case of the giraffe as a form undoubtedly due to the inherited effects of functional activity. For as he rightly says, in order that the giraffe may carry his long neck, the forelegs must be lengthened, and the hind legs shortened. In fact, the whole shape of the body has to be altered, involving changes in a great many tissues and organs. If a breeder is trying to produce a variety having a new combination of characters, he selects individuals, some having one character, some another, and still others a third, and so on; and by causing these to breed together finally obtains individuals in which these characters are all combined. The Boston terrier and the Plymouth Rock fowl are excellent examples of such a blending of characters by artificial selection.

Now Spencer argues that it is impossible for co-adaptation to be produced by an analogous process in nature, for it is inconceivable in the case of the giraffe, for example, that any one of its peculiarities occurring alone in an individual could be of sufficient value to lead to the preservation of the animal by natural selection. In fact, some peculiarities without the others, for instance, the long heavy neck without unusually strong shoulders to support it, might be so great a disadvantage as to lead to speedy elimination. In order that the giraffe should be produced by natural selection, according to Spencer, it would be necessary for all of the co-ordinated adaptations to appear at the same time and in a large number of individuals. For, in the first place, these variations could be of no value unless all were present and co-ordinated; and in the second place, unless they occurred at the same time in a large number of individuals, they would be lost by the swamping effect of intercrossing. Moreover, they must continue to vary in the right direction in a large number of individuals. All of this Spencer holds to be impossible without the aid of the inheritance of acquired characters.

A new variety may be supposed to arise in one of two ways, either (1) from the blending of a series of adaptations each in itself of selective value, or (2) by the co-adaptation of a number of variations each so slight as not alone to have selective value, but when combined with the others producing a form sufficiently superior to its fellows to be preserved in the struggle for existence. Even Spencer would admit that the first method is easily explained by natural selection, if the swamping effect of intercrossing can be eliminated by some mode of isolation. But, if new forms are produced in the other way, by co-adaptation of variations in themselves not of selective value, as Spencer supposes in the case of the giraffe, natural selection is not so easy an answer.

These phenomena of co-adaptation present one of the best lines of evidence that has ever been brought forward in support of the theory of the inheritance of the effects of use, and yet it does not seem to be at all conclusive. To begin with the case of the giraffe, it would seem that the development of this species from an antelope-like ancestral form may be explained by the mingling of adaptations as well as by the sudden appearance of true co-adaptations. Those who take the opposite view, while insisting upon the adaptive value of functional modifications, that is, characters acquired as the result of the use of parts, seem to forget, as has been pointed out by C. L. Morgan and others, that purely fortuitous, or accidental, congenital variations in the same direction may occur at the same time. The element of environment that has led to the evolution of the giraffe was evidently the need of reaching high foliage. Now in order that the animal shall reach this foliage the head must be raised high from the ground, and this may be accomplished by lengthening the neck or by lengthening the fore-limbs, or by lengthening both at the same time. At the beginning, therefore, of giraffe evolution, those animals which varied toward greater length of neck and those which varied toward greater length of fore-limb or greater height of shoulder would have an equal chance of surviving in the struggle for existence, provided the muscles necessary for carrying this increased weight were equally *capable of being strengthened by exercise.* These individuals would breed freely together, and finally offspring would be produced having both neck and fore-limbs longer than in the ancestral form. Again, the effects of exercise would compensate for the increased weight, and, again, the individuals best developed would survive. Now we know practically that every part must have varied on both sides of the average character of the race. A large number of individuals inheriting the above characters must have presented congenital variations of the co-operating parts of the body of the same character as those modifications produced in the others by functional activity. Such congenital characters might occur separated, some in one individual, some in another; but wherever they occur the animal will have a distinct advantage, for so much will be, so to speak, ready-made, and just so much less to be developed by exercise. You can make an athlete of a man with a congenitally strong back and weak legs more quickly than you can make one of a man whose back and legs are both congenitally weak. In time, by careful training, the two men might become equally strong, but in natural selection time counts. The sooner an animal can hold its own with its fellows, the better its chance for surviving to produce offspring.

It seems to us then, that if we remember that *fortuitous, congenital variations and modifications due to functional activity may be of the same character and may occur side by side,* there is no longer any difficulty in the theory that even so complicated a co-adaptation as is presented by the giraffe may arise by blending of minor congenital adaptations and therefore may be explained by natural selection. Moreover, it is to be borne in mind that it is a fallacy to speak of any one character as being selected. It is not a single character that is even preserved by natural selection, but it is the individual as a whole that is selected. While a favorable character may not of itself be of selective value, it may be perpetuated because it occurs combined with other favorable characters *either congenital or acquired,* all so blended as to give their possessor superior advantages. Individually acquired modifications may, therefore, become important factors in evolution, not because they are inherited, but because by their acquirement the individual is able to supplement the deficiencies in its congenital characters. And when thus supplemented by individually acquired adaptive modifications, the inheritable congenital characters may be preserved by natural selection and continued from generation to generation, until by the operation of fortuitous variation and natural selection the acquired modifications are replaced by congenital characters of the same kind. So we may have two forms of co-adaptation: first, co-adaptation of mingled congenital and acquired characters, which precedes and prepares the way for the second, co-adaptation of purely congenital characters.

The question whether co-adaptation by the blending of favorable congenital variations really occurs in nature is answered best, according to Romanes, by a study of reflex actions and of instincts. Turning now to the evidence from reflex actions, it seems to us that Romanes has been unfortunate in selecting this line of evidence upon which to pin his faith in the *occasional* inheritance of acquired characters. He asks what use an animal can have for lower reflex centres when the higher brain centres are capable of originating the same nervous impulses. Now no one who has ever learned to dance, to swim, or to ride a bicycle will fail to appreciate the superiority of reflex over conscious action. No one can become an expert swimmer or rider until the movement is of the nature of a reflex, although the higher centres, the rational processes, may still be indispensable in case of accident. Romanes argues at length in regard to the apparent uselessness of many reflexes, together with the completeness of the mechanism required, and the consequent difficulty of explaining them by natural selection, and then proceeds to show that "if function produces structure in the race as it does in the individual," all is easily explained.

Now, in the first place, does function produce structure in the individual? Function may be said to produce size, strength, hardness, flexibility, and the like, but no case is on record where new muscles, new nerves, or any other new structure has been produced by any amount of functioning. Moreover, how can a structure be the result of a function when the function arises from the activities of the structure in question? A given intelligent act cannot take place until the whole neuro-muscular mechanism concerned in that act is complete, any more than if it were a reflex; and it is not evident how one can be explained by gradual development any better than the other. (It is like saying that a man can make a bicycle by riding it.) But even if we allow that a reflex mechanism may be the inherited result of intelligent action, this action must have been of a great deal of use to have been repeated often enough to make so great an impression on the organism. And if it has been of so great use it may well have had a selective value, and its development may then be explained by variation and natural selection.

It would seem, therefore, that reflex mechanisms and actions may be explained best by the principles of change of function and natural selection. When you learn to ride a bicycle, or better, when you learn to swim, you develop a new set of reflexes, but no new sense organs, nerves, or muscles, only the old ones in new combinations. Now the study of the morphology of the nervous system in any great group of the animal kingdom shows that a change of function in different parts of the nervous system is just what has taken place as we go higher in the scale of organization; and it is easy to see how any variation toward more intimate union of parts habitually used together would be preserved by natural selection until their interaction would be so easy as to become reflex.

Turning to instinct—if we regard it as "hereditary habit," that is, if we suppose it to contain an element of transmitted experience, all is easily explained. The simple instincts are easily explained by natural selection, "but in all cases where instincts become complex and refined, we seem almost compelled," according to Romanes, "to accept Darwin's view that their origin is to be sought in consciously intelligent adjustments on the part of ancestors." He cites the case of a species of wasp of the genus *Sphex,* which paralyzes caterpillars by stinging them in each of the nine minute nerve centres before depositing them in the cells for the larva to feed upon. He regards it as impossible that such an instinct could have arisen by natural selection unaided by originally intelligent action. In regard to this it may be said that, if the complicated maternal instinct of the *Sphex* wasp is an "inherited habit," its ancestors must not only have possessed great industry, but also a very remarkable knowledge of anatomy. Moreover, it has been shown very recently (1898) by Mr. and Mrs. Peckam ("Instincts and Habits of the Solitary Wasps") that the instinct of *Sphex* is not so exact as was formerly supposed. Not only is there a great deal of individual variation in the instinct of this species, but there is a gradation from this through other genera to those having much simpler instincts. They have shown that instinct may be acted upon by natural selection, just as may any other function or structure.

In conclusion it may be said, therefore, that in the writer's opinion, while acquired characters are of great importance to the individual, and their periodic recurrence in successive generations may be necessary in the formation of co-adaptations as an aid to natural selection, the *inheritance* of acquired characters is not only not the prime factor in evolution, but that it is not a factor in any degree.

Differential fertility appears to be an important factor, being, according to the circumstances, either an aid or a hindrance to evolution; preferential mating is the best explanation of the origin of certain secondary sexual characters; and some form of isolation must be present, or else divergent evolution is impossible, and without isolation it would be impossible to explain the differentiation of species by characters of less than selective value; but the chief cause of organic evolution is natural selection, or the survival of the fittest in the struggle for existence. *Robert Payne Bigelow.*

EVOLUTION OF MAN.—The science of anthropology has advanced with surprising rapidity since the discovery of the two principles, evolution and psychic unity, the latter contributing evidence in support of the theory of evolution similar to that furnished by the homologies of biology. From each of the recognized divisions of anthropology evidence has been accumulated to establish the unity of the human species and to warrant the assumption that it has developed from the original mammal through the lemuroid and anthropoid stages. A few zoologists would derive man directly from the lemurs, but while it is recognized that man has many characters in common with the half-apes and even with lower forms, anthropologists are unanimous in deriving him from a generalized anthropoid precursor. The phylogeny of the mammalian group is given in the preceding article upon *Evolution*, so that we may devote our attention here to the problems involved in the determination of man's immediate ancestry. We shall seek such evidence as may be found within the human group, neglecting argument by analogy, which can never be wholly convincing.

I. SOMATOLOGY.—The modern science of physical anthropology interprets the data supplied by embryology, ethnic and comparative anatomy, and statistical anthropometry by the aid of the theory of evolution which alone renders them comprehensible.

1. *Embryology.*—In addition to the indications of relationship to lower animal forms there are many marks of phylogenetic proximity to the anthropoids in the human fœtus. By the dictum of "the first biogenetic law" we interpret the greater resemblance of the young of anthropoids and man to mean that both sprang from a common ancestral type. Not to deal too exclusively with general statements let us review a few of the more salient facts.

The lanugo of the fœtus recalls the hairiness of primitive man and his immediate ancestor, a condition seen even now in an occasional unfortunate adult. The free projecting tail of the embryo certainly pertains to an earlier form than the anthropoid but not necessarily earlier than the lower primates. Again it is to be noted that this character sometimes persists in human beings until maturity, either with or without free vertebræ. Until the very end of the nineteenth century rumors of the discovery of tribes of tailed men were circulated from time to time. It has been suggested that such fables may have arisen from the practice of wearing a sort of caudal appendage, as among the Sioux Indians and the Nagas of Manipur. The theory of an ontogenetic shifting of the pelvic girdle is generally accepted, reducing the number of presacral vertebræ from the number existing in most of the anthropoid families and from the ancestral condition. The presence of cervical and lumbar ribs in the embryo recalls the type prevailing among the anthropoids where the orang alone has as few as twelve pairs. The shape of the entire thorax in the embryo is of the primary type seen in the lower apes. One of the most noticeable simian characters to be seen in the embryo is the proportionately long fore-arm which in the embryo of two and a half months equals 88.88 per cent. of the length of the humerus as compared to 72 to 73 per cent. in the adult European, 78 or 79 in the adult negro, and 90 to 94 in the chimpanzee. The os centrale of the human embryo is found in but one group of anthropoids among adults, though it occurs in most monkeys. The short lower limbs of the fœtus suggest the adult anthropoid condition. The fibular malleolus, much less important than the tibial in apes, is less developed in the fœtus and among Australians and other low races. The opposable condition of the great toe in fœtal, and even infantile life is an often cited example of the retention of an ape-like character.

Among the muscles we may refer to the condition of the pyramidalis which in the child resembles that of the apes and lower mammals; also to the interossei pedis muscles which in the human embryo are distributed as in some of the lower apes and in lesser degree the chimpanzee and orang. The vermiform appendix is proportionally larger in the fœtus.

In the brain, the most distinctively human of all the organs of the body, the ontogenetic changes in the character of the surface and the disposition of the vesicles repeat phylogenetic development in a marked degree. Resemblance between the young of the two groups is nowhere more striking than in this organ. Hints of the anthropoid condition are not numerous in the sense organs of the embryo, but in the external ear such conditions are fairly prominent; the tip shifts downward and not until the eighth month does the human ear fold begin to roll inward. The palatal ridges of the embryo (six or seven) suggest the anthropoid condition, though they are rather more numerous in the apes. The milk teeth of man and anthropoids are closely similar and the dental formulæ are identical in the two groups.

These are a few of the more important characters that point to an anthropoid ancestry. They are but a fraction of the number of characters that occur in the human embryo which are indicative of lower stages of development, but taken altogether they lend strong support to the evolutionary hypothesis.

2. *Ethnic and Comparative Anatomy.*—Together with physiology and anthropometry it comprises the greater part of the science of somatology as now taught in our universities, and the evidence of the relationship of man to the anthropoids is rapidly accumulating, both from the work done in our laboratories and from that accomplished among what we are pleased to term the lower races, though it must be understood that in many respects these races as well as some of the lower animals exhibit characters of decided superiority. We may summarize the facts as follows: Man resembles the anthropoids more closely than do the latter the American monkeys. In other words, the gap between the human and the nearest non-human group is far less striking than that between many mammalian groups. Among skeletal characters we find that the spinous processes of the cervical vertebræ are simple and undivided among low races. The clavicle and the scapula are proportionately longer and hence more simian in the negro than in the Caucasian. The arm of the negro exhibits two opposing characters: it is higher in its shorter humerus and lower in the longer radius than the white; the proportion of the radius is more exaggerated in the Veddahs of Ceylon. With a slightly shorter femur and a tibia of equal length the negro possesses lower limbs of a more simian type than the white. In the torsion of the humerus the black races stand midway between the anthropoids (130°) and Europeans (164°). The condition known as perforate humerus or the occurrence of the supratrochlear foramen, which is most frequent in Veddahs and Bushmen, is common in the gorilla and the orang. Among non-European races it is not the blacks alone that retain the ape-like prehensile foot beyond the period of infancy; many Eastern peoples possess this character, notably the Japanese. However, it is a pincer foot, not a hand foot.

The skull continues to be the most significant portion of the skeleton for classificatory purposes notwithstanding some contradictions presented by single characters. The projecting brows of the gorilla are seen in certain prehistoric crania to be described later and in the Melanesians as well as in rare instances among Caucasians. Many human groups possess the flat nose of the anthropoids. The fusion of the nasal bones that is normal in apes occurs more frequently in lower races than in higher. Australians, Hawaiians, and others have no sharp line of demarcation between the nasal opening and the maxilla beneath it. The temporal crest assumes a simian appearance among the Oceanic blacks. The meeting of the temporal with the frontal in the form known as pterion in K is most frequent in the Veddahs, Australians, and negroes; in anthropoids it is seen in the gorilla. Considerable variation in the foramina of the skull occur: the parietal are more frequently wanting in the higher races, the middle lacerated is larger in Europeans than in lower races and is wanting in anthropoids. The palatine suture of certain low races by its curved and irregular course resembles that of the apes. The form of the palate among low races often resembles the U-shaped alveolar arch of the anthropoids and occurs occasionally among Caucasians as an individual variation. The teeth of the Australians increase in size backward as in the apes. The New Caledonians not rarely develop a third pre-molar, the normal condition in New World monkeys. The shortened inferior maxillary of the European is causing a reduction in the number of teeth so that the upper outer incisors are sometimes wanting and the wisdom teeth as well. This change is also taking place among Amerinds. We have observed cases of suppressed third molars among the Esquimaux and all stages between rudimentary third molars and those larger than the first and second molars among other Amerinds. The hyoid of negroes resembles that of apes more closely than does that of Caucasians. The prognathism of the ape is conspicuous in the extinct Kalangs of Java, the Akkas and other Africans.

The only well-marked gap existing between the crania of man and anthropoids is in capacity. The highest recorded capacity for the latter is about 590 c.c. while the lowest for the former is that of a normal Veddan skull of 950 c.c. While the methods of determining cranial capacity are unsatisfactory, and the results of different observers are scarcely comparable one with another, yet approximately correct averages have been recorded for most human groups which show that the lowest capacity exists among the dwarf races of Africa, the Veddahs of Ceylon and their neighbors, the Andamanese. The question of capacity is the most interesting one concerning fossil human crania.

3. *Variation.*—Notwithstanding the potent influence of mixture of races, the constant mingling of blood owing to conquest, slavery, or friendly alliance, all tending toward uniformity of type, the human body is in the highest degree variable. The tendency toward uniformity has produced a well-defined species with varietal differences within the group; but each organ of the body and the proportions of the whole vary to such a degree that the examination of a large series of anthropometric data cannot but cause the investigator to marvel at the continuance of the human type. We now know that the black, white, yellow, and red varieties of the race perfectly intergrade; hence we need not expect by such comparisons as have been made in the preceding paragraphs to discover differences in the various human groups that shall equal those existing between this species and the anthropoids belonging to four separate families.

Even in the size of brain case, the range of normal variation in man is from 900 to 1,800 c.c. while the range from microcephalic idiots to pathologic megacephalic skulls is from 350 to 3,500 c.c. The range of variations in cranial capacity in a small series of 42 Auvergnat skulls was 676 c.c. The range from the earliest times to the present is inconsiderable and inconclusive. The proportions of the brain case are fairly constant within the tribe but not in the larger divisions of the species: we have long-and-round-headed Caucasians, Mongolians, negroes, and Amerinds, with all possible intermediate forms. In the torsion of the humerus, often cited as a good zoological character separating man from the other animals, the variation is from 164° in Europeans to 134° in Australians, the minimum being at least seven degrees below the average for the gorilla, less than the gap separating the lowest anthropoid from the lower apes and monkeys which, in their turn, are lower than the marsupials and others. Independently of the normal variation in the length of the humerus, the difference between the right and left sides sometimes amounts to 2 cm. The other long bones exhibit a corresponding variability; indeed, the tibia has been termed the most variable long bone in the limbs of man. The thickness of its shaft varies from forty to one hundred per cent. of the antero-posterior diameter and the outline varies from almost a circle through oval, triangular, and quadrangular forms. Physiological causes are supposed to bring about the platycnemic or flattened condition and the retroversion of the head as well as various degrees of curvature of the shaft. Examples of similar variations might be multiplied indefinitely from an examination of other parts of the skeleton and of the other tissues, particularly the muscles, where variation becomes excessive, and we yet continue in our laboratories to record cases of "new muscles."

II. ETHNOLOGY.—The study of the culture of living races furnishes little evidence in favor of our thesis; although it is true that in the Amerindian division the Fuegians, the Seri of the Gulf of California, and perhaps the Botocudo stand out little above the apes. Subsisting mainly upon raw food and manufacturing implements and weapons of the simplest sort they are not industrially much superior to the anthropoid that has learned to preserve the conveniently shaped stone for breaking cocoanut shells. Among the blacks, the Andamanese, the Veddahs, some Australians, and perhaps a few other groups are equally savage in culture.

From the discoveries of recent years it is now known that the earliest migrations peopled the earth before or shortly after the transition to the human stage of development, so that the several native cultures have been moulded by environment and acculturation rather than by common descent. Naturally, similar environments, similar conditions, result in like products which are termed ethnic parallels, and the phenomenon is known as psychic unity. The extreme position which maintains that "thinking merely goes on within us" governed by unalterable laws that direct every race through the same phases in its upward struggles has been abandoned by most anthropologists, but the controversy has stimulated research and indicated the true factors governing primitive cultural development. By the study of present-day savages we learn of those of prehistoric times. But again we are not forced to rely solely upon analogy. Let us see what positive evidence is available.

III. Prehistoric Archæology.—From the Glacial gravels of Europe, Asia, and Africa have been taken flaked stone implements of a rude and simple sort that mark the beginning of the industrial art in stone. Apparently without domestic animals, possessing a knowledge of the use of fire, our Pleistocene ancestors appeared in Europe at least as early as the Interglacial epoch and possibly before. Cultural remains are fairly abundant from which we may reconstruct the history of this far-off people, but of skeletal remains but few have been discovered. Many mistakes have been made in the identification of more modern skeletons as of Pleistocene provenance; however, at least two skulls and two other inferior maxillaries are referred to the Chellian or earliest paleolithic period; about a dozen in all may be assigned to the Quaternary epoch; and these are in but a fragmentary condition. Obviously the attempt to reconstruct the physical type of the earliest known inhabitants of Europe from such scanty material is extremely hazardous. Naturally enough the most minute and exhaustive study is made of these specimens, the observer usually bent upon discovering pithecoid or anthropoid characters.

The human remains that may be accepted without controversy are the skulls from Olmo, near Chiana in Tuscany, and from Egisheim in Alsace. The maxillaries are those from the cave of La Naulette, near Furfooz in Belgium, and the fragment from the Schipka cave in Moravia. The skulls are dolichocephalic but not at all ape-like. The jaws present certain low characters that are not uncommon among whites at the present day. One of the most widely known skulls is that of Neanderthal, Rhenish Prussia, which cannot be proven to be a genuine Quaternary relic, and even if it be such no great weight can be attached to its somewhat simian brows and low frontal because we find its modern counterpart in men of no inferior intelligence, as, for example, Robert Bruce. Possibly such individuals are to be accepted as examples of reversion, though here again we must remember that normal variation about a mean will produce a low frontal in the millionth skull. It is noteworthy that the oldest skulls of Europe present fairly uniform proportions of breadth to length, and are dolichocephalic. In America both long and round skulls are found in Quaternary strata, showing that at that distant day differentiation had proceeded far enough to establish two distinct types. At Santos, on the south coast of Brazil, was found a skull that resembles the Pithecanthropus erectus of Java. It is somewhat less dolichocephalic but has the same marked constriction behind the orbital region, a characteristic of the gibbon skull. Other South American skulls show this same trait, and from their study the conclusion has been reached that man is more closely related to the gibbon than to any other anthropoid. This conclusion is independently reached from the study of the skull or brain cap together with two molars and a femur from Trinil in northeastern Java. These remains indicate that the animal to which they belonged was dolichocephalic, had a cranial capacity of about 1,000 c.c. (average for Europeans 1,565 c.c.), was tall, and walked erect. This creature was named Pithecanthropus erectus by its discoverer, who believes that it represents a true transition form from the anthropoids to man and that continuity in the upward scale of development has been established at last. The skull differs from the ape's cranium in having a higher vault, in being devoid of strong crests and ridges, and in having an occiput arched like that of man though somewhat suggestive of that of Hylobates. Pithecanthropus is regarded as having descended from Anthropopithecus sivalensis of the Indian Miocene which with Hylobates stands nearest to man of all the anthropoids. Pithecanthropus comes from the Upper Pliocene or Lower Pleistocene, hence in sequence of time stands between anthropopithecus and man. The discussion concerning the significance of this fossil is not yet closed notwithstanding the fact that various authorities announce from time to time that it is; however, the preponderance of opinion is in favor of the acceptance of the original theory that pithecanthropus is a true transition form.

Both in the New World and in the Old the discussion yet continues concerning the length of the last Glacial and the Post-Glacial period. The estimates vary, according to the method or the prejudice of the investigator, from a few centuries to hundreds of thousands of years. Could we definitely establish the existence of Tertiary man the period of human occupation would be immensely increased. We may postulate a Tertiary "precursor," a "proanthropos," but exhibit one of his bones in the broad light of day we cannot. Human bones have been occasionally found buried in Tertiary strata, but they have been shown to be much later than the strata in which they had been interred. Artifacts purporting to be of the Tertiary epoch are announced from time to time, but there is always some flaw in the evidence: they are natural flint flakes that are erroneously supposed to be artificial, worked animal bones that are found to have been gnawed by wild beasts, whale bones that have been grooved by the teeth of sharks, cracked bones that are shown to have been naturally broken, and, finally, there is often doubt as to the exact age of the strata themselves. Again, fraud is suspected, as in the case of the Calaveras skull, and the evidence must be rejected. However, no valid objection to the existence of Pliocene or even Miocene man can be maintained. The hypothesis that man could not have retained his specific characters throughout such a long period of time without doing violence to the natural laws of zoologic development seems untenable when we see how slight has been the change in other animal species, for example the lion, that was the contemporary of the European cave-dwellers of early Quaternary times, as compared with the modern species.

Whether man lived in Europe before the Interglacial period is, then, an unsolved problem, but if true that he first appeared on that continent after the first Glacier, we know next to nothing of the length of time that he had lived in more tropical regions. The now sterile Sahara was once a well-watered region, as is shown by the terraced valleys worn by flowing streams and by the crocodiles that yet survive from the aquatic period in the Ahaggar Mountains. There, too, we find pictographs portraying animals that no longer live in the region. It is nearer the centre that archæologists now regard as the place of origin of the entire race. That there was but one place of origin is no longer disputed by any competent anthropologist, and this centre is located in either the northern or northeastern part of Africa or in the so-called Lemuria, the region now occupied by the Indian Ocean. The geologic evidence of the existence of this continental area is indisputable; that it was occupied by primitive man seems probable from the fact that the climatic conditions were most favorable for the welfare of a naked frugiverous animal; it is within the limits of this area that the most primitive fossil form has been found; it is on the borders of this area that the most ape-like human beings now live; and on the eastern and western limits of this zone that anthropoids yet flourish; it is on the northen borders of this area that the earliest civilizations have arisen. The dispersion from this centre must have taken place not later than the Old Stone Age, and the primary divisions of mankind were already specialized in their several geographic areas before the development of any distinctive culture. Paleolithic implements are regarded as very much the same in character in the Eastern and Western hemispheres, but all Neolithic and subsequent artifacts differ according to the locality whence they come.

Since the first peopling of the earth there seems to have been little migration in the New World, Australia, or to any significant extent in Central Africa. These countries have produced strongly marked varieties. The evidence is rapidly accumulating to show that the Caucasic division arose in Africa in the region of the Sahara and northward, and not in Asia. Two or three land bridges then spanned the Mediterranean, and there was land connection to the British Isles, so that no obstacle prevented the invasion of Europe or the migration to and fro of the tropic and temperate fauna of the two continents. The movements of the European and Asiatic races have been chiefly within limits of similar environmental conditions, so that the extensive migrations, as contrasted with the limited ones of the black and red races, have not apparently interfered with the specialization of racial types. Indeed, we are discovering that the principal types of Caucasians were already specialized in Africa before the migrations to Europe began.

We may summarize the facts so far as known concerning the time and place of man's origin and the characteristics of his early culture as follows: Before the period of proto-historic Egyptian, Mediterranean, and Eastern civilizations there was an epoch during which implements and weapons were made of stone and were smoothed and polished. At a yet earlier period chipped or flaked flints and other stones were used. The rudest types of these come from strata that are referred to the Interglacial period of Europe. In those strata human artifacts cease; there also occur the earliest traces of human skeletal remains. These remains are few and fragmentary, but they indicate that the race of that remote epoch differed but little in physical characters from that of today. The order of succession of these geologic and culture periods is known, their duration is not. The place of origin is provisionally located in the tropical region north of the Soudan in Africa or in the sunken Lemuria. Paleontology furnishes but one bit of evidence of any value, the remains from Java. No other skeletal remains have been found anywhere that can be regarded as belonging to any generalized precursor of the human race. In fact only a few fragments of fossil ape bones have been discovered. Embryology and ethnic and comparative anatomy combine to prove the theory of development from a generalized primate the remains of which may be found to-morrow or which may never be found. The Pliocene fossil-bearing beds of the lands bordering upon the Indian Ocean offer the most promising fields for research to-day. The problem is now one for paleontology and geology to settle, biology can do little more. *Frank Russell.*

EXALGINE.—Exalgine is the trade name of methylacetanilid. Its chemical formula is $C_6H_5NCH_3C_2H_3O$; it is formed by the addition of the methyl group, CH_3, to acetanilid, $C_6H_5NHC_2H_3O$, replacing one atom of hydrogen.

It occurs as beautiful needle-shaped crystals, colorless, and with a faintly aromatic odor and slightly pungent taste. It is almost insoluble in cold water, slightly soluble in hot, and very soluble in dilute alcohol. From sixteen to twenty grains may be dissolved in half a drachm of rectified spirit, and this solution may be diluted with two or three ounces of water without producing any precipitation. Its melting point is 100° C., and it may be heated to its boiling point, 240° or 250° C., without causing decomposition. By the addition of soda it is decomposed and partially converted into methylaniline. Hydrochloric acid causes the same decomposition. Exalgine may be distinguished from acetanilid, phenacetin, and methacetin by treating two grains of the suspected salt with twenty minims of hydrochloric acid. Phenacetin remains undissolved; acetanilid dissolves but separates again in crystals; methacetin also dissolves and gradually colors the solution reddish-brown on the addition of one drop of nitric acid. Another test for the presence of phenacetin or acetanilid is to treat a chloroform solution with ten volumes of petroleum ether; if either of these substances is present a turbid mixture is formed. The presence of methylaniline and other compounds of the same base may be detected by the irritating fumes produced when the impure salt is heated with alcoholic solution of potash and chloroform. Its purity may be further tested by dissolving in nitric acid, which forms a colorless solution; when heated this becomes of a bright yellow color, and evolves irritating fumes.

Methylacetanilid was discovered in 1874 by A. W. von Hofman. Its therapeutic properties were studied to a certain extent by Kahn and Hepp during their researches upon acetanilid and other antipyretics, but it was not until March, 1889, that Dujardin-Beaumetz and Bardet made known its value as an analgesic, in a communication to the French Academy. A very careful series of experiments, both physiological and clinical, enabled them to indicate its therapeutic qualities with a marked degree of accuracy. In common with the other members of the aromatic series it was found to possess antiseptic, antipyretic, and analgesic properties, and they also pointed out that its action on the nervous system should make it of value in the treatment of many functional diseases. It was as an analgesic that they particularly advocated its use; the addition of the methyl atom to acetanilid had intensified this action without affecting its antipyretic properties, but it was found that a dose large enough to produce antipyresis was accompanied by such alarming toxic symptoms that this use could not be considered. They advocated its employment in headache, migraine, neuralgia, neuroses of the viscera, the pains of locomotor ataxia, and in all non-febrile affections accompanied by pain. The dose they advised was from gr. iv. to gr. vi. (0.25 to 0.40 gm.) in a single dose, or from gr. vi. to gr. xiss. (0.40 to 0.75 gm.) in the twenty-four hours.

In Great Britain the notice of the profession was particularly directed to the value of this remedy by Professor Fraser, of Edinburgh,[1] who gave the results of his experience with it in the Royal Infirmary. The remarkable point in Professor Fraser's paper was the smallness of the dose and the success that followed its use in such quantities. The usual dose was half a grain in spirituous solution, repeated three or four times a day, according to the return of the pain. In some cases it was increased to one or even to two grains, and in a few instances four grains were given; the largest quantity given was fourteen grains during the twenty-four hours. In the cases of neuralgia and angina half-grain doses relieved the pain in ten or fifteen minutes, and in one hour there was perfect ease, which lasted for from three to nine or ten hours, and in many instances a complete cure was obtained. In sciatica and locomotor ataxia one and two grains secured the same freedom from suffering. In cancerous disease and in the pain accompanying an aneurism the success was less marked, and it was in these cases that the larger doses were given. Dr. Fraser considers that the smaller dose is the proper method of administering the drug, and that all its virtues may thus be as readily secured as with the larger doses.

Following Dr. Fraser's paper came a number of reports of successful results with half- and one-grain doses, by Drs. Herschell,[2] Farrar,[2] Holden,[3] Maloney,[4] and many others. Further experience has proved exalgine to be an analgesic and antispasmodic of much value, which, although not in very general use, is constantly employed. It is of service in all pains of a purely neurotic origin, and by many it is thought to be particularly valuable during the course of a febrile attack. It has proved of less value in painful conditions due to organic disease or mechanical causes. In England the small dose advocated by Fraser appears to predominate, but in other European countries and in America the larger dose of four grains is generally given.

Exalgine has been used with favorable results in infantile troubles. Dr. Moncorvo[5] publishes his experience of its use in twenty-one cases of children ranging from one to twelve years of age, in which it was given for the relief of pain. He considers it a very useful agent. It was well borne in every case, no unfavorable symptoms being ever noticed. The dose commenced with was three-fourths of a grain, increased in some cases to five grains. In one case choreic symptoms were present and were improved.

Its use in chorea has been reported upon by Dr. Hugo Löwenthal.[6] Thirty-five cases were treated with doses of three grains, given usually three times a day and never exceeding fifteen grains in the twenty-four hours. The effects were very satisfactory. The mild cases were cured quickly, but the more severe ones were less influenced and required more time. The beneficial effects of the treatment were most marked in the cases in which it was given early in the course of the disease, in two cases a cure being effected in eight days. A favorable influence over the mental state was also noticed; the fear and nervousness were lessened and the intelligence brightened. In some of the cases in which it was administered for a prolonged period, nausea, vertigo, headache, and other distressing symptoms were noticed.

Unfortunately the occurrence of toxic symptoms is not infrequent. No fatal termination has yet been reported, but the condition of the patient sometimes becomes very alarming both to the friends and to the physician. The toxic disturbances, however, occur long before the fatal dose is reached. Experiments on animals have shown that the lethal quantity is seven and a half grains for each two pounds of the weight of the animal, and three grains, it has been found, will give rise to severe symptoms. The poisoning arises from the action of the drug on the nervous centres as well as from the alteration that occurs in the condition of the blood. The changes in the blood are the same as those which are produced by all aniline compounds; that is, the hæmoglobin is altered into methæmoglobin and the function of oxidation is interfered with. The patient is made aware of the approach of the toxic action by a sense of fulness in the head, a constriction and oppression of the chest, dyspnœa, vertigo, dizziness, numbness, and disturbances of vision. This is followed by a rapid pulse, shallow respiration, and all the sensations of death with symptoms of asphyxia and collapse. Unconsciousness is common in the severe cases of poisoning; convulsions do not so frequently occur.

Generally, very large quantities are given before any ill effects are noticed. It is very rarely that any disturbance of the skin takes place, but cases have been reported in which an erythematous rash has appeared on the skin, and in some instances the buccal mucous membrane is also affected.[7] In one instance[8] the drug was continued for seventeen days, in gradually increasing doses, and during the last seven days eighteen grains were administered daily. In another case[9] thirty-six grains were given within nine hours, and in still another[10] twenty-four grains within two hours. The ill effects of the drug generally follow its prolonged use or the administration of large doses, but in some instances quite small doses have produced very alarming effects. An instance[11] is reported in which two doses of three grains each caused all the serious symptoms of poisoning, and another instance is known in which two doses of five grains each were given with the same effect. A remarkable case[12] is reported in which, in an adult, two doses of one and two grains, respectively, produced most profound prostration. The symptoms came on about an hour after the administration of the last dose, while the patient was sitting at a table engaged in a game of cards. He first complained of a fulness in the head and suddenly fell prostrate, unable to speak or move, and gasping for breath. A second attack took place in about an hour, and the oppression and dyspnœa continued for several hours. In another instance a dose of eight grains produced alarming symptoms.[13]

Very different from these cases are those in which very large quantities have been given without evil consequences. Dr. Churton[14] reports two such cases. In the refilling of a bottle of medicine a mistake was made by which a solution was prepared of one grain to a drachm, instead of one grain to the ounce. The medicine was given as usual, four grains instead of half a grain being contained in each dose. This was continued for several days, and during the last twenty-four hours before the mistake was detected the patient was given forty grains. The pulse and respiration were rapid, and the patient complained of a burning sensation in the stomach, but no other effects were noticed. The second patient was given twenty-four grains from the same preparation, but it failed to produce any other effect than slight vertigo and a sense of being "dazed," which caused her to walk unsteadily. The quality of the drug is vouched for, as it was given to a number of patients with satisfactory results, and small doses were again given to the first patient, and its analgesic action was secured.

The quality of the drug undoubtedly affects its action, and in many instances explains the varying results that follow its use; but certain conditions of the system must exercise a decided influence, probably by promoting the decomposition of the drug and the formation of more toxic compounds. Mr. Bokenham[8] dwells upon this point in his remarks upon two cases of poisoning and suggests that some condition of the blood preceding menstruation may assist this reaction. The activity of the action is also influenced by the time of its ingestion. Professor Fraser and others, who find benefit in the small doses, always recommend that it should be given on an empty stomach, while those who use the larger doses advise it to be given after meals, and others still have remarked that the toxic symptoms arise when it has been given before meals. In the majority of cases the toxic symptoms pass away without requiring any assistance, but when the depression and dyspnœa are severe, stimulating remedies must be used. Alcohol has been resorted to, in most of the cases of poisoning, with apparent benefit, and hypodermic injections of ether have also been employed. In the cases reported by Dr. Jones[8] marked relief was secured by the use of strychnine in addition to the stimulants. Two minims of the liquor strychninæ were given hypodermically and ten minims of tincture of digitalis by the mouth. In these cases the inhalation of nitrite of amyl and the administration of nitroglycerin by the mouth, in doses of gr. $\frac{1}{100}$, increased the cyanosis, showing that the arterial as well as the venous blood was altered.

Upon the lower animals the hypodermic injection of exalgine produces violent epileptiform convulsions, salivation, fall of temperature, dyspnœa. The blood becomes dark in color and contains an abundance of methæmoglobin.

The following conclusions have been arrived at by Marandon de Montyel[15] from clinical observations on patients in whom the use of the drug had been pushed to its physiological limits: It has no influence on digestion. If the stomach is empty it causes an increased flow of saliva, a bitter taste, and a sense of tightness about the epigastrium. The pulse, respiration, and temperature are lessened in patients without convulsive tendencies. Vertigo, flashes of light, and ringing in the ears are frequent. A local or general cyanotic surface, sensations of cold, numbness, and formication, are prominent symptoms. The action of the drug is prompt and the effects are recovered from promptly, the brain being the first organ affected and the first to recover. When it is administered after meals its physiological action is less marked.

Beaumont Small.

EXAMINER, MEDICAL.—The State of Massachusetts, in common with other States of the Union, employed the coroner's inquest as the official mode of inquiry in cases of deaths from sudden, violent, or suspicious causes, from the early history of the colony until 1877.

In consequence of corrupt practices which had become of frequent occurrence, and also in consequence of the inefficiency of the existing system, and of the inherent incongruity of an office requiring expert knowledge both of law and of medicine, a persistent movement was made by the Massachusetts Medical Society,[1] ably assisted by T. H. Tyndale, Esq., and other members of the legal profession, having as its prime object a radical change in the coroner system. This movement was heartily endorsed by the Massachusetts Legislature of 1877, and resulted in the enactment, by that body, of the following statutes, which constitute in the main the law now in force in Massachusetts:

ACTS OF 1877.—[Chap. 200.] *An Act to abolish the office of Coroner and to provide for Medical Examinations and Inquests in cases of Death by Violence.* Be it enacted, etc., as follows:

"SECTION 1. The offices of coroner and special coroner are hereby abolished.

"SEC. 2 The governor shall nominate, and by and with the advice and consent of the council shall appoint, in the county of Suffolk not exceeding two, and in each other county not exceeding the number to be designated by the county commissioners as hereinafter provided, able and discreet men, learned in the science of medicine, to be medical examiners; and every such nomination shall be made at least seven days prior to such appointment.

"SEC. 3. In the county of Suffolk each medical examiner shall receive, in full for all services performed by him, an annual salary of three thousand dollars,* to be paid quarterly from the treasury of said county; and in other counties they shall receive for a view without an autopsy, four dollars; for a view and autopsy, thirty dollars; and travel at the rate of five cents per mile to and from the place of the view.

"SEC. 4. Medical examiners shall hold their offices for the term of seven years from the time of appointment, but shall be liable to removal from office at any time by the governor and council for cause shown.

"SEC. 5. Each medical examiner, before entering upon the duties of his office shall be sworn, and give bond, with sureties in the sum of five thousand dollars, to the treasurer of the county, conditioned for the faithful performance of the duties of his office. If a medical examiner neglects or refuses to give bond as herein required, for the period of thirty days after his appointment, the same shall be void and another shall be made instead thereof.

"SEC. 6. The county commissioners in each county shall, as soon as may be after the passage of this act, divide their several counties into suitable districts for the appointment of one medical examiner in each district under this act; and when such division is made, shall at once certify their action to the secretary of the Commonwealth, who shall lay such certificate before the governor and council; but nothing herein shall prevent any medical examiner from acting as such in any part of his county.

"SEC. 7. Medical examiners shall make examinations as hereinafter provided, upon the view of the dead bodies of such persons only as are supposed to have come to their death by violence.

"SEC. 8. Whenever a medical examiner has notice that there has been found, or is lying within his county, the dead body of a person who is supposed to have come to his death by violence, he shall forthwith repair to the place where such body lies and take charge of the same; and if on view thereof and personal inquiry into the cause and manner of the death he deems a further examination necessary, he shall, upon being thereto authorized in writing by the district attorney, mayor, or selectmen of the district, city, or town where such body lies, in the presence of two or more discreet persons, whose attendance he may compel by subpœna, if necessary, make an autopsy, and then and there carefully reduce or cause to be reduced to writing every fact and circumstance tending to show the condition of the body, and the cause and manner of death, together with the names and addresses of said witnesses, which record he shall subscribe. Before making such autopsy he shall call the attention of said witnesses to the position and appearance of the body.

"SEC. 9. If upon such view, personal inquiry, or autopsy he shall be of opinion that the death was caused by violence, he shall at once notify the district attorney and a justice of the district, police or municipal court for the district or city in which the body lies, or a trial justice, and shall file a duly attested copy of the record of his autopsy in such court, or with such justice, and a like copy with such district attorney; and shall in all cases certify to the clerk or registrar having the custody of the records of births, marriages, and deaths, in the city or town in which the person deceased came to his death, the name and residence of the person deceased, if known, or a description of his person, as full as may be for identification, when the name and residence cannot be ascertained, together with the cause and manner in and by which the person deceased came to his death.

"SEC. 10. The court or trial justice shall thereupon hold an inquest, which may be private, in which case any or all persons other than those required to be present by the provisions of this chapter may be excluded from the place where the same is held; and said court or trial justice may also direct the witnesses to be kept separate, so that they cannot converse with each other until they have been examined. The district attorney, or some person designated by him, may attend the inquest and may examine all witnesses. An inquest shall be held in all cases of death by accident upon any railroad; and the district attorney or the attorney-general may direct an inquest to be held in the case of any other casualty from which the death of any person results, if in his opinion such inquest is necessary or expedient.

"SEC. 11. The justice or district attorney may issue subpœnas for witnesses, returnable before such court or trial justice. The persons served with such process shall be allowed the same fees, and their attendance may be enforced in the same manner, and they shall be subject to the same penalties, as if served with a subpœna in behalf of the Commonwealth in a criminal prosecution pending in said court, or before said trial justice.

"SEC. 12. The presiding justice or trial justice shall, after hearing the testimony, draw up and sign a report in which he shall find and certify when, where, and by what means the person deceased came to his death, his name if known, and all material circumstances attending his death; and if it appears that his death resulted wholly or in part from the unlawful act of any other person, he shall further state, if known to him, the name of such person and of any person whose unlawful act contributed to such death, which report he shall file with the records of the superior court in the county wherein the inquest is held.

"SEC. 13. If the justice finds that murder, manslaughter, or an assault has been committed, he may bind over, as in criminal prosecutions, such witnesses as he deems necessary, or as the district attorney may designate, to appear and testify at the court in which an indictment for such offence may be found or presented.

"SEC. 14. If a person charged by the report with the commission of any offence is not in custody, the justice shall forthwith issue process for his apprehension, and such process shall be made returnable before any court or magistrate having jurisdiction in the premises, who shall proceed therein in the manner required by law; but nothing herein shall prevent any justice from issuing such process before the finding of such report, if it be otherwise lawful to issue the same.

---

* This sum was changed to four thousand dollars by an act of 1890.

"Sec. 15. If the medical examiner reports that the death was not caused by violence, and the district attorney or the attorney-general shall be of a contrary opinion, either the district attorney or the attorney-general may direct an inquest to be held in accordance with the provisions of this act notwithstanding the report, at which inquest he, or some person designated by him, shall be present and examine all the witnesses.

"Sec. 16. The medical examiner may, if he deems it necessary, call a chemist to aid in the examination of the body, or of substances supposed to have caused or contributed to the death, and such chemist shall be entitled to such compensation for his services as the medical examiner certifies to be just and reasonable, the same being audited and allowed in the manner herein provided. The clerk or amanuensis, if any, employed to reduce to writing the results of the medical examination or autopsy shall be allowed for his services two dollars per day.

"Sec. 17. When a medical examiner views or makes an examination of the dead body of a stranger, he shall cause the body to be decently buried; and if he certifies that he has made careful inquiry, and that to the best of his knowledge and belief the person found dead is a stranger, having no settlement in any city or town of this Commonwealth, his fees, with the actual expense of burial, shall be paid from the treasury of the Commonwealth. In all other cases the expense of the burial shall be paid by the city or town, and all other expenses by the county, wherein the body is found.

"Sec. 18. When services are rendered in bringing to land the dead body of a person found in any of the harbors, rivers, or waters of the Commonwealth, the medical examiner may allow such compensation for said services as he deems reasonable, but this provision shall not entitle any person to compensation for services rendered in searching for such dead body.

"Sec. 19. In all cases arising under the provisions of this act, the medical examiner shall take charge of any money or other personal property of the deceased found upon or near the body, and deliver the same to the person or persons entitled to its custody or possession; but if not claimed by such person within sixty days, then to a public administrator, to be administered upon according to law.

"Sec. 20. Any medical examiner who shall fraudulently neglect or refuse to deliver such property to such person within three days after due demand upon him therefor shall be punished by imprisonment in the jail or house of correction not exceeding two years, or by a fine not exceeding five hundred dollars.

"Sec. 21. The medical examiner shall return an account of the expenses of each view or autopsy, including his fees, to the county commisioners having jurisdiction over the place where the examination or view is held, or in the county of Suffolk to the auditor of the city of Boston, and shall annex thereto the written authority under which the autopsy was made. Such commissioners or auditor shall audit such accounts and certify to the treasurer of the Commonwealth, or the treasury of the county, as the case may be, what items therein are deemed just and reasonable, which shall be paid by such treasurer to the person entitled to receive the same.

. . . .

"Sec. 25. For the purposes of the appointment and qualification of medical examiners and the action of the county commissioners herein provided for, this act shall take effect upon its passage, and shall take full effect on the first day of July next." [Approved May 9th, 1877.]

(Sections 22, 23, and 24, pertaining to the vicarious functions of the coroner, when acting as a sheriff, and also to certain verbal corrections in other statutes, are omitted.)

The principal features in the foregoing act, which constitute the chief difference between the medical examiner system of Massachusetts and the coroner system, are the following:

1. The separation of the medical from the legal duties involved in the investigation of the cause of death, the former being entrusted to medical officers ("able and discreet men, learned in the science of medicine") (Sections 2–9, 16–21, Acts of 1877, Chapter 200; and the latter to properly qualified legal magistrates, Sections 10–14).

2. The abolition of the coroner's office, and also of the jury (Sections 1 *et seq.*).

3. The limitation of the number of medical officers (Sections 2, 6).

This law is the result of a successful attempt to introduce into a New England commonwealth, imbued with a traditional adherence to old and firmly established customs, the plan of continental Europe modified and adapted to a republican form of government.

In Rhode Island a somewhat similar statute was enacted, providing for the appointment, by the governor, of medical examiners in twenty-four districts, for a term of six years.

The town councils also elect "suitable" persons as coroners for three years, and each coroner can appoint a deputy. The coroner may take ante-mortem statements. The expenses of the medical examiners are returnable to the State auditor and are paid by the State. The records of medical examiners are returnable to the State board of health and are published by the board.

In Connecticut the coroner and his jury still exist, but the coroner may appoint a medical examiner in each town. The medical examiner pays fifty cents to each person who first reports a death by violence. The medical examiner may hold an inquest in certain instances.

As may be seen by an examination of Section 8 of the present law of Massachusetts, the medical officer takes the initiative steps in the investigation of each case requiring the exercise of his duties. This method of procedure rests upon the assumption of a natural sequence in the investigation of all cases of death by violence. "The *inquest* is held by the court, and is the inquiry into the facts outside the body; the *examination* is made by the (medical) examiner, and it leads the way to the inquest."

"The purpose of the law is the detection of crime; its method, the division of functions among those properly qualified to perform them."[2]

Financially, the medical examiner system has also proved successful. Comparing the cost of coroner's inquests and views in Massachusetts for three years under the old law (1874, 1875, and 1876) with the cost of similar inquiries under the new law for a like period (1878, 1879, and 1880), as nearly as could be ascertained, the result was for the former period, $63,712.04; and for the latter, $54,509.31; leaving a difference of $9,202.73 in favor of the medical examiner system, notwithstanding an increase of population between the two periods of at least one hundred thousand, and a consequent increase in the amount of work done.[3]

The average expense of the medical examinations ranged from a maximum of $13.08 each in 1886 to a minimum of $11.68 each in 1890.

When considered as a per capita tax upon the population the expense of conducting the medical examiner system is shown to be far less than that of the coroner system.

The budget brought before the Board of Estimate of New York City in January, 1898, contained an item of $239,050 for coroners in the five boroughs, in an estimated population of about three and one-half millions or seven cents per capita of the population for the cost of the coroner system. In the same year in Massachusetts, under the Medical Examiner System, the cost was less than $40,000 in a population of about two and two-third millions, or less than one and one-half cents per capita, for conducting all examinations extending over more than 8,000 square miles of territory. The court expenses were included in this sum.[5]

The chief causes of this diminution in expense are the abolition of the coroner's jury, and the decrease in the number of inquests. In the three years specified under the old law, there were held, in three counties in Massachusetts, one hundred and twenty-four inquests. In three years, under the new law, with a larger population the number of inquests held in the same counties was but seventy-five.

Under the old law the ratio of inquests to cases of all sorts examined throughout the whole State was about forty per cent. Under the medical examiner law the ratio has not been more than twenty-two per cent. "The reasons for this change may be found in the appointment, to fill the offices formerly held by coroners, of men whose education necessarily fits them for the work which they are expected to perform. Under the old law a man found dead, even without the least suspicion of violence, as in simple cases of heart disease or apoplexy, would in all probability be reported to the village coroner, provided the most common hypostatic marks of post-mortem discoloration were observed by a bystander, and interpreted by him as significant of a violent death. Hence the coroner sets in motion the cumbrous machinery of his office. In the first place he sends for a constable. The constable summons a jury. The witnesses come next; and last of all, the nearest physician is summoned, whose evidence finally shows that the man died a natural death. Under the working of the present law the order of procedure is reversed. The medical officer first views the body, and in a case like that just cited he simply reports it as a view. If, however, he believes there is reasonable suspicion of violence, as revealed by the evidence shown him from an external examination of the body, and a personal inquiry of the witnesses, and also by an autopsy, if that be requisite, the case is then reported to the proper authorities for inquest."[3]

After the medical examiner law had been in operation for a period of seven years and a half, the Legislature of 1885 carefully considered certain measures which were proposed for the further improvement of the existing law. These were: the reporting of cases to some central authority who should be entrusted with the compilation, classification, and publication of the returns of the medical examiners; the proper remuneration of medical witnesses at autopsies; and a provision for more definite authority for making autopsies on the bodies of persons found dead.

The first of these duties had been performed very efficiently for seven years by the Massachusetts Medico-Legal Society, an association having as its object "to elevate the official character of the medical examiner, and to assist him in the discharge of his duties; to collect and utilize such facts as have a medico-legal value; and to excite a general interest in the subject of forensic medicine, and to promote its successful cultivation."[4]

The transactions of this society form a valuable contribution to the literature of forensic medicine. It was desirable, however, that the State should have the supervision of the reports of its medical officers, since it could by statutory enactment require a complete report from each examiner, a measure which was clearly impossible in a voluntary association. The following is the substance of the amendments enacted in 1885:

[Chap. 379.] *An Act relating to Medical Examiners.*—Be it enacted, etc., as follows:

"SEC. 1. Section nine of chapter twenty-six of the Public Statutes is amended to read as follows: *Section* 9. In the county of Suffolk each medical examiner shall receive from the treasurer of the county, in full for all services performed by him, a salary of three thousand dollars a year, and the associate medical examiner a salary of five hundred dollars; but if the said associate medical examiner serves in any year more than two months, at the request of either medical examiner he shall, for such service in excess of two months, be paid at the same rate as such medical examiner, and such compensation shall be deducted from the salary of the medical examiner in whose stead he serves. The medical examiners in other counties shall receive fees as follows: For a view without an autopsy, five dollars; for a view and autopsy, thirty dollars; and for travel, at the rate of ten cents a mile to and from the place of view.

"SEC. 2. When a medical examiner deems it necessary to have a physician present at an autopsy as one of the witnesses, as provided in section eleven of chapter twenty-six of the Public Statutes, such physician shall be allowed five dollars for his services. Other witnesses required by law to be present at an autopsy shall be allowed two dollars each.

"SEC. 3. Medical examiners are to transmit copies of the records of all deaths investigated by them to the Secretary of the Commonwealth, annually, before March 1st

"SEC. 4. Fees for returning such copies, twenty cents each for first twenty entries and ten cents for each subsequent entry. Penalty for refusal or neglect ten to fifty dollars.

"SEC. 5. Secretary to provide blank book for records.

"SEC. 6. Secretary to collect returns and tabulate them and report to general court.

"SEC. 7. Medical examiners to report all autopsies to the district attorneys, and affirm their necessity."

The present number of medical examiners is seventy-three, being about one to each 38,000 of the population. Boston has two, with an associate who acts in the absence of either of the others. Each one of the larger cities has also one medical examiner, who also acts in the neighboring towns. The remainder are distributed with a fair degree of uniformity throughout the State.

By an act of 1898 provision was made for the appointment of one associate examiner in each district.

The following statistics relative to the operation of this law are quoted from the registration reports of Massachusetts, for the years 1885 to 1899 inclusive:

TOTAL DEATHS, AND DEATHS BY SEXES, INVESTIGATED UNDER THE MEDICAL EXAMINER LAWS IN MASSACHUSETTS, 1885–1899, TOGETHER WITH THE NUMBER OF AUTOPSIES MADE.

Years.	Males.	Per cent.	Females.	Per cent.	Unspecified.	Per cent.	Totals.	Autopsies.

[5] The Time and the Hour, Feb. 5, 1898.

EXAMINING AND LICENSING BOARDS.—There is no national authority in the United States that can prescribe standards for degrees or for license to practise the professions. Each State makes its own professional laws. As a result there are almost as many standards as there are political divisions. The desirability of uniform standards throughout the country for admission to professional practice is recognized generally, but varying conditions as to density of population, educational advantages, and general development make it impracticable to hope for the attainment of this end for some time to come. Conditions are such that some States cannot maintain the standards demanded elsewhere, others cannot afford to lower theirs, but needless multiplication is unfortunate. Instead of a separate standard for almost each political division, two or at most three should answer for all. In the first group should come the strongest States, and the standards maintained by these States would act as a stimulus to weaker political divisions.

Thirty years ago the public had little protection from incompetency in professional practice. The bar is said to have been at its lowest ebb. Medical laws were crude and largely inoperative. In several States only were there any acts designed to control the practice of pharmacy and dentistry. There was no law whatever restricting the practice of veterinary medicine. There has been extraordinary progress, specially in the last decade, in restrictive professional legislation, and in the admission and graduation requirements of professional schools throughout the United States. In medicine all political divisions except Alaska now have examining and licensing boards. In view of these facts the growth in professional students is remarkable. From 1888 to 1899 the increase was as follows: theology 24 per cent., law 224 per cent., medicine 84 per cent., dentistry 380 per cent., pharmacy 31 per cent., veterinary medicine 17 per cent.

Power to Confer Degrees.—Low standards in many professional schools are due to a failure to subject the degree-conferring power to strict state supervision. In New York and Pennsylvania the laws now prevent an abuse of the power to confer degrees. In Massachusetts and Vermont bodies formed under the general corporation acts are prohibited from conferring degrees. In Ohio and Nebraska the statutes require only the nominal endowment of $5,000 for a degree-conferring institution. In other States and Territories as a rule any body of men may form an educational corporation with power to confer degrees "without any guaranty whatever that the privilege will not be abused."

This matter has been under discussion recently in various educational bodies, and there is a strong sentiment in favor of a strict supervision by the State of the degree-conferring power.

Preliminary General Education for Degrees.—In New York, high standards in preliminary general education are demanded both for degrees and for licenses, and in each case the question of attainments is determined by a central authority, the University of the State of New York. As a rule in other States medical schools conduct their own entrance examinations, and the tests are often mere matters of form, even though the standards may appear satisfactory on paper. In 1898 21 per cent. of the students of medicine in the United States held either B.A. or B.S. degrees as compared with 53 per cent. of those in theology and 29 per cent. of those in law.

Preliminary General Education for Licenses.—In New York State a preliminary general education equivalent to graduation from a four years' high-school course after a completed eight years' elementary course is prescribed by statute as the minimum standard for license to practise medicine. This standard approximates that required in continental Europe. New Hampshire and Ohio have similar requirements, but they are not so rigidly enforced. California makes the requirements "in no particular less than those prescribed by the Association of American Medical Colleges." Wisconsin requires the elementary education necessary for admission to the junior year including one year of Latin. The statutes of Delaware, Maryland, New Jersey, and Pennsylvania prescribe a "common-school education." Louisiana demands a "fair primary education," Maine a standard of preliminary education approved by the medical board. The rules in Vermont prescribe a high-school course; in Maine a good English education; in Illinois and Iowa less than one year of high-school work; in Virginia "evidence of a preliminary education." In remaining political divisions laws and rules are either silent in this respect or so indefinite as to be of little value.

Length of Professional Courses.—The following table shows great progress, specially since 1885, in the adoption of higher standards for graduation.

	Four years.	Three years.	Two years.	One year.	Not stated.

* Distinction between medical schools with two- and three-year courses not certain. † Including three medical preparatory schools.

Influence of Medical Societies.—In 1839 the New York State Medical Society resolved that teaching and licensing ought to be separated as far as possible. In 1837 the same view had been advocated in Philadelphia. Further discussion led to a call for a convention of delegates from all medical schools and societies in the United States. The convention was held in New York in 1846, and from it sprang the American Medical Association.

Results of examinations show the importance of separating teaching and licensing. Under the New York laws, for example, 6,349 physicians have been examined, of whom 1,379 or 21.7 per cent., were rejected. In these statistics each candidate who fails is counted as often as examined, but nevertheless so large a per cent. of rejections is astonishing in view of the fact that admission to licensing examinations presupposes the preliminary education required by statute and also graduation with a degree from a registered medical school. Including those unable to meet the requirements for admission to licensing examinations, more than 30 per cent. of all applicants have failed to secure licenses.

The following societies have exercised an important influence in promoting higher standards: Association of American Medical Colleges (1890), American Institute of Homœopathy (1844), National Confederation of Eclectic Medical Colleges (1871), Southern Medical College Association (1892). The first and fourth of these societies prescribe for admission to medical schools a preliminary general education equivalent to one year in a high school; the second and third demand work equivalent to about two years in a high school. All prescribe four courses of lectures in different years as a condition for an M.D. degree, though they give an allowance of one year to graduates of reputable literary colleges and of other professional schools. All tend to improve facilities for teaching, dissection, and clinics. These societies registered in 1900 72, 71, 6, and 11 medical schools respectively.

The American Academy of Medicine (1876) and the National Confederation of State Medical Examining and Licensing Boards (1891) should also be mentioned. The former of these societies has emphasized since 1884 the importance of a proper preliminary education, a graded professional course, and a state licensing examination; the latter has recommended a four years' high-school course for admission to medical schools or an alternative examination representing somewhat less than three years of high-school work.

Medical Sects.—As commonly understood, regular physicians have no distinctive theory or practice; homœopaths treat diseases with drugs that excite in healthy persons symptoms similar to the morbid condition treated; eclectics make use of what they regard as specific remedies, chiefly botanical; physiomedicalists use only botanical remedies, discarding those which are poisonous. In practice these distinctions are not always observed.

In addition to the medical sects to which detailed reference is made, a number of *pathies* flourish in many States unmolested under such names as osteopath, vitapath, electropath, hydropath, divine healer, magnetic healer, Christian scientist, faith curist, mind curist, sun curist, etc. Men and women without preliminary or professional training treat diseases under these or similar systems to such an extent that the health of the people is endangered. These so-called systems are followed with impunity in many States in what seems to be open violation of laws restricting the practice of medicine. This is due largely to the fact that so many statutes lack specific definitions as to what constitutes the practice of medicine, and without these definitions the conviction of such practitioners cannot be secured through the courts.

Osteopathy was "discovered" in 1874. It is based on the theory that "a natural flow of blood is health" and that the bones may be "used as levers to relieve pressure on nerves, veins, and arteries." Oseteopathy is now recognized by law in California, Connecticut, Indiana, Kansas, Ohio, Iowa,* Michigan, Missouri, Montana, Nebraska, North and South Dakota, Tennessee, Vermont, and Wisconsin. Practice of "the system, method, or science of osteopathy" is restricted to licensed physicians and to graduates of "a legally chartered and regularly conducted school of osteopathy." The use of drugs and operations in "major or operative surgery" are not permitted in the practice of osteopathy.

In Georgia, Kentucky, Nebraska, New Jersey, New Mexico, Montana, and West Virginia there are stringent laws against non-medical practitioners. In some other States, like Illinois, they receive such legal protection that any person may treat "the sick or suffering by mental or spiritual means, without the use of any drug or material remedy." Under these conditions any person in Connecticut, Maine, Massachusetts, and New Hampshire is free to practise "the sun cure, mind cure, hypnotism, magnetic healing, Christian science, etc." The greater part of New England seems to be on about the same footing in this respect with the Cherokee nation, Indian Territory, where entire liberty is given to "enchantments in any form." In striking contrast Hawaii inflicts heavy fines on any person convicted of an attempt to cure "another by practice of sorcery, witchcraft, anaana, hoopiopio, hoounauna, hoomanamana, etc."

There is much misunderstanding in this country regarding the duty of the state in relation to the health of the people. It does not consist in discriminating between schools or systems of medicine, but in requiring without prejudice or partiality of all who seek a license to practise for gain on the lives of fellow-beings a minimum preliminary and professional training.

Midwifery.—Special tests for certificates of registration as midwives are required in Arizona, Connecticut, District of Columbia, Illinois, Indiana,* Iowa, Louisiana, Missouri, New Jersey, Ohio, Texas, Utah, Wyoming.

In the following political divisions the provisions of the medical practice acts do not apply to women engaged in the practice of midwifery: Alabama, Arkansas, Florida, Georgia, Idaho, Kentucky, Maine, Maryland, Mississippi, Montana, New Mexico, North Carolina, Rhode Island, South Carolina, Tennessee, Vermont,† Virginia, Washington, West Virginia.

In other political divisions, though there are some special provisions for certain localities, the general acts regulating the practice of medicine make no reference whatever to the practice of midwifery by women.‡ It would seem, therefore, that these laws restrict the practice of midwifery to licensed physicians. Nevertheless a large proportion of the children in these political divisions are brought into the world by ignorant midwives, and as stated by Dr. M. J. Lewi, of New York, many women are physical wrecks through their incompetence. Practically the conditions in political divisions where the laws seem to restrict the practice of midwifery to licensed physicians are little better than in political divisions where the practice of midwifery by women without a license is authorized by statute. There will probably be little change for the better till the midwife receives legal recognition and the practice of midwifery is regulated by definite statutory provisions.

Early Legislation.—The earliest law relating exclusively to physicians was passed by Virginia in 1639, but like the later act of 1736 it was designed mainly to regulate their fees. The act of 1736 made concessions to physicians who held university degrees. In only two of the thirteen colonies were well-considered laws enacted to define the qualifications of physicians. The General Assembly of New York in 1760 decreed that no person should practise as physician or surgeon in the city of New York till examined in physic and surgery and admitted by one of his majesty's council, the judges of the supreme court, the king's attorney-general and the mayor of the city of New York. Such candidates as were approved received certificates conferring the right to practise throughout the whole province, and a penalty of £5 was prescribed for all violations of this law. A similar act was passed by the General Assembly of New Jersey in 1772.

In 1840 laws had been enacted by the legislatures of nearly all the States to protect citizens from the imposition of quacks. Between 1840 and 1850, however, most of these laws were either repealed or not enforced as a result of the cry that restrictions against unlicensed practitioners were designed only to create a monopoly.

---

* Either examination or approval of diploma.

† Those practising midwifery without a certificate cannot enforce collection of fee, but this does not apply to the practice of midwifery by women in the town or locality in which they reside.

‡ In Nebraska, North and South Dakota the practice of "medicine, surgery, or obstetrics" without a license is prohibited.

Synopsis of Requirements to 1902.—In the following political divisions medical diplomas do not now confer the right to practise medicine, an examination being required in all cases: Alabama, Arizona, California, Connecticut, Delaware, District of Columbia, Florida, Georgia, Hawaii, Idaho, Illinois, Indiana (after January 1st, 1905), Indian Territory, Cherokee and Choctaw nations, Iowa, Louisiana, Maine, Maryland, Massachusetts, Minnesota, Mississippi, Missouri, Montana, New Hampshire, New Jersey, New York, North Carolina, North Dakota, Ohio, Oregon, Pennsylvania, Tennessee, Texas, Utah, Vermont, Virginia, Washington, West Virginia, Wisconsin.

The following require for admission to the licensing examination:

Alabama, requirements of State Medical Association.

Arizona, diploma from recognized medical school.

California, diploma from legally chartered medical school, requiring in no particular less than the Association of American Medical Colleges.

Connecticut, diploma from reputable medical school.

Delaware, competent common-school education, diploma from legally incorporated medical school.

District of Columbia, diploma of school authorized by law to confer M.D. degree.

Florida, diploma from recognized medical school.

Georgia, diploma from legally organized medical school.

Idaho, diploma from legally chartered medical school.

Illinois, less than one year of high-school work, diploma from approved medical school.

Indiana, diploma from reputable medical school.

Indian Territory, Cherokee nation, diploma from reputable medical school; Choctaw, one term's attendance at reputable medical school.

Iowa, less than one year of high-school work, diploma from recognized medical school.

Louisiana, fair primary education, diploma of recognized medical school.

Maine, diploma of reputable medical school maintaining an approved standard of preliminary education and medical instruction.

Maryland, common-school education, diploma from legally incorporated medical school.

Minnesota, four full courses of lectures at recognized medical school.

Montana, diploma from legally chartered medical school.

New Hampshire, full high-school course, diploma from regularly organized medical school.

New Jersey, common-school education, diploma from legally incorporated medical school.

New York, four years' high-school course or its equivalent, diploma from registered medical school.

North Carolina, diploma from medical school in good standing.

North Dakota, three six months' lecture courses.

Ohio, full high-school course or its equivalent, diploma from legally chartered medical institution.

Pennsylvania, common-school education, diploma from legally chartered medical school.

Utah, diploma from chartered medical school in good standing.

Vermont, high-school course or equivalent and diploma from a United States medical school.

Virginia, evidence of a preliminary education, diploma from medical school.

Washington, diploma from authorized medical school having at least a three years' graded course.

Wisconsin, elementary education equivalent to admission to junior year of a credited high-school.

The following require the licensing examination only: Hawaii, Massachusetts, Mississippi, Oregon, Tennessee, Texas, West Virginia.

The following require approval of medical diploma by duly qualified boards: Kentucky, Nebraska, South Dakota; diploma must evidence four full courses.

The following require either approval of medical diploma or examination by State or other duly qualified boards: Arkansas, Colorado, Indian Territory (Creek nation), Kansas, Michigan, Nevada, New Mexico, Oklahoma, Rhode Island, South Carolina, Wyoming.

The following requiring either approval of medical diploma or examination, admit to examination on: Arkansas, a good literary education; Kansas, four periods of study of six months each; Nevada, five years' practice in the State just prior to act or diploma from a reputable school without the United States; Oklahoma, full course of lectures. Rhode Island approves diplomas of schools that require for matriculation a high-school diploma or its equivalent, and for graduation four regular courses in four different years; Alaska has no law. In Cuba, the Philippines,[*] and Porto Rico[†] the requirements are in process of transition.

The following political divisions have mixed examining boards, that is, the boards are composed of representatives of the several schools of medicine: Alabama, Arizona, Arkansas, California, Colorado, Hawaii, Idaho, Illinois, Indian Territory, Indiana, Iowa, Kansas, Kentucky, Maine, Massachusetts, Michigan, Minnesota, Mississippi, Missouri, Montana, Nebraska, Nevada, New Jersey, New Mexico, North Carolina, North Dakota, Ohio, Oklahoma, Oregon, Rhode Island, South Carolina, South Dakota, Tennessee, Utah, Virginia, Washington, West Virginia, Wisconsin, Wyoming.

The following have separate examining boards for each recognized school of medicine: Connecticut, Delaware, District of Columbia, Florida, Georgia, Louisiana, Maryland, New Hampshire, New York, Pennsylvania, Texas, Vermont.

Alaska has no examining board.

James Russell Parsons, jr.

EXCELSIOR SPRING.—Onondaga County, New York.

Post-Office.—Syracuse. This spring is located in the city of Syracuse. It was analyzed by Charles A. Goessman in 1868, with the following result:

One United States Gallon Contains:

Solids.	Grains.
Calcium carbonate	15.24
Calcium sulphate	36.45
Sodium chloride	584.53
Alumina Silica	1.02
Sodium sulphate	13.16
Magnesium chloride	17.69
Magnesium bromide	.15
Total	668.24

Carbonic acid gas present.

This analysis indicates a very potent saline water, with diuretic and slightly aperient properties.

James K. Crook.

EXOPHTHALMIC GOITRE. See the Appendix.

EXPECTORANTS are medicines that are used in catarrhal affections of the larynx, trachea, and bronchi, to modify secretion and facilitate the removal of morbid products.

Until recently our knowledge of their use was founded entirely on careful clinical observations. It had been observed that certain remedies ameliorate cough and increase expectoration in the early stage of acute inflammations of the air passages. Most of them, when given in large doses, produce nausea and vomiting, and a notable depression of the general circulation. They were therefore called *depressant, sedative,* or *nauseant* expectorants. Other remedies had been found to ameliorate cough and diminish expectoration in the latter stage of acute catarrhs, and in chronic catarrhs attended by copious secretion. In large doses many of them cause local irritation, with more or less excitement of the general circulation. Hence they were called *stimulant* expectorants. The recent experiments of Rossbach have confirmed the theory, founded on clinical observation, that some expectorants increase and others diminish secretion. They have rendered our knowledge more precise, and, besides, have established the important fact that some expectorants cause a diminution of the vascularity of the respiratory mucous membrane.

---

[*] The assistant secretary to the military governor in the Philippines wrote September 4th, 1899, that "the Spanish law as to admission to practice still governs. In general this requires a diploma from a reputable college, school, or university of such profession or in lieu thereof an examination."

[†] General Davis established, September 30th, 1899, in Porto Rico an examining committee for licenses to practise medicine, midwifery, and professional nursing. Only those with satisfactory credentials are admitted to the examinations.

DEPRESSANT OR SEDATIVE EXPECTORANTS.—*Apomorphinæ Hydrochloras.*—Soon after apomorphine came into vogue, clinicians observed that it exerts a very decided influence in catarrhal inflammations of the air passages. In a short time after its administration is begun expectoration is effected more easily, and the sputa become more copious and less viscid. Usually these effects occur without any noteworthy nausea, or this is observed only after the first dose.

According to the experiments of Rossbach, the expectorant action of apormorphine is due to augmented activity of the mucous follicles; for it caused a very decided increase of the quantity of mucus of the exposed tracheal mucous membrane, when the nerves passing to the trachea had been divided, and all the large blood-vessels supplying this organ had been ligated.

In expectorant doses, apomorphine does not diminish the appetite, nor cause diarrhœa.

Apomorphine is indicated in catarrhal affections of the larynx, trachea, and bronchi, when only small quantities of viscid mucus are secreted; hence, especially in the early stage of bronchitis, when dry, sibilant râles are heard, and when coughing occurs frequently, and is attended by little or no expectoration.

Trustworthy observers state that they have obtained more speedy and more decided success from apomorphine than from all other means in bronchitis, tracheitis, laryngitis, phthisis, and the stage of resolution of pneumonia. Rossbach employed it in pseudo-membranous croup with excellent results, the membranous exudation becoming detached and expelled.

Apomorphine is contraindicated in the above-named affections when moist râles are heard and expectoration is copious. It should never be given when the bronchial tubes are overloaded with secretions which are not expectorated from want of strength.

When a cough is frequent and very severe, and little mucus is secreted, as shown by the scanty, viscid sputum, morphine may be combined with the apomorphine, if the latter do not speedily ameliorate the cough. Morphine does not prevent the action of apomorphine. The combination simultaneously increases secretion and lowers the excitability of the respiratory centre.

No fixed rules can be given as to the dose of apomorphine, on account of the differences in susceptibility to its action, and the great variations in extent and intensity of the catarrhal inflammations of the air passages. For adults, from gr. ss. to gr. i. in twenty-four hours is usually sufficient; but sometimes from gr. iss. to gr. ij. are required. Doses of gr. $\frac{1}{16}$ to gr. $\frac{1}{6}$ may be given every two or three hours. To children apomorphine may be given in doses of gr. $\frac{1}{60}$ to gr. $\frac{1}{10}$, according to their age. At the age of one year the single dose may be gr. $\frac{1}{60}$, and this may be increased by the gr. $\frac{1}{120}$ for each additional year, so that at the age of two years the dose will be gr. $\frac{1}{40}$, at three years gr. $\frac{1}{30}$, and so on. It may be prescribed as follows: ℞ Apomorph. hydrochlor., gr. ss.–i.; acid. hydrochlor. dil., gtt. x.; aq. destill., ℥ iss. M. Sig.: One teaspoonful every two or three hours. The acid is added to prevent the change of color, which rapidly takes place if no acid is added, and the medicine is not dispensed in a dark bottle. A syrup may be added, or, if desirable, each dose may be taken in sweetened water. Morphine may be added to the apomorphine, as in the following formula: ℞ Apomorph. hydrochlor., gr. ss.–i.; morph. hydrochlor., gr. ss.; acid. hydrochlor. dil., gtt. x.; aq. destill., ℥ iss. M. Sig.: One teaspoonful every two or three hours.

Ipecacuanha.—This medicine is frequently employed in catarrhal affections of the air passages, especially in the early stages, when cough is severe and expectoration scanty. It acts most rapidly when given in such doses as produce nausea. As the activity of the mucous glands becomes increased during nausea, it has generally been held that ipecacuanha acts by increasing secretion, but that this takes place only when nauseating doses are used. But it is frequently observed that the symptoms of broncho-tracheal catarrh become ameliorated by doses which do not produce notable sickness.

The action of ipecacuanha is due to the alkaloid emetine, which it contains in small and variable quantities.

Rossbach found that emetine causes a decided increase of the mucus of the trachea, without augmenting the quantity of blood in the mucous membrane. The increase of secretion also took place when the nerves going to the trachea had been divided, showing that it results from a direct action on the mucous glands or on the secretory nerves.

Ipecacuanha is indicated in acute and chronic catarrhs of the air passages attended with scanty and viscid expectoration. It is the expectorant generally employed in the bronchial inflammations of very young, very old, and feeble patients, and is especially applicable when these affections present more or less fever, a dry skin, soreness of the chest, oppressed breathing, painful cough, viscid sputum, and dry râles.

The dose of ipecacuanha varies from gr. ss. to gr. ij., on account of the variable quantity of emetine that it contains, and the differences in intensity and extent of the catarrhal inflammations. If small doses do not speedily cause a decided change in the expectoration, larger ones should be given, so as to induce slight nausea. The syrup and wine of ipecacuanha are given in doses of ♏ x. to ♏ xl.

Antimonii et Potassii Tartras.—Tartar emetic is a very depressing expectorant. When administered in small doses, gr. $\frac{1}{16}$ to gr. $\frac{1}{6}$, at intervals of several hours, it usually produces no immediate effects; but after several doses have been taken a decided action on the heart and secretions becomes manifest, the heart's action becoming slower and feebler, and the secretions of the mucous membranes and skin decidedly augmented. After several days, if the medicine is continued, very marked debility ensues.

Tartar emetic is held to be serviceable in severe forms of bronchitis occurring in robust individuals. It is especially indicated when there are present dyspnœa, flushed face, full and strong pulse, soreness of the chest, with little or no secretion, as shown by the dry, sibilant râles heard on auscultation. On account of its depressing action, which is most evident in weakly persons, it is not a suitable remedy for debilitated, very young, or very old patients. It is contraindicated in catarrhs of the air passages complicated with severe disorders of the alimentary canal.

Tartar emetic is usually administered in doses of gr. $\frac{1}{12}$ every two or three hours. ℞ Antim. et potass. tart., gr. i.; syr. althææ, ℥ ss.; aq. destill., ℥ i. M. Sig.: One teaspoonful every two hours. Sometimes minute doses are given at very short intervals, as by dissolving one grain in five or six ounces of water, and directing a teaspoonful of the solution to be taken every ten minutes until nausea ensues. As soon as this takes place, a marked increase of secretion and expectoration occurs, with decided relief of the soreness of the chest and dyspnœa. The wine of antimony, containing 1 part in 250 parts, is given in doses of ♏ x. to ♏ xl. It is one of the ingredients of the *compound mixture of glycyrrhiza,* which is given in doses of a tablespoonful.

Lobelia is used as an expectorant when bronchial catarrh is complicated with spasmodic contraction of the bronchial tubes, or when a severe cough is attended with difficult breathing, abundant sibilant râles, and viscid sputum. From its utility in such cases it has been inferred that it increases secretion, and at the same time relaxes the bronchial muscles. In spasmodic asthma it is frequently employed with much benefit. But it usually fails to produce any marked effect, unless given so as to cause nausea. The dose varies from gr. i. to gr. v., as an expectorant. Of the tincture (1 in 5) the dose is ♏ v. to ♏ xxv., and of the vinegar (1 in 10) double these quantities.

Pilocarpine.—This alkaloid was found, in the experiments of Rossbach, to cause a very profuse secretion of watery, transparent mucus from the trachea and bronchia, so that moist râles could be heard over all parts of the thorax. Trials of the remedy in cases of bronchitis were attempted, but the action on the salivary and sweat glands, and on the heart, was so disagreeable to the patients that they refused to persevere in its use. The ordinary therapeutic use of this medicine has occasionally been followed by pulmonary œdema.

Alkalies.—It has been frequently observed that bronchial catarrhs improve during the internal use of alkalies. Usually, expectoration takes place more readily, and the sputum is less adhesive. Hence it has been inferred that alkalies increase the bronchial secretion and render it more fluid.

The results of Rossbach's experiments are at variance with this view. After exposing the tracheal mucous membrane of cats, he injected into a vein 2 gm. of carbonate of sodium. The mucous membrane rapidly became pale, presenting a peculiar grayish-white color, and the secretion of mucus gradually diminished, and soon ceased completely. As this result was unexpected, the experiment was often repeated, but the same phenomena uniformly took place. Rossbach was unable to determine the cause of the arrest of secretion. That it was not due to the anæmia was evident from the fact that even more decided anæmia, produced by irritating the nerves distributed to the trachea, did not diminish the secretion of mucus. The local application of solutions of carbonate of sodium, containing from one to two per cent., caused no obvious change in the appearance of the mucous membrane.

The experiments of Rossbach confirm the clinical observation that increased alkalinity of the blood modifies the secretion of mucus, although they contradict the theory that it becomes increased. Perhaps it will be found hereafter, as suggested by Brunton, that the modification of secretion depends upon the quantity of alkali administered, small doses increasing and large ones diminishing the secretion.

If further observation should show that the action of alkalies is the same in man as in Rossbach's experiments, it would follow that alkalies might be used in all stages of bronchial inflammation, and that they would be serviceable not merely to modify secretion, but to diminish the hyperæmia, the chief morbid phenomenon of the disease.

STIMULANT EXPECTORANTS.—*Ammonii Chloridum.*—No medicine is more frequently employed in bronchial catarrhs than this salt. It is held to be suitable when no fever is present, and expectoration is difficult on account of viscidity of the secretion, and to be useless when the sputum is abundant and easily coughed up.

In observations on himself, Wibmer found a very decided increase of the bronchial mucus after doses of gr. viij. to gr. xv., taken hourly. Other careful observers also noticed an augmentation of the bronchial secretion from its use. The experiments of Rossbach seem to show a different mode of action. Under the influence of the salt the tracheal mucous membrane became anæmic, and the secretion of mucus gradually ceased. The utility of chloride of ammonium in catarrhs of the air passages may therefore depend upon a favorable modification of the vascularity of the mucous membrane, not merely upon a change of the quantity of the secretion.

Chloride of ammonium is indicated in bronchitis after the fever has subsided. When secretion is very viscid, it is frequently combined with ipecacuanha, or with minute doses of tartar emetic. To adults it is given in doses of gr. v. to gr. x. every two or three hours. ℞ Ammon. chlor., ℈ij. to ℈iv.; ex. glycyrrh., ʒ ss. to ʒ i.; aq. destill., ℥ iv. M. Sig.: One tablespoonful every three hours. The extract of liquorice of this prescription renders the taste of the salt less disagreeable. If slight elevation of temperature exist, or if dry râles be heard, ipecacuanha may be added, or, in robust subjects, tartar emetic as follows: ℞ Ammon. chlor., ℈iv.; ex. glycyrrh., ʒ ss.; syr. ipecac., ʒ ij. to ʒ iv.; aq. destill. ad ℥ iv. M. Sig.: One tablespoonful every three hours. ℞ Ammon. chlor., ℈iv.; antim. et potass. tart., gr. ss. to gr. i.; ex. glycyrrh., ʒ ss.; aq. destill., ℥ iv. M. Sig.: One tablespoonful every three hours.

Ammonii Carbonas.—This salt is employed in bronchitis, catarrhal pneumonia, and croupous pneumonia, when the fever has subsided or abated, and the general condition of the patient requires the use of stimulant remedies. It is held to act on the mucous glands of the air passages, thus increasing the quantity of mucus and rendering it more fluid. At the same time it stimulates the respiratory centre when given in tolerably large doses, and thus augments the efficiency of the expulsive efforts. The recent researches on the physiological action of this salt have fully confirmed the theory held in the early part of the last century that it possesses great utility in pulmonary affections, because it stimulates the nervous system, and hence enables debilitated patients more readily to cough up accumulated masses of mucus.

Usually it is given to adults in doses of gr. v. to gr. x. every two or three hours. On account of its pungency it is combined in prescriptions with gum arabic and sugar or liquorice. ℞ Ammon. carb., ℈ij. to ℈iv.; pulv. acaciæ, sacch. albi, āā ʒ ij.; aq. menth. pip. ad ℥ iv. M. Sig.: One tablespoonful every three hours.

Aqua Ammoniæ and *Spiritus Ammoniæ Aromaticus*, in appropriate doses, may be used as stimulant expectorants, to increase secretion and excite the respiratory centre.

Scilla.—Squill is perhaps more frequently used than any other expectorant in the advanced stage of acute bronchitis and in chronic bronchitis, especially when secretion, though not scanty, is tenacious, and hence expectorated with difficulty. The investigations on the physiological action of squill have not fully explained its expectorant action, no special modification of secretion of mucus having been observed. But they have conclusively established that squill modifies the action of the heart in the same manner as digitalis, rendering its contractions slower but more forcible. The general blood pressure, therefore, becomes increased, and the circulation in the respiratory mucous membrane accelerated. It is hence quite probable that catarrhal symptoms subside as the result of the improved pulmonary circulation. The fact frequently observed that squill is most effectual in bronchial catarrhs with obstructive heart disease, strongly supports this view.

Squill is usually administered in the form of the syrup, in doses of ♏ xx. to ♏ xl. every two or three hours. It is often combined with ipecacuanha and camphorated tincture of opium when secretion is scanty and the cough severe. ℞ Syr. scillæ, syr. ipecac., tinct. opii camph., āā ℥ i. M. Sig.: One teaspoonful every three hours.

Senega.—The use of senega as an expectorant is based upon careful clinical observation, although it has been found to cause cough and expectoration of mucus in healthy persons. Experience has shown that it is most useful in the second stage of acute bronchitis, in chronic bronchial catarrh, and in pneumonia in the stage of resolution, when the symptoms indicate that the bronchial tubes contain large quantities of secretion. It is held to be especially serviceable when the sputa are muco-purulent and the power to expectorate is small.

The use of senega in bronchitis and pneumonia is indicated by the presence of numerous moist râles, purulent or muco-purulent expectoration, and oppression of the chest. It should not be administered as long as the temperature is much above the normal. It is, however, doubtful whether senega tends to increase fever, as it has been found experimentally that saponin, which appears to be identical with the active principle of senega, lowers the temperature.

The preparations of senega most frequently used are the fluid extract and the syrup, in doses of ♏ x. to ♏ xx. and ʒ i. or ij., respectively.

Oleum Terebinthinæ.—It has frequently been observed that oil of turpentine diminishes the sputum in various forms of bronchitis with profuse secretion, and lessens the offensive odor of the expectoration in fœtid bronchitis and pulmonary gangrene. That it really lessens the amount of secretion in bronchial catarrhs was conclusively shown by Jürgensen (Ziemssen's "Handbuch," Bd. v., p. 182), who in numerous cases carefully measured the quantity of sputum, and constantly found a diminution. The clinical observations have been fully confirmed, and the mode of action of oil of turpentine plausibly explained by the investigations of Rossbach. In carefully conducted experiments he found that the oil exerts a very decided influence on the mucous membrane of the air passages. When a current of air which had passed through oil of turpentine, so as to become loaded with it, was applied to a part of the mucous membrane, the secretion of mucus gradually diminished, and finally ceased, and the membrane became very dry. A watery solution containing from one to two per cent., dropped upon the mucous membrane, caused an immediate increase of secretion and notable anæmia.

Oil of turpentine, when taken internally, is partly eliminated by the respiratory mucous membrane. In passing through the membrane it doubtless exerts an irritant or stimulant action on the blood-vessels, in consequence of which they contract. This contraction of the vessels is soon followed by absorption of exudation and lessened activity of the mucous glands. The decided improvement observed in the odor of the sputum in fœtid bronchitis and pulmonary gangrene is doubtless attributable to the antiseptic power of oil of turpentine, by which it arrests the process of decomposition in the secretions. Rossbach supposes that its antipyretic action, its property of slowing respiration, and its depressing effect on sensory nerves may contribute to its therapeutic utility.

Oil of turpentine is indicated in all forms of bronchitis with free secretion, but especially when the expectoration is profuse, muco-purulent, and fœtid.

It is usually given in doses of gtt. v. to gtt. xx. every two or three hours. Frequently it is administered in emulsion, as follows: ℞ Olei terebinth., ʒ i.; vitellum ovi unius; syr. aurant., ℥ ss.; aq. cinnam. ad ℥ iv. M. Sig.: One tablespoonful every three hours. Jürgensen administers the oil in doses of about twelve drops six times daily in several ounces of milk. If the oil is taken in capsules, a small quantity of milk may be drunk after each one, in order to prevent irritation of the stomach.

Terpin Hydrate, $C_{10}H_{16}3H_2O$, is a hydrate of oil of turpentine that often forms when the oil is in contact with a small quantity of water for some time. On a large scale it is obtained by mixing oil of turpentine with alcohol and nitric acid. It is in the form of large colorless crystals, having no odor and only a very slight aromatic taste. It dissolves in 250 parts of water at 15° C., in 32 parts of boiling water, and in 10 parts of alcohol.

Terpin hydrate was introduced by R. Lepine, of Lyon, as an effective remedy for chronic bronchitis. He had used it in several hundred cases, and had observed that doses of 0.2 to 0.6 (gr. iij. to gr. ix.) daily rendered the sputa less tenacious and more copious, and facilitated expectoration. In cases of bronchorrhœa larger doses, 1.5 (gr. xxij.) daily, lessened the quantity of sputum. Such doses also increased the action of the kidneys, but, when these organs were normal, never caused albuminuria or hæmaturia.

The observations of Lepine have been corroborated by a number of clinicians in large hospitals. Thus Germain Sée found terpin hydrate very effective in catarrhal affections of the respiratory mucous membrane, the morbid secretion gradually diminishing under its prolonged use. In catarrhal forms of phthisis, he observed that the muco-purulent secretion lessened and often entirely ceased. He employed it also to arrest the hæmoptysis of the early stage of phthisis, and held it to act more rapidly than ergotin.

Dr. Manasse, of Berlin, found terpin hydrate very useful in whooping-cough, of which he treated forty-one cases, varying in age from nine months to twelve years. Every case was carefully observed, the frequency and severity of the paroxysms being noted daily. To children under one year of age he sometimes gave as much as 1.5 (gr. xxij.) daily, and never observed any injurious action on the digestive or urinary apparatus. And in no case, when 2.5 to 3.0 daily were given to older children, did the urine become albuminous or bloody. As a rule, in four or five days the paroxysms were less numerous and always less severe. The bronchial catarrh, which was present in most cases, diminished more rapidly than usual, and finally disappeared entirely. All the cases treated with terpin hydrate recovered. The medicine was given in the form of powder as follows:

℞ Terpini hydrat. 5.0–10.0 (gr. lxxv. to gr. cl.). Div. in part. æqual. No. x. S.: One powder three times daily.

The following formulæ have been recommended:

℞ Terpini hydrat. 3.0 (gr. xlv.); sacch. alb., mucil. acaciæ, āā q. s. M. ft. pil. No. xxx. S.: One to four pills three times daily. ℞ Terpin. hydrat. 2.0 (gr. xxx.); spiritus (alcohol), aq. dest., syr. menthæ pip., āā 50.0 (ʒ xiij.). M. S.: One tablespoonful from three to six times daily.

Copaiba.—Although the action of this agent on the mucous membrane of the air passages has not been investigated experimentally, it seems highly probable that it is analogous to that of oil of turpentine. Numerous careful observers have found it useful in chronic and in fœtid bronchitis, and some of them state that it is equalled by no other medicine in catarrhs attended with profuse expectoration. It is usually given in emulsion in doses of ♏ x. to ♏ xx. from three to six times daily.

Pix Liquida.—Tar seems to be useful in chronic catarrh of the bronchi and in phthisis, when copious secretion is taking place. It often lessens the expectoration, eases the cough, and diminishes the oppression of the chest. Usually it is administered in the form of the officinal syrup, of which the dose is ʒ i. to ʒ iv. The following formula was recommended by Adrian: ℞ Picis liq., vitell. ovor., āā 25.0; glycerini, 50.0. M. Sig.: One or two teaspoonfuls from three to six times daily.

Eucalyptol.—This volatile oil has recently gained some repute in bronchorrhœa and fœtid bronchitis. It is a powerful antiseptic. Taken internally, it is eliminated by the kidneys and the lungs, and seems to act upon the respiratory mucous membrane in the same manner as oil of turpentine. It is administered in doses of gtt. v. to gtt. xv. in capsules or emulsion.

Grindelia has lately been strongly recommended in spasmodic and catarrhal affections of the bronchial tubes, and in whooping-cough. According to some of the published reports, in some instances "it acts like a charm, instantly controlling the cough, and relieving the tickling in the throat and bronchial tubes." The fluid extract is given in doses of ♏ x. to ♏ lx.

Ammoniacum, benzoic acid, myrrh, balsam of Peru, balsam of tolu, garlic, and *sanguinaria* have been employed in bronchial catarrhs with good effects. They are, however, at the present time, rarely prescribed.

MORPHINE AND ATROPINE.—These alkaloids are so useful in diseases of the air passages, and so frequently administered simultaneously with some of the expectorants, that a very brief consideration of their mode of action is here appropriate.

Atropine is in constant use in phthisis to arrest night sweats. Many observers have noticed, during its administration, a decided lessening of expectoration and cough. This effect was usually ascribed to an action on the vagi in the lungs, and on the mucous glands, which were supposed to become affected in the same manner as the sweat glands. In experiments, Rossbach observed that atropine acts very strongly upon the tracheal mucous membrane. He invariably found that the membrane, which had been secreting normally and was very moist, became absolutely dry. Gradually very decided hyperæmia supervened; yet no secretion occurred for an hour or longer, and afterward returned very slowly and feebly. The persistence of the dryness, notwithstanding the hyperæmia, proved that atropine acts on the mucous glands or secretory nerves. It is therefore an appropriate remedy in bronchial and pulmonary diseases, when the cough depends upon copious secretion in the trachea and bronchial tubes.

Morphine lessens cough in two ways—by diminishing secretion, and by lowering the excitability of the respiratory centre.

Rossbach observed that, normally, after removal of the mucus from the tracheal mucous membrane, about twenty seconds passed before the membrane was again completely moist. But after subcutaneous injections of morphine, the membrane did not become equally moist before the lapse of from eighty to one hundred seconds.

Cough may be very readily produced by slightly irritating the normal mucous membrane of the larynx and trachea, especially near the bifurcation of the bronchi. An hour after injecting morphine, Rossbach found that only very severe irritation produced cough, while gentle irritation had no effect.

When used simultaneously, both alkaloids act, lowering the excitability of the respiratory centre and notably lessening secretion. In chronic catarrhs, emphysema, and phthisis, with copious expectoration, they have been found of great utility. In phthisis, when the expectoration comes from cavities, no very marked diminution can be produced.

As a rule, the two alkaloids should be prescribed separately—atropine to be taken only in the evening, between six and ten o'clock; and morphine, in very small doses, during the day.

Codeine.—Codeine has recently come into use as a means of allaying cough. According to numerous reports, it is generally as effectual as morphine or the preparations of opium. Often it has been observed that the cough of mild forms of bronchitis ceased in a few days. But its principal advantage is that it does not depress the functions of the alimentary canal. The use of morphine is usually followed by a diminution of appetite, and often by constipation. Codeine, while it allays the cough, does not interfere with the appetite, or with the normal action of the bowels. This has been especially observed in phthisis, in which codeine was found to mitigate the cough without lessening the desire for food. When, to test the difference in action, Dover's powder was given to patients that had been taking codeine, the appetite, which had improved under the use of codeine, diminished again, showing the decided superiority of codeine. It has been found to be very useful in the bronchitis of children, and, in appropriate doses, has been given to infants, without any unpleasant effects.

Codeine should therefore be preferred to morphine in all cases of severe cough in which it is necessary to maintain a good appetite, as in bronchial catarrhs complicating chronic wasting diseases, in children, and in persons subject to constipation. Especially, should codeine be preferred to morphine to relieve the cough of phthisis; for if the means used to mitigate this tormenting symptom interfere with digestion and nutrition, little hope of saving life can be entertained.

The salts of codeine commonly used are the sulphate, phosphate, and hydrochloride. They all readily dissolve in water, and are usually prescribed in aqueous solution with a small quantity of syrup, or together with sugar in the form of powder. The dose for adults is gr. $\frac{1}{4}$ to gr. $\frac{3}{4}$; for infants, gr. $\frac{1}{60}$; and for children three or four years of age, gr. $\frac{1}{15}$ to gr. $\frac{1}{10}$, from three to five times daily.

Heroine, a derivative of morphine—diacetyl morphine—is rapidly coming into use as a cough remedy. It is a white powder, having a bitter taste, not easily soluble in water, but readily soluble in water acidulated with a few drops of acetic acid. Its salt, heroine hydrochloride, is soluble in two parts of water.

Heroine was introduced in 1898 by Prof. H. Dreser, of Elberfeld. In experiments upon animals Dreser had found that heroine notably slows the respiratory process and renders it deeper. He administered it in doses of 0.01 to patients having cough and found it to give much relief.

Harnack in experiments upon dogs observed also notable slowing of respiration, but it became decidedly weaker; hence he concluded that heroine is more poisonous than morphine and should not be given in doses larger than 0.005. Strubbe experimented upon dogs, cats, and rabbits, and obtained results agreeing essentially with those of Dreser. Sartissen, on the contrary, found the respirations shallower, although slower.

Numerous clinical observations of the action of heroine have been made in hospitals and in private practice, and with nearly uniformly good results. Perhaps the most careful observations are those of Brauser, made in Ziemssen's clinic. In eighty cases an accurate record was kept, and control trials were made with simple sugar, codeine, and morphine. The cases treated embraced phthisis, acute and chronic bronchitis, croupous pneumonia, pleuritis, cardiac dyspnœa, and patients having pain from other causes. In the great majority of the cases heroine promptly lessened the cough. Usually this result followed when 0.005 was given in the morning and at noon, and 0.01 in the evening. In most cases the respirations were slowed, often from five to eight in a minute, sometimes only two or three. In the same patients sometimes the respirations were lessened, sometimes uninfluenced. In about one-third of the cases no change in the frequency of respiration could be observed, especially in cases not presenting any marked acceleration. This occurred, however, also when the respiratory process was greatly accelerated, especially in pneumonia. In some cases of cardiac dyspnœa the action of heroine was notably beneficial, the breathing becoming slower and more nearly normal.

From these and numerous other cases Brauser concluded that heroine acts as promptly and effectually as morphine in relieving cough, and that it is very useful in dyspnœa, though not certain, giving decided relief in only about two-thirds of the cases treated.

Floret observed that heroine when given together with apomorphine produced disagreeable effects—vertigo and headache. In phthisis, when not far advanced, the combination of heroine and duotal (heroine 0.005–0.01; duotal 0.5, given four times daily) was followed by general improvement and a notable retrogression of the objective symptoms. *Samuel Nickles.*

EXPECTORATION. See *Sputum.*

EXPERT MEDICAL EVIDENCE.—In the last few years the medical expert witness has figured prominently in many celebrated criminal and civil actions. At first his evidence was received by the court and jury with the deference and respect which honesty, intelligence, and learning always inspire. But in more recent times many things have conspired to place the medical expert witness on a much lower plane than he formerly occupied. The principal reasons for this degeneration may be found in the seeming partisanship of some of those who take the stand as experts; the employment of witnesses who are qualified neither by education nor by experience to act as experts; and the opinion, which has become impregnated in the public's mind, owing to the methods of procedure followed by the attorneys in the case, that the most able experts can be hired to swear to diametrically opposite conditions of facts. All of these things together have operated to prejudice the people, and consequently the jurors, against the introduction of medical expert evidence. Indeed in more than one instance talesmen have been rejected as jurors because of their avowed disbelief in, and determination to reject, all expert evidence.

Medical expert evidence should, theoretically, often be of inestimable service in that it is perhaps the only way in which certain facts vital in importance can be brought to the attention of the jury, and the relation of these facts to the case explained. A medical expert is one who by study and experience has become especially learned or skilled in some branch of medical science and whose judgment and opinions therefore are sounder than those of the average physician. It is of the greatest importance, therefore, that one who poses as an expert should actually be qualified to act as such. Attorneys are not always careful in the selection of their medical witnesses, either from ignorance or because they cannot or will not pay the fees which the expert generally demands, and they often call to the stand physicians of excellent general knowledge but who are not at all prepared to meet the ingenious questions of a skilful cross examination. Again, the fault is with the physician who, tempted either by the pecuniary reward for his services or by the opportunity of achieving a certain degree of notoriety, places himself in a position which his limited knowledge and experience are inadequate to support. His answers to questions clearly show, to the expert at least, that he does not possess an intimate knowledge of his subject, and when confronted by an expert witness there often follows a flat contradiction of opinion. The evidence of the medical witness, like the evidence of any other witness, is addressed to the jurors and is for their consideration. They do not always know who are experts and who are not; so generally regard all the medical witnesses as possessing the same degree of skill and ability. They cannot, of course, be expected to detect the ignorance on the part of a medical witness which is so apparent to the expert. They simply recognize the contradictions which necessarily arise in a conflict between ignorance on the one hand and knowledge on the other; and confusion of mind and doubt naturally follow. For this reason medical evidence is sometimes completely ignored by the jurors and falls greatly in public estimation. The medical witness should never allow himself to act in the dual rôle of witness and associate counsel. The spectacle is seen at nearly every trial of prominence, and in many others, of one or more physicians sitting close to counsel, taking copious notes of the evidence, formulating questions to be used in direct and cross examinations, looking up references and in reality conducting the medical part of the prosecution or defence, and then when their turn comes taking their place in the witness chair to act as experts. Associate medical counsel is often of valuable assistance. No matter how skilful an attorney may be or how thoroughly he has studied his case, a well-trained medical mind can point out to him many features, and give him many suggestions which would otherwise escape him. A counsel often strengthens his case by the help of a medical associate and the employment of a physician as such is perfectly proper from every standpoint. But for such a one to take the stand as a witness stamps him as a partisan to the jury. It cannot help but regard him as a biassed witness, who comes prepared to fight for "his side" of the case. The influence of his testimony is, of course, much less than that of the witness who confines himself to his duties as a witness only. It is, of course, incumbent on a physician who purposes to act as an expert witness to point out the medical aspects of the case to counsel and to suggest such questions for the direct examination as will enable him to express his investigations, deductions, and opinions in his own way and to his best advantage. He may also with propriety suggest the general course of the direct and cross examination of other experts, but further than this he should not go and cannot go without seriously compromising himself as an unbiassed witness. Even the construction of hypothetical question which generally terminates the expert witnesses' direct examination, should not be performed by him. He may point out to counsel the medical facts which should be incorporated in the question. But should the fact be elicited from the witness that he was the author of the question he has just replied to, the force of his answer is lost and his value as a witness is greatly diminished.

It generally appears to the public, particularly in notorious trials, that a certain number of experts called by one side swear positively and diametrically opposite to the experts called by the other side. It is this feature which has called down so much and so unfavorable criticism upon the medical expert witness and upon the value of expert testimony in general. A great deal has been written and much thought given to the formation of a plan by which medical expert testimony can be employed without the objectionable features which now mar it and yet preserve the constitutional rights of the prosecution or defence. It is not a simple question for solution, and none of the methods which have so far been advocated seems to fulfil all the requirements of the case. The fault lies mainly with the attorneys and not with the experts. It seems, at first glance, as if the experts on one side flatly contradict the experts on the other. This may be the case in some instances, for two minds working upon the same assumption may come to different conclusions. But it is not generally so, at least, in medicine. In trials, as they are conducted at the present time, there is no possible chance for an agreement of the experts. The witnesses for the two sides are not asked to give opinions based upon the same assumptions; each counsel has his own hypothetical question which differs from that of his opponents as night differs from day. They are based upon absolutely different assumptions of facts, and the answers given are in accordance with the assumption in each question. Should the opposing counsel exchange hypothetical questions, the answer of every expert witness would be changed also.

The expert opinions are of no value at all unless the assumptions contained in the hypothetical question are proved to be true. If the jury believes the assumptions in one hypothetical question, then the expert opinions based thereon are worthy of consideration; otherwise not. If these points were generally understood, it would be comprehended that the seeming clashing of expert opinions is in reality nothing of the sort, but that the opinions given are nearly what they claim to be, honest answers to absolutely different questions.

Another feature which stands in the way of obtaining the best expert evidence is the purposeful and wilful interference with which one attorney in the action foils every attempt, to the best of his ability, of the expert called by his opponent to obtain those details of the case which are requisite for the establishment of a sound medical opinion, while every facility is freely granted for every investigation his own experts desire to make. Thus a man on trial for murder pleads insanity. The experts called by his counsel have frequent interviews with the accused, and on these occasions he talks freely and openly and submits willingly to any examination they may desire. The relatives and friends communicate the family history, the personal history, and any other facts which may be of service to the examiner, and he comes into court well informed in every detail of the medical features of the case. But how is it with the expert called by the state? Has he had an equal chance for rendering a truthful solution of the question? He certainly has not. When he interviews the accused he is not welcomed. The prisoner sees in him a man who is to assist in taking his life and therefore gives as little information as he can. He is often carefully coached as to the replies he is to make to certain questions, and the friends and relatives either give no information at all or else give that which is either false or misleading. As a rule the examiner obtains but little more information than can be derived from a study of the physical symptoms, which in many cases is absolutely insufficient for a satisfactory diagnosis. These defects in the present system of expert medical evidence are frankly admitted by both physicians and lawyers, and any method by which an unbiassed and uncontradicted expert opinion could be obtained without infringing upon personal rights, would be gladly welcomed by both professions. The plan most constantly urged is the appointment of a board of experts commissioned by the court to make a physical or mental examination, or both, as the case may be, and then to report the result of its findings to the court and jury. This seems simple, and no doubt it would prove to be a most satisfactory method if the question could be ended then and there. But it would not end there. A party to an action has a right to call any witness whose testimony will tend to prove his allegations. Should the report of the commission of experts be adverse to his interests he may call his own experts, who may not agree with the commission and then there is the same old story of expert against expert.

A most simple and effective method and one which, while it preserves the rights and liberties of all the parties concerned, would result in more harmonious expert evidence, is the following: Each party to the controversy shall select such expert or experts as they may desire. When this has been accomplished to the satisfaction of both parties, it shall be obligatory that every examination of the plaintiff or defendent, as the case may be, shall be made in the presence of all the experts together and shall be participated in by all the experts. And that at each examination counsel for both parties shall be present, and an official stenographer who shall report verbatim what was said and also what was done by each examiner in the line of his examination, and that a copy of the report of each examination shall be furnished to each counsel and to the court to be used by counsel on the direct and cross examination of each expert; and that all information relating to the question supplied to or acquired by any expert shall be furnished to every other expert. By this means all the experts will have an equal knowledge of the case and each will have every opportunity for forming a correct opinion. The stenographer's report, showing each expert's complete examination, in the hands of counsel will do more to secure a unanimity of opinion than anything else could do.

When everything has been said, however, and the question has been considered from all its standpoints, it must be admitted that expert medical testimony, which should be a valued, scientific, and honored method of assisting justice to know the truth, has been prostituted by those attorneys who are willing to use any means to save a client or secure a verdict, and by physicians who are willing to lend themselves for such a purpose. The medical expert should be regarded as a scientist, and expert evidence should be received by court and jury with respectful consideration. It is the medical expert himself who is to blame. When he recognizes this fact the remedy will quickly follow. The medical profession is respected everywhere but in the courts. Let it be seen to that it is respected there also.

Graeme M. Hammond.

EXTRA-UTERINE PREGNANCY.—By extra-uterine pregnancy we mean those instances in which the fertilized ovum is arrested somewhere in its course from the ovary to the uterus and there undergoes development. The term ectopic gestation has a somewhat broader meaning than extra-uterine pregnancy, and has reference not only to such cases as mentioned above, but also to those instances in which the pregnancy occurs in some abnormal diverticulum of the uterus.

Until as recently as 1883 the condition was of interest chiefly from its pathological standpoint; and few or even no cases were recognized clinically. But from that date, at which time Tait operated on his first case of ruptured tubal pregnancy, the clinical interest in the affection has been markedly increasing, as is shown by the decided increase in the literature on the subject and the apparent increase in the frequency of the condition.

FREQUENCY.—Before extra-uterine pregnancy came to be recognized clinically and at autopsy, observers were much misled as to its frequency; and consequently such statements as that made by Hennig, in 1876, to the effect that the affection is so rare that the directors of large obstetrical clinics might never see a case of it, were not to be wondered at. On the other hand, the data now available might readily lead one to suppose that the frequency has markedly increased since that time. Thus, for example, Parry, in 1876, was able to collect only five hundred cases that had been reported up to that time, while in 1892 Schrenck collected six hundred and ten cases which had been reported in the five previous years.

This apparent increase in frequency has also been noted in the experience of individual operators and in single clinics. The increase, as a matter of course, is more apparent than real; it is due unquestionably to our improved methods of diagnosis and greater knowledge of the subject.

ETIOLOGY.—So many theories have been advanced to explain the occurrence of extra-uterine pregnancy that it is impossible to make any very definite statements as to its etiology. J. Whitridge Williams, after a most exhaustive review of the literature, gives the following classification, which, although somewhat complicated, is probably the best which, in the present state of our knowledge, can be offered. He divides the etiological theories into four groups:

I. *Conditions which Interfere Mechanically with the Downward Passage of the Ovum.*—(*a*) Peritoneal adhesions. This is one of the earliest explanations for the occurrence of extra-uterine pregnancy and is still held by many to be the principal one. The adhesions act either by directly compressing the lumen of the tube, or by interfering with its muscular action; both of which conditions are sometimes verified at operation or at autopsy.

(*b*) Tubal polypi, projecting into the cavity of the tube and therefore impeding the downward passage of the ovum, have been found by certain operators. Williams in his analysis is of the opinion that only a few of the cases in which this condition was stated to have been the cause are at all convincing, and he agrees with Ahlfeld in thinking that in many cases the "tubal polypi" are merely decidual ingrowths, the result rather than the cause of the extra-uterine pregnancy.

(*c*) Tumors of the tube wall and in some instances tumors of adjacent organs have been said to play a similar part by compressing the lumen of the tube.

(*d*) Salpingitis. The suggestion was made by Schroeder and Tait that inflammation of the lining of the tube so damaged the cilia of the mucous membrane that a downward current was no longer produced and consequently no obstacle was offered to the entrance of the spermatozoon into the tube. This view presupposed that fertilization normally took place in the uterus and that the ciliary currents favored a meeting of the male and female cells at the fundus. We know now, however, that the currents throughout the utero-tubal tract run in the same direction, viz., from above downward, that the spermatozoon has to work against the stream from the time it enters the internal os, and that as fertilization normally takes place in the tube all pregnancies are primarily tubal. Microscopic examination, furthermore, has not confirmed the view put forward by Schroeder and Tait, for in these cases of tubal pregnancy ciliated epithelium is usually found covering the mucosa.

(*e*) Obstruction by twin ova. The comparative frequency of the coexistence of extra- and intra-uterine pregnancy has led certain observers to suggest the possibility of the mutual interference of twin ova as a cause for tubal pregnancy.

(*f*) Fœtal twisting of the tube. While the Fallopian tube in adult life is a comparatively straight canal, that of the fœtus is a convoluted one. These convolutions may persist in adults, and may then stand in causative relation to certain forms of tubal disease, notably extra-uterine pregnancy.

(*g*) Diverticula of the lumen of the tube. The occasional presence of these diverticula was demonstrated by Williams in 1891, and he at that time suggested that they might be shown to act as a causative factor in certain cases of tubal pregnancy. While he is still of the opinion that such a state of affairs *may* exist, he admits that he has been misled by some of his specimens in which he found the fertilized ovum lying outside of an apparently intact tubal lumen. Since Peters has demonstrated in the uterus that the ovum burrows down beneath the epithelium, which finally closes to form an intact surface over it, there is reason to believe that the same thing occurs in the tube; thus explaining the fact that in early cases of tubal pregnancy the ovum may be entirely outside of the lumen of the tube.

(*h*) Puerperal atrophy of the tube. Dührssen has reported cases of extra-uterine pregnancy which have occurred in an incredibly short time after labor, in some instances even while the mothers were nursing their children. In these instances he considers the cause to be a puerperal atrophy of the tube which interferes with its peristalsis. In one case operated upon by the author this factor may have been present. The pregnancy probably began six weeks after the birth of a dead child, and tubal rupture took place six weeks later.

(*i*) External migration of the ovum, which is quite a common occurrence in extra-uterine pregnancy, has been given as a causative factor by some investigators, they holding that the fertilized ovum in its transit through the peritoneal cavity attains such a size that its transmission through the opposite tube is an impossibility.

II. *Abnormal Conditions Resulting from Inflammatory Diseases of the Tubes, Ovaries, and Pelvic Peritoneum.*—Mention has already been made of the part that the absence of cilia is supposed to play in the causation of extra-uterine pregnancy and little need be added to this statement. Most cases of tubal pregnancy will reveal a history of pre-existing inflammatory trouble, and it is the rule to find some other abnormality besides the pregnant tube at operation or autopsy. This has given rise to the statement that an inflammatory condition of the pelvic organs is the principal cause of extra-uterine pregnancy, but, unfortunately for the correctness of this statement, actual examinations, at operation or at autopsy, show that such an inflammatory condition is not present in all cases. On the other hand, the fact that tubal pregnancy occurs repeatedly in women suffering from gonorrhœa certainly favors the above statement.

III. *Physical and Developmental Conditions which Favor Decidual Formation in the Tubes.*—This theory was originated by J. C. Webster, who was not satisfied with the numerous etiological views that had been advanced. He recalls the fact that as the uterus and tubes are both developed from the same embryonic structure, the Müllerian ducts, there is no reason why the ovum should not be implanted upon the upper as well as upon the lower portion of the tract. Normally, the lower portion of this duct becomes differentiated from the upper, so that in the latter the conditions are not such as to favor the formation of a decidua. Abnormally, on account of some developmental anomaly or reversion to an earlier type, the condition of the tubal mucosa is such that a decidua can form, and in such instances we can get an extra-uterine implantation of the ovum. This view has been adopted by a number of observers, but, as is readily seen, it is based upon a theoretical rather than upon a practical basis.

Other observers, among whom may be mentioned Moericke and Fehling, have elaborated Webster's idea in that they claim that the occurrence of extra-uterine pregnancy is a reversion to an earlier type, brought about by poor hygienic conditions. The former authority, basing his conclusions upon a large number of gynecological patients who were under his care in Chili, states that extra-uterine pregnancy is a very rare occurrence among them, whereas at the Clinic in Stuttgart it was observed quite frequently. He attributes this marked difference to the fact that the Chilian women lead an outdoor life, while those of Stuttgart are subjected to very poor hygienic surroundings.

External migration of the ovum, the frequency of which in extra-uterine pregnancy has already been referred to, has led Sippel to put forth a view that is more or less closely allied to that of Webster. Sippel claims that it is necessary for a certain length of time to elapse between fertilization and decidual formation. Thus, when external migration occurs, the ovum is delayed in reaching the genital tract, and then finds in the tube conditions favorable for the formation of a decidua. This view is an interesting one, but is purely theoretical.

IV. *Conditions of the Ovum which may Favor its Arrest in the Tube.*—A few years ago, when the general opinion was that the uterine and tubal epithelium was converted into syncytium, Strassman was of the opinion that as the ovum entered the tube covered by the cells of the membrana granulosa, it could not become attached to the syncytium of the tube until this layer of granulosa cells had disappeared; but if the layer of granulosa was diminished in amount, or if for any reason it was absent, the naked ovum came into direct contact with the syncytially changed tubal mucosa and there became attached, while normally the layer of granulosa prevented this occurrence until the ovum had reached the uterus. This view is no longer tenable, for opinion is now unanimous that the tubal and uterine epithelium does not undergo this change,—*i.e.*, into syncytium,—but that the latter is derived from the fœtal ectoderm.

It is therefore very evident that there is no lack of theories as to the causation of extra-uterine pregnancy. The mechanical theories must be given a certain amount of consideration, but they are open to the objection that while mechanical obstacles are frequently present, the existence of extra-uterine pregnancy is of comparative rarity. On the other hand, recent experimental work on animals—ligation of the tubes and uterine cornua—has failed to cause extra-uterine development of the ovum, after the animal under consideration has been put to the male. Thus these experimenters believe that the supposed extra-uterine pregnancy in the lower animals is really uterine, the mistake being due to confounding the tubes and uterine horns with one another. Tubal diverticula may play an important part, and in some cases undoubtedly exist; but this again cannot hold good for all cases. The same may be said of inflammatory conditions.

We had best close this portion of the subject by quoting from Williams, who summarizes as follows: "The etiology of extra-uterine pregnancy is not a simple matter, and there is no universal cause for all cases. Careful study of the specimen and of the patient's history will give us a satisfactory explanation for its occurrence in the majority of cases, but in a small number we cannot account for the production of the affection, and its cause will remain to us as great a problem as to our predecessors."

CLASSIFICATION.—The fertilized ovum may be arrested at any point between the ovary and uterus. We may thus distinguish between ovarian and tubal pregnancy according as the development occurs in either of these organs. To these two forms some add a third, viz., abdominal pregnancy; but there is considerable doubt as to whether a primary implantation can take place on the peritoneum and thus give rise to this form of pregnancy.

Ovarian Pregnancy.—Ovarian pregnancy was first described early in the seventeenth century, and in the eighteenth was pretty generally recognized. In 1835 Velpeau made the statement that many of the cases described as ovarian pregnancy were open to objections, and he took the rather radical view that none of the cases reported gave to him conclusive evidence as to their ovarian origin. Observers in general agreed with him, and at present there are few who believe in the existence of ovarian pregnancy.

There is evidence, however, that the condition undoubtedly does exist, although very rarely; and, since Spiegelberg reported a case of this nature in 1878, we are in possession of certain criteria by which an ovarian pregnancy can be recognized. Spiegelberg demands that the following conditions be noted before we can make a diagnosis of a given extra-uterine pregnancy being ovarian: (1) The tube on the affected side must be intact. (2) The fœtal sac must occupy the position of the ovary. (3) It must be connected with the uterus by the utero-ovarian ligament. (4) Definite ovarian tissue must be demonstrated in its walls. When judged by these criteria it is clearly seen that many of the cases reported as ovarian pregnancy will be found wanting. Williams, in discussing these points brought out by Spiegelberg, calls attention to the fact that in certain cases of tubal and broad-ligament pregnancy, the ovary may be so flattened out as apparently to occupy a portion of the sac wall, and for this reason he suggests that the fourth condition be so modified as to read: "Definite ovarian tissue must be demonstrated, not at a single point in the sac wall, but at several points a considerable distance from each other."

Williams has carefully reviewed the literature of ovarian pregnancy in the past hundred years and has applied the above criteria to the reported cases. The results of his analysis show that only four cases can be classified as *positive cases*, eleven cases as *highly probable*, and twenty as *fairly probable;* thus clearly demonstrating that, although ovarian pregnancy undoubtedly does exist as a primary condition, it is of the greatest rarity. He also shows that one-half of the positive or probable cases reached full term, indicating that the ovarian tissue can more readily accommodate itself to the increase in size of the growing ovum than can the tube.

In ovarian pregnancy rupture with formation of a secondary abdominal pregnancy can occur, or the case may go to term and the formation of a lithopædion be the result.

Tubal Pregnancy.—When the ovum is arrested in the Fallopian tube and develops there, we have what is known as a tubal pregnancy; this is by far the most frequent variety of extra-uterine pregnancy. According as the arrest of the ovum occurs in the various portions of the tube we can distinguish between ampullar, isthmic, and interstitial pregnancy, the relative frequency being in the order named.

Tait's idea was that the invariable fate of a tubal pregnancy was rupture into the peritoneal cavity, and that this rupture always occurred not later than the twelfth week. Further investigation, however, has proven this view to be an erroneous one, and that many cases terminate at a much earlier period, in what is known as tubal abortion, or that in rare instances the tube may so accommodate itself to the growing ovum that the case may go on to term.

Tubal abortion was thought to be, until quite recently, a pathological curiosity, but in 1887 Werth called attention to the fact that it was not infrequent for the ovum to be extruded through the fimbriated end of the tube into the peritoneal cavity. Attention having been directed to the fact, it is now generally believed that this is the most frequent termination of tubal pregnancy, and in the last three years statistics collected by Martin, Orth, Mandl, Schmidt, and others show that seventy-eight per cent. of the cases end in tubal abortion as against twenty-two per cent. rupturing into the peritoneal cavity. Martin indeed considers that abortion is the general rule and says that rupture occurs only in those cases in which abortion is prevented by closure of the fimbriated end of the tube.

The abortion which occurs in the tube is in a measure analogous to that which takes place in the uterus. The liability to hemorrhage is increased owing to the imperfect development of the decidua. The maternal vessels are opened up by the downgrowth of fœtal ectoderm or trophoblast, and the hemorrhage loosens the embryo from its attachment to the tube wall. If the separation is complete, the ovum is forced through the fimbriated extremity and the abortion can be designated as "complete." On the other hand, if the separation of the ovum is only partial, the hemorrhage continues and the ovum remains in the tube; here the abortion is "incomplete."

It is probable that two factors act in the expulsion of the ovum—viz., the actual contraction of the muscular walls of the tube, and the force from behind furnished by the blood clot. If the abortion is complete, hemorrhage will be profuse; but if the ovum remains in the tube, it may be converted into a "fleshy mole," similar to those observed in uterine abortions.

What has been just gone over has served in the last few years markedly to change the views that were held as to the causation of pelvic hæmatocele and hæmatosalpinx. Opinion is now pretty general that both of these conditions are secondary results of tubal pregnancy. In the first instance the blood flowing through the fimbriated end forms a clot in the neighborhood of the ovary, and in the second the hemorrhage occurs into the tubal lumen and the blood remains there.

Rupture into the Peritoneal Cavity.—As has already been stated, rupture in this manner is not so common as was thought by Tait. When it does occur the pregnancy is usually situated at some distance from the fimbriated end of the tube—either at the isthmus or in the interstitial portion. If it is situated at the isthmus, rupture usually takes place within the first twelve weeks of the pregnancy, and not infrequently during its first month; but if it is situated in the interstitial portion rupture occurs later, for this portion of the tube, being surrounded by uterine muscularis, more readily responds to the influence of pregnancy and allows the ovum to attain a larger size.

Rupture may occur spontaneously or may be brought about by violence; the most frequent form of violence being a rough vaginal examination. The writer recalls a case in charge of a friend in which death from hemorrhage took place twelve hours after a vaginal examination; the diagnosis of extra-uterine pregnancy had not been made. When rupture occurs spontaneously it usually follows some exertion on the part of the patient.

The underlying causes of rupture are twofold, viz., (*a*) overdistention of the tube by the growing ovum and (*b*) perforation of the tube wall by the chorionic villi, which grow down rapidly between the muscle fibres and not infrequently penetrate to the peritoneal coat. The fœtal ectoderm or trophoblast proliferates and causes a certain amount of degeneration of the muscle fibres and connective tissue of the tube wall. If then, as frequently happens, a maternal blood-vessel be opened, the rapid discharge of blood into the tube will cause its overdistention and rupture.

Rupture usually takes place in the neighborhood of the placental site, and hemorrhage and discharge of the ovum will occur either into the peritoneal cavity or between the folds of the broad ligament, depending on the original site of implantation of the placenta.

When rupture occurs into the peritoneal cavity, as a rule the entire ovum is extruded; but if the wound be a small one, there may be profuse hemorrhage without the ovum being discharged. In either case, however, the hemorrhage is profuse and the patient will show marked signs of collapse—or will die before relief can be obtained. In the event of an operation or if a fatal issue should not take place, the result will depend upon the amount of damage which has been done to the ovum.

If the entire ovum escapes into the peritoneal cavity its death is inevitable, and, unless the fœtus is beyond the third month, absorption of the entire product of conception is the rule. The old view that in such a case the placenta may become attached to some neighboring organ and thus form vascular connections is now scarcely tenable; but if the fœtus alone escape from the tube and the placenta remains *in situ*, the effect of the rupture on the pregnancy will vary according to the amount of damage done to the placenta. In those cases in which the greater portion of the placenta remains attached, the fœtus will go on to term as a secondary abdominal pregnancy, and if the original tubal wound has been a small one the placenta will develop in a sac formed by the remains of the tube; but if the rent were large and close to the margins of the placenta, this organ will overgrow its tubal attachments and become adherent to some neighboring organ, viz., uterus, pelvic floor, or intestines. Most observers agree that further growth of the fœtus after escape from the tube is impossible unless it is surrounded by the amnion. There are, however, exceptions to this rule.

Rupture between the folds of the broad ligament takes place in a few cases through that portion of the tube wall which is not covered by peritoneum, and here the tubal contents will pass downward into that space which is situated between the broad ligament and its peritoneal covering. This is considered the most favorable termination of an extra-uterine pregnancy and usually results in the death of the ovum and the formation of a broad-ligament hæmatoma. More rarely the pregnancy may go on to term in this situation; and in such a case it is evident that the placenta, being attached to the unruptured portion of the tube wall, will lie at the superior part of the gestation sac, which condition has given rise to the erroneous idea that the placenta may be attached to some remote organ such as the liver or the diaphragm. In such a case the pregnancy is entirely outside of the peritoneal cavity, and the condition has been spoken of as a broad-ligament or extraperitoneal pregnancy. The gestation sac here has been known to rupture, and a secondary abdominal pregnancy is then the result.

The intimate relation that exists between these pregnancies and the rectum renders them more prone to invasion by intestinal bacteria, and if suppuration should occur the proximity to the bladder explains the discharge of fœtal bones, etc., by way of the urethra—an occurrence which has been noted in such instances.

Williams and others are of the opinion that the frequency of this form of pregnancy has been overestimated, as Williams has observed it only once in about forty cases.

Abdominal Pregnancy.—There is at present little doubt in the minds of most operators that those cases which were thought to be primary abdominal pregnancies have turned out to be only secondary abdominal pregnancies, *i.e.*, secondary to a pre-existing tubal pregnancy, and there is uncertainty as to the possibility of the existence of a pregnancy primarily abdominal. Recent work by Zweifel, Martin, and others, has shown that the fertilized ovum can become implanted upon that thin strip of tubal tissue which extends from the fimbriated extremity of the tube to the ovary, the fimbria ovarica. It is readily seen, however, that such cases are not abdominal but in reality tubal in origin, which, when we bear in mind the fact that small structures covered by ciliated epithelium have been found in the wall of the gestation sac of many cases described as primary abdominal pregnancy, materially weakens the theory as to the possibility of such a form of extra-uterine pregnancy existing. If, for example, an ovum became implanted upon this portion of the tube, the placenta would very rapidly overgrow the very narrow limits of the fimbria ovarica and give one the impression that the pregnancy were primarily abdominal. Williams, in his discussion of this part of the subject, says that, of the cases thus far described, not a single one appears to him to furnish sufficient evidence to justify its being considered primarily abdominal. Nevertheless, in view of the fact that decidual formation has been noted in the sub-peritoneal connective tissue, the possibility of such a thing cannot be denied.

FATE OF THE FŒTUS IN EXTRA-UTERINE PREGNANCY.—Attention has already been called to the fact that when small embryos are extruded into the peritoneal cavity absorption is the rule. This fact is made manifest by the circumstance that one rarely succeeds in finding any trace of the fœtal body in the blood clots which fill the peritoneal cavity after tubal rupture. Absorption frequently takes place within the gestation sac inside of the tube, and when we cut into such a tube it is by no means unusual to find a shapeless mass hanging to the umbilical cord, or even no trace of embryonic body at all, while the cord simply hangs free in the amniotic cavity.

Such a termination, however, is impossible when the fœtus has reached a certain size; it then undergoes one of the following changes: mummification, suppuration, conversion into a lithopædion or into adipocere. In the first of these conditions the fluid portions of the embryo are absorbed and the fœtus becomes converted into a dry, mummified mass, nothing remaining but the bones, covered by a shrivelled skin. When suppuration takes place, as is quite common in cases of broad-ligament pregnancy, the sac first suppurates and the process then extends to the fœtus. The patient, under these circumstances, shows marked signs of sepsis, and, unless the pus is evacuated by operation or by rupture, she will die. Rupture into the bladder or rectum is not an uncommon termination in such instances.

In a small number of cases neither of the above changes takes place, but the fœtus and membranes, by a deposition of lime salts within them, become converted into a calcareous mass or lithopædion. A structure of this character has, in certain instances, been carried by the mother for years, giving no trouble except when it blocks the pelvis and forms an obstacle to normal labor. Küchenmeister has carefully reviewed the literature of this portion of the subject and divides lithopædia into three classes: (1) Calcification limited to the fœtal membranes (lithokelyphos); (2) both fœtus and fœtal membranes partially calcified (lithokelyphopædion); and (3) calcification limited entirely to the fœtus (lithopædion).

The last possible termination—conversion into adipocere—occurs only rarely. Here the fœtus is transformed into a greasy yellow mass; the material is thought to be an ammoniacal soap.

ANATOMICAL CONSIDERATIONS.—It has been the privilege of the writer to examine most of the sections of the specimens of Williams, also to read the manuscript of his as yet unpublished article on extra-uterine pregnancy. In the present section, therefore, I shall quote somewhat fully from his report.

Structure of the Sac Wall in Tubal Pregnancy.—If one is lucky enough to get a specimen of early unruptured tubal pregnancy, one finds that the tube is the seat of a fusiform swelling about 1 or 2 cm. from its uterine end. Sections through a pregnancy at this age show that the sac wall is made up of the muscularis of the tube. The individual muscle cells, however, do not seem to be increased in number but spread apart by œdema. There is marked dilatation of the arteries and veins in this situation, particularly in the neighborhood of the placental site, and there may be some hemorrhage into the lumen of the tube. Later, one will notice marked degenerative changes in the tube wall in the neighborhood of the chorionic villi, so that at this period the sac wall consists of a tissue closely resembling fibrin. The thickness of the tube wall diminishes as the pregnancy advances, and the muscular elements appear to have diminished in number. If the case reach term the sac wall will be found to be composed almost entirely of connective tissue with here and there a muscle fibre, indicating that the muscularis of the tube has not the same tendency to proliferate under the influence of pregnancy as has that of the uterus.

It is not possible to make definite statements as to the part played by the ovary in the formation of the sac wall of an ovarian pregnancy. Maybe if an early specimen could be obtained the entire sac wall would be found to consist of ovarian tissue. The diagnostic value of the presence of ovarian tissue in the sac wall of pregnancies thought to be ovarian has already been referred to, and it is evident that positive statements cannot be made as to the ovarian origin of the pregnancy unless ovarian tissue can be demonstrated in several parts of the sac wall more or less remote from one another.

The condition of the fimbriated end of the tube varies: if tubal abortion has taken place, it is of course patent; while if abortion has not occurred it may or may not be opened. The relation of the lumen of the tube to the pregnancy is also a subject of variation. In certain instances it can be traced into both ends of the fœtal sac, while in others it is apparently completely shut off.

Decidua.—It has long been known that the uterine mucosa under the influence of extra-uterine pregnancy becomes converted into decidua just as it does in uterine pregnancy, and the statement is usually made that its structure is the same under both conditions. However, recently observers such as Williams, Dobbert, and Tussenbroek have pointed out that there exist certain differences in the structure of the two membranes. For example, in uterine pregnancy the spongy layer of the decidua is not so well developed as in extra-uterine pregnancy, and in the former there is a portion of decidua lying under the spongy layer that maintains the appearance of the normal, non-pregnant mucosa. In extra-uterine pregnancy the vessels are markedly enlarged and lie near the surface of the decidua, their rupture accounting for the uterine hemorrhage so frequent in this condition.

Soon after the death of the fœtus the uterine decidua is cast off, either as a whole or in small pieces, a phenomenon said to possess considerable diagnostic importance.

Decidua Vera in the Tube.—The opinion of all of the earlier writers on extra-uterine pregnancy was that a definite decidua vera was developed in the pregnant tubes. In 1891 Bland Sutton denied its existence, and since then there have been many conflicting statements regarding it. If one expects to find a distinct decidual membrane in the pregnant tube analogous to that found in the uterus one will be disappointed, as it does not occur as such; but beyond any possible doubt changes take place in the connective-tissue stroma cells of the tubal folds by which they are converted into cells morphologically similar to the decidual cells in the uterus. This change does not take place throughout the entire length of the tube, but only in discrete patches, and undoubtedly a great part of the tissue which has been described as decidual is in reality fœtal ectoderm. In the specimens of Williams the decidual changes are beautifully shown and the distinct transition from a connective-tissue to a decidual cell can be traced.

The view that a decidua forms in the tube has been materially strengthened by the discovery of analogous changes in the opposite non-pregnant tube, so that at present we cannot deny that a decidua vera is formed, although not to the same extent as in the uterus. The specimens of Williams also show that the columnar epithelium of the tube becomes flattened out just as it does in the uterus.

Decidua Serotina and Reflexa.—From what has just been said, it is evident that the decidua serotina does not reach the same state of development in the tube that it does in the uterus, and undoubtedly that which has so frequently been described as serotina is nothing more than a mass of fœtal ectoderm or "Zellschicht." Careful examination, however, at the point of attachment of the ovum will enable one to differentiate between three varieties of cells, viz., syncytium, "Zellschicht," and true decidual cells.

The same may be said of the reflexa—*i.e.*, while undoubtedly present it never reaches the same stage of development that it does in the uterus. Its existence has been denied by many, but if one examines a carefully prepared intact specimen, one finds a thin layer of tissue separating the ovum from the lumen of the tube. This band of tissue is usually covered on its outer side by flattened tubal epithelium; it contains few if any true typical decidual cells. The cells in this situation can be identified with "Zellschicht" cells, and as pregnancy advances marked degenerative changes in them are seen to occur.

This appearance, particularly in early pregnancy, has led to a number of different explanations: for example, that two tubal folds had grown over the ovum, or that the pregnancy had taken place in an accessory tube lumen. The question has lately been entirely cleared up by the monograph of Peters, in which he describes a young ovum in the uterus (certainly the earliest one as yet described) in which the reflexa has not yet closed over the ovum. Peters is of the opinion that the ovum burrows beneath the epithelium of the endometrium which then closes over it, and there is every reason to believe that the same process occurs on the tube.

Placenta.—Except for the difference in the structure of the tube wall and uterus, and the difference in the formation of the decidua, the structure of the placenta in tubal pregnancy does not differ materially from that in uterine pregnancy. The chorionic villi, not being separated from the muscularis and vessels by a thick layer of serotina, invade more deeply and quickly the tube wall and open up the vessels, thus accounting for the hemorrhage and early tubal abortion. The villi themselves present practically the same appearance in extra- as in intra-uterine pregnancy, their stroma is made up of a loose mucoid connective tissue, and in early cases one can distinguish two layers of epithelium—"Zellschicht" and syncytium. When a villus comes in contact with the serotina its behavior is the same in the tube as in the uterus; viz., there is marked proliferation of the "Zellschicht" at the point of contact, resulting in the formation of a "cell node." If abortion does not occur at an early period, a definite intervillous circulation is established, the intervillous spaces being lined with syncytium just as in uterine pregnancy. The old view that in certain instances the placenta continues to grow after the death of the fœtus is now scarcely tenable.

SYMPTOMS.—The symptoms of an early unruptured extra-uterine pregnancy are by no means characteristic, and frequently one has no idea of the existence of the condition until rupture takes place and the patient is in a state of collapse.

The patient usually considers that she is beginning an ordinary uterine pregnancy, and has the usual subjective symptoms of that condition. There is not uncommonly some pain in one or the other ovarian regions, but usually of so slight significance as not to alarm either the patient or her friends. Menstrual suppression, while not the rule, sometimes occurs. Statistics show that the menses persist in about forty-three per cent. of the cases.

If the fœtus dies at an early period—*i.e.*, before rupture or tubal abortion—there is usually a discharge of blood from the uterus. This may be mistaken for the return of a delayed menstrual period or an early abortion.

In the majority of cases the first indication of anything being wrong is the occurrence of a sharp, lancinating pain in the ovarian region, followed soon by signs of collapse. When collapse occurs it is usually the result of intraperitoneal hemorrhage, either from a rent in the tube wall or from the fimbriated extremity after tubal abortion, and it is readily seen how, unless immediate relief be obtained, the collapse may become deeper and deeper and the individual finally bleed to death into her peritoneal cavity. On the other hand, the hemorrhage may not be of sufficient extent to be fatal, and here the result will be a retro-uterine hæmatocele.

If the hemorrhage is severe the symptoms are those of collapse—weak, rapid pulse, subnormal temperature, pallor, etc.,—while in those cases in which the hemorrhage is slight and is followed by the formation of an hæmatocele, we have a general improvement of the symptoms. The present opinion is that by far the majority of pelvic hæmatoceles are the result of an extra-uterine pregnancy.

Hæmatocele usually is the result of tubal abortion and not of tubal rupture, and according as the hæmatocele occupies the greater part of the pelvis or forms a smaller mass on the region of the fimbriated end of the tube we can differentiate between diffuse and solitary pelvic hæmatoceles. In the former case adhesions of the pelvic viscera are necessary to prevent the escape of the blood into the general peritoneal cavity, but not in the case of the latter, for according to Sänger the solitary hæmatocele is the result of a gradual dripping of blood from the fimbriated end of the tube. The formation of an hæmatocele is almost always a favorable termination for extra-uterine pregnancy, for in this way the acute hemorrhage is checked. However, cases have been reported in which the hemorrhage at the centre of the mass continues, finally causing its rupture into the peritoneal cavity and death. Another unfavorable termination of hæmatocele is suppuration.

Occasionally the patient does not succumb to the first loss of blood, and here, if the placenta is not entirely separated from its attachment to the tube wall, a secondary abdominal pregnancy will result. In such a case the ordinary symptoms of pregnancy will continue, possibly with an abnormal amount of pain.

In a small number of cases rupture may occur between the folds of the broad ligament, and further development go on only to rupture again into the peritoneal cavity; then the fœtus becomes abdominal while the placenta remains between the folds of the broad ligament. Term may be reached in such an instance.

When a patient with a secondary abdominal pregnancy reaches term, what is known as false or spurious labor sets in, during which there are distinct contractions similar to those occurring in the early stages of normal labor. The contractions, however, are not of the gestation sac, for this structure contains so few muscle fibres that its contraction is a matter of impossibility; but the contracting organ is the uterus. False labor continues for several days and during that time the child dies. After fœtal death the placental circulation becomes obliterated; the fœtal sac shrinks and becomes closely applied over the body of the child, which then undergoes one of the changes above mentioned. The abdomen here of course becomes smaller, a symptom which is usually noticed by the patient.

In certain instances the extra-uterine pregnancy may exist at the same time as an intra-uterine one. Parry pointed out the frequency of this occurrence and found that it occurred 22 times in 500 cases. To his 22 cases Williams has recently added others, making the present number of reported cases 49. Parry called the conditions "combined pregnancy." More rarely twin extra-uterine pregnancy has been noted, and in very rare cases both fœtuses were in the same tube.

Repeated tubal pregnancy has been observed and reported in a number of instances. Williams has collected a total of sixty-six such cases in which the diagnosis has been confirmed at operation or autopsy. This phenomenon has been utilized by certain observers to explain points in the etiology of the affection. The anatomical findings, however, have not been uniform, and little information has been gained from this source.

Diagnosis.—The symptoms of an early unruptured extra-uterine pregnancy are so uncertain that they render a diagnosis at this stage almost an impossibility. Tait made the statement that it was impossible to make a diagnosis, and most operators agree with him. In rare cases a diagnosis of the condition is made, but it is almost the rule that after such a diagnosis the operator finds the mass in question to be either an inflamed tube or a small ovarian cyst.

The diagnosis would be based upon the following symptoms: A patient who had been sterile for some time thinks herself pregnant, having the usual subjective symptoms, with possibly an abnormal amount of pain in the ovarian region. If such a patient were the subject of a tubal pregnancy, on examination the uterus would be found to be enlarged and somewhat soft and boggy, and off to one side there would be a small pulsating (?) tumor roughly the size of the supposed pregnancy. But as has already been said, it is common to find after such a diagnosis (?) that the mass is of other than the suspected nature. Taylor has called attention to the fact that the pregnant tube may prolapse into the cul-de-sac of Douglas and give one the impression of a retroflexed pregnant uterus—a statement proven by the fact that several cases have been reported in which rupture of the tube followed an attempt to replace that which was thought to be the fundus.

According to Williams, Veit in Germany in 1883 and Janvrin in this country in 1888 were the first to confirm by abdominal section the diagnosis of unruptured tubal pregnancy. This state of affairs is very rare, the writer never having seen a case in a considerable experience as resident obstetrician in the Johns Hopkins Hospital, and he knows of only one case in the hands of a colleague (Upham, of Columbus, Ohio).

If the fœtus die before rupture of the tube a diagnosis is still very difficult, such cases usually being taken for uterine abortion associated with an inflammatory tubal mass. The source of error is that when the fœtus dies the uterine decidua is cast off in shreds giving the appearance of the discharge of a normally implanted ovum.

Most observers believe that the discharge of a more or less complete decidual cast of the uterine cavity is an infallible sign of extra-uterine pregnancy. The fallacy of this sign is shown, however, by the fact that, relying on this sign alone, some operators (Griffith and Dolan) have opened the abdomen only to find it free from abnormality, or that the supposed extra-uterine pregnancy had been simulated by a small ovarian cyst.

It has been advised that the uterus be curetted for diagnostic purposes, the presence of decidua on the scrapings affording conclusive evidence as to the existence of extra-uterine pregnancy; but as the decidua may have been cast off early in the pregnancy, the discharge being considered by the patient to be a menstrual period, the uncertainty of this procedure is obvious.

A probable diagnosis after death of the fœtus and before rupture can be made in some cases by a careful sifting of the history of the case and by an examination of the patient. For example, she thinks herself pregnant; she has discharged shreds of tissue which may have been decidual. If now an enlarged uterus is found with a small mass on one side corresponding in size to the supposed duration of the pregnancy, a fairly probable diagnosis can be made.

At the occurrence of rupture or of tubal abortion with intraperitoneal hemorrhage, the symptoms are so characteristic that an almost certain diagnosis can be made even without an examination. The patient may or may not have given the above history when suddenly, with a sharp attack of pain in the ovarian region, she goes into a condition of collapse, with weak rapid pulse, pallor, subnormal temperature, etc. Vaginal examination here usually reveals but little, as the patient is too sensitive to allow a thorough exploration. A crepitating sensation may be imparted to the examining finger in the cul-de-sac, due to pressure upon recently clotted blood. With the above symptoms the diagnosis of ruptured tubal pregnancy is practically a certainty, and if not speedily relieved by operation the patient will die. If she recover from the collapse the probabilities are that a tubal abortion has taken place and that the hemorrhage has been checked by the formation of a pelvic hæmatocele.

As tubal rupture may occur very early in pregnancy, even before the patient has thought herself pregnant, one should always regard collapse with signs of intraperitonal hemorrhage as strong probabilities in favor of ruptured extra-uterine pregnancy; and in such a case only by acting promptly can the life of the patient be saved.

If, as is often the case, she is not seen until after primary rupture, examination will reveal a large tumor filling the posterior portion of the pelvis, and an exploratory puncture through the posterior vaginal fornix will render the diagnosis certain.

In cases in which the fœtus has survived the damage done at the time of primary rupture and has continued to develop in the abdominal cavity or in a gestation sac, the diagnosis is not usually made, because our attention is not directed to the fact of early rupture, and it is not until false labor sets in that our suspicions arise as to the child's not being in the uterine cavity. If careful examination be made, however, the condition should offer little difficulty; the child is found to be more easily palpable than normal, its movements give the mother a certain amount of pain, and by bimanual examination the uterus is found to be practically normal in size. If an hæmatocele has formed between the folds of the broad ligament, the mass will lie largely in the small pelvis and the uterus will be pushed over to one side.

When an extra- and an intra-uterine pregnancy occur together and have reached term, the diagnosis of twins has usually been made, and it is not until the cause of delay in the birth of the second child is investigated that its extra-uterine existence is noted.

TREATMENT.—*Before Rupture.*—When an extra-uterine pregnancy is diagnosed before rupture, it must be regarded as a malignant growth and removed by laparotomy as soon as possible. This procedure cannot be too urgently advised, for until it is removed the patient is in imminent danger of a fatal rupture. All methods which have as their end the destruction of the fœtus, such as electricity or the injection of medicinal substances, are to be strongly condemned; for, as we know, even the death of the child does not preclude the possibility of rupture of the tube. However, from what has already been said, it is apparent that such a line of treatment will rarely be thought of owing to the uncertainty of diagnosis at this time.

After Rupture.—Although laparotomy was advised some years ago for the removal of a ruptured tube, operators were not willing to accept this plan of treatment until Tait demonstrated the ease with which the diseased tube could be removed and hemorrhage checked. This method is now almost universally employed, and all of us can recall numerous instances in which life has been saved by it.

The diagnosis of ruptured tube and intraperitoneal hemorrhage once having been made by the very characteristic symptoms already discussed, the abdomen must immediately be opened (unless the degree of collapse is so great that the patient is moribund when first seen). Then immediately afterward long clamps are to be passed down into the pelvis and applied on both sides of the tubal mass. This will at once check all hemorrhage, and the injured tube can be excised without unnecessary haste. If the peritoneal cavity is filled with clotted blood which obscures the field of operation, the clamps must be applied by the sense of touch alone.

An excellent method of counteracting the effect of the loss of blood is by the infusion of normal salt solution. This can be done during the operation and the infusion allowed to run into the submammary subcutaneous tissue or injected directly into the circulation.

In tubal abortion some operators have made the attempt to save the affected tube. The advisability of such an attempt appears to be of doubtful nature, as it has not been proven that the tube once affected ever regains its functional activity.

Operation through the vagina has lately been advised and even now has many adherents. As it has many obvious disadvantages, it is mentioned here only to be condemned. Among the disadvantages may be mentioned the small field of operation in the vaginal method as compared to the large one in the abdominal, and the frequent necessity of having to open the abdomen to arrest hemorrhage which has been started in the vaginal operation.

Hæmatocele.—It has been shown that the majority of cases of pelvic hæmatocele undergo spontaneous cure and rarely require operation. Thorn reports 157 cases, in only 6 of which was operation thought necessary, the rest having been treated by careful watching and rest in bed. The total mortality here was only six-tenths of one per cent. Fehling has reported 91 cases, treated in a similar manner, without a single death. A disadvantage of the method, however, is that it is extremely slow and the patients have to remain many weeks in bed.

On the other hand, there are certain conditions which render operation imperative in cases of hæmatocele: such indications as rapid increase in the size of the tumor, signs of suppuration, or pressure on important organs. When such conditions are present the hæmatocele is best attacked by way of the vagina. An incision is made through the posterior vaginal wall, the clot is evacuated, and the cavity is at once packed with sterile gauze. This usually gives most excellent results, but all operators agree that it is frequently necessary to open the abdomen in order to check hemorrhage that cannot be controlled by the pack; therefore one should always have the abdomen prepared for a laparotomy before making the vaginal incision.

Treatment during the Latter Months of Pregnancy.—Occasionally in the latter half of pregnancy we shall find the fœtus enclosed in a large tubal or ovarian sac; more commonly, however, the fœtus has escaped through the rent in the tube wall and we have to deal with a secondary abdominal pregnancy in which the placenta is attached to the pelvic floor while the fœtus lies free. In such cases, as there is always danger of a secondary rupture, prompt laparotomy is indicated. If the child is within a few weeks of viability some have advised a waiting policy, thus giving the child a chance that it would not have were immediate operation done. If such a course be decided upon the dangers to the mother should always be explained to the family.

As to the best method of operating in such cases, unquestionably the ideal procedure is to open the abdomen and remove the entire gestation sac; but frequently, on account of adhesions to neighboring organs, such a course is inadvisable, and here the sac should be incised, care being taken to avoid wounding the placenta if possible. Then the child should be removed and the edges of the sac should be stitched to the margins of the abdominal wound, the cavity being packed with gauze and the placenta allowed to come away piecemeal. This entails a longer convalescence, but on the whole is better than endangering the life of the patient by attempting to remove an adherent placenta. In certain cases this plan cannot be carried out, and then the entire sac must be removed no matter how serious the procedure may seem.

When the fœtus dies the danger to the mother materially diminishes, for, when the fœtal circulation ceases, the hemorrhage from the placental site is not so much to be feared. If a diagnosis of the death of the child be made, operation should be deferred for a short time in order to favor closure of the maternal blood spaces and separation of the placenta; it being understood, however, that immediate operation may be necessary at any time.

George W. Dobbin.

EXUDATION, PATHOLOGICAL.—One of the chief phenomena of inflammation is the passage of a portion of the fluid and cellular constituents of the blood from the blood-vessels into the tissue spaces or out upon one of the free surfaces of the body. This process is known as exudation, and the fluid and cells which have left the vessels as an exudate. *Exudation* is distinguished from *transudation* in that it is always a part of an inflammatory process, while the latter term is commonly restricted in its application to an increase in the formation of lymph not due to inflammation, but dependent upon changes in blood pressure, alterations in the blood, or in the vessel wall which favor an increased lymph production (œdema). *Exudates* differ from *transudates* in their higher albumen content, higher specific gravity (1.016–1.025), and their greater richness in cellular elements. Transudates have a low specific gravity (1.006–1.008, rarely reaching 1.012), contain but few cells, and differ but little in their composition from that of normal lymph, their albumen content being very slight, sometimes lower and sometimes slightly higher than that of lymph. Exudates are usually turbid from the large number of leucocytes contained in them, while transudates are usually clear or but slightly cloudy.

The source of both the fluid and the cellular constituents of exudates is the blood, and the escape of these from the vessels is due to some alteration in the vascular walls which forms an essential part of the inflammatory process. Evidences of this alteration are seen in the dilatation of the vessels, the increased resistance offered to the blood current with consequent slowing of the circulation, the increased adhesion of the cellular elements of the blood to the vessel wall, and, most important of all, the increased permeability of the walls. The composition of the exudate is therefore dependent upon the degree of pathological alteration as well as upon the peculiar property of the affected vessel. The greater the injury the greater the exudate and the amount of albumen and cellular elements contained in it. Moreover, since the properties of the blood-vessel walls differ in different regions of the body, the character of inflammatory exudates in different parts will also vary; thus the albumen content of pericardial and pleural exudates is higher as a rule than that of peritoneal. Exudates differ further in the proportionate amounts of the various blood elements contained in them. In one case the exudate may be almost entirely fluid with a very small number of cells (serous exudate); in another, the leucocytes may be so numerous as to give the exudate a more or less thick, creamy appearance (purulent exudate); or the escaped fluid may contain large amounts of fibrinogen and fibrin ferment (fibrinous exudate). Further, many red blood cells may escape by rhexis or diapedesis (hemorrhagic exudate), or large numbers of blood plates may be present in the exudate. Combined characteristics exist, so some exudates may be properly styled sero-fibrinous, sero-purulent, fibrino-purulent, etc. Besides the blood constituents inflammatory exudates also contain tissue débris, fluids arising from cellular liquefaction and degeneration, etc. The high proportion of albumen in many exudates is due partly to proteids derived from cellular destruction. In exudates there may be contained also poisons arising from tissue destruction or, in infective inflammations, from the growth of micro-organisms; the bacteria themselves, and cells arising from the proliferation of fixed cells of the tissue, may likewise be present.

The various problems regarding the manner of escape of the exudate from the blood-vessels have offered abundant scope for investigation and speculation, and a survey of the various theories evolved to solve these problems forms one of the most interesting historical chapters in the development of pathology. The existence of pathological exudates was very early recognized. Rokitansky believed that they arose from an increased permeability of the wall of the vessels due to thinning from overdistention. Vogel, Paget, and others explained their formation as being due to an increased attraction between the tissues and the elements of the blood. Virchow distinguished two kinds of exudates: one the result of mechanical pressure in the vessels, pressed-out blood serum; the second as nutritive, the result of an increased attraction between the tissues and blood constituents. The cellular portion of the exudate he believed to originate from a proliferation of the tissue cells in the inflamed area.

Dutrochet in 1842 and Waller in 1846 first observed the migration of leucocytes from the vessels, but these observations were forgotten until Cohnheim in 1867 rediscovered the phenomenon. This observer affirmed that the passage of leucocytes from the vessels formed the essential feature of inflammatory exudation; that the cells in inflamed areas did not arise from the tissue cells; and he explained the origin of the fluid portion of the exudate as due to a molecular change in the vessel wall. This view was opposed by many, notably Stricker, who held that the greater part of the cells in inflammatory exudates were not leucocytes but new cells arising out of the inflamed tissue, pus cells therefore taking their origin from connective-tissue cells.

Heitzmann believed also that the cells of the exudate were not leucocytes, but were embryonic cells arising from the softened or dissolved intercellular substance. More recently Grawitz has taken a similar position, in that he declares the cells of the exudate to arise from so-called "slumbering cells" in the intercellular substance of connective tissue which under normal conditions are not visible. The views of Stricker, Heitzmann, and Grawitz find little acceptance at the present time, the almost universally accepted opinion being that the chief part of the cells of inflammatory exudates at least arises from the blood.

Heidenhain explains the formation of lymph as a process of secretion on the part of the cells of the vessel walls and not as a pure filtration process. Pathological stimulation of this process or alterations in the vascular walls will change the amount and character of this secretion. A portion of the fluid of exudates at least must be regarded as being of the nature of a pathological cell secretion. According to Arnold, Thoma, and Engelmann the formation of the exudate is due chiefly to changes in the lines of cement substance lying between the endothelial cells of the vessel wall. Through distention of the vessel the cement substance may be so thinned as to form small openings through which both fluid and cellular elements escape. Other writers hold that the escape of the leucocytes is not due to alterations in the vascular walls but to chemotactic influences acting from outside of the vessels and causing the cells to pass through the wall.

At the present time the exact nature of the process by which exudates are formed cannot be said to be definitely fixed. The most commonly accepted view is that the chief part of the fluid and cellular elements comes from the blood, and that both pathological secretion and alterations in the wall, as well as chemotaxis, play parts in the formation of the exudate. The escape of the leucocytes is considered an active process brought about by means of their amœboid power in response to chemotactic stimuli. In the very earliest stages of the inflammatory process the cells of the exudate are wholly leucocytes; later, tissue proliferation begins and a part of the cells of the exudate may thus be derived from tissue cells.

Recently much attention has been given to the closer study of the leucocytes found in exudates. Lubarsch divides the cells of inflammatory exudates into hæmotogenous wandering cells and histogenic wandering cells, in the former case descendants of immigrated cells, in the latter arising from fixed connective-tissue cells. The relative proportion of these cells varies in different forms of inflammation, and in different stages of the same form; but the immigration of leucocytes forms the most prominent feature of the majority of inflammations. Until recently it was affirmed that the migrating leucocytes were chiefly polynuclear forms and that these only possessed the power of active movement. Welch, Councilman, and others have shown that lymphoid cells may also migrate, a fact which was formerly denied. The so-called plasma cell also appears to play an important rôle in many exudates, particularly those of chronic inflammation. This cell is now believed by the majority of writers to be of hæmatogenous origin, most probably a form of lymphocyte. It is characterized by a protoplasm staining blue with methylene blue, an eccentrically placed nucleus, a perinuclear clear space, and a nucleus possessing a number of coarse particles of chromatin arranged on the inner surface of the nuclear membrane. Plasma cells occur in large numbers in the cellular exudate of chronic inflammations, particularly, as Councilman has shown, in the interstitial nephritis of scarlatina. This observer believes that they are lymphocytes which migrate as such or as plasma cells from the blood, and multiply outside of the vessels in response to chemotactic stimuli. It would appear, then, that there are selective chemotactic stimuli; part influencing the migration of lymphoid and plasma cells, part the polynuclears or other varieties of leucocytes. Some exudates contain large numbers of eosinophiles and mast cells, but the significance of such occurrence is not yet known.

Wieniarski confirms the assertion of Korczynski and Wernicki that lymphocytes predominate in exudates not due to malignant disease or showing a tendency to become purulent. When neutrophile polynuclears predominate the exudate is caused either by malignant disease or by pus-forming agents. According to these observers the presence of eosinophile cells and red blood cells in exudates is without significance. In pleural and peritoneal transudates the cells are almost exclusively lymphocytes; in pleural exudates of serous nature they are also lymphocytes; the predominance of polynuclears always indicating a purulent process in case no malignant disease is present. In one case in which but few leucocytes were present in the exudate, but these all polynuclears, a purulent exudate developed later; in another case in which 6,230 lymphocytes were present in a cubic millimetre of the exudate the inflammation did not become purulent in character. The same facts apply also to peritoneal exudates. In serous pleural exudates the number of lymphocytes varies from 270 to 9,270 per cubic millimetre, in transudates from 60 to 300. In peritoneal transudates even smaller numbers of lymphocytes are usually present. During the absorption of exudates the number of leucocytes increases; during fibrinous exudation they are found in smaller numbers. Much work yet remains to be done along this line, as many important problems regarding the fate of the migrated cells have yet to be settled.

The fluid and cellular exudates from the vessels collect first around these, but soon spread into the lymph spaces of the neighboring tissues forming an infiltration. If the exudate is very abundant the neighboring healthy tissue may be infiltrated to such an extent that it may be damaged and the inflammatory process spread. The tissue elements may absorb a portion of the exudate, and become swollen or vacuolated; or all of the tissues may become dissolved in the exudate. If fibrinogen and fibrin ferment are present, coagulation may take place either before or after liquefaction of the affected tissue takes place. Open spaces in the tissues, such as the lung alveoli, may become filled with the exudate; if the inflammation involves a body surface the exudate may either collect in one of the body cavities or be discharged from a free surface.

The first pathological changes which find expression in the formation of a pathological exudate are vascular phenomena which are due either to irritation or paralysis of the vaso-motor system, or to a direct action upon the walls of the vessels themselves, the result in either case being a dilatation of the vessel. This change may, however, take place without the production of an exudate, but it always precedes exudate formation when the latter occurs. Following the dilatation of the vessel there is a slowing of the blood stream and with this a marginal collection of the leucocytes along the vessel wall; and finally diapedesis of the cellular elements takes place simultaneously with the passing out of the fluid portion of the exudate. The passage of the leucocytes is an active process accomplished by means of amœboid movement, and is only an increased degree of a process which takes place to a limited extent normally (wandering cells). The cause of the increased diapedesis of leucocytes in inflammation is probably partly chemotaxis and partly changes in the vessel wall. According to Arnold and Thoma the leucocytes pass through the endothelial cement substance which is stretched and thinned by the distention of the vessel. The leucocyte first sends a process through the thinned portion of the wall, and through the opening thus made the remainder of the cell body slips after. Through the opening formed in this manner the red blood cells and fluid elements of the blood may also pass.

The passage of a serous exudate into a body cavity, as the pleural or peritoneal, is spoken of as a serous effusion. Serous exudates on mucous membranes are styled catarrhs; localized collections of fluid beneath the horny layer of the skin are blisters, vesicles, bullæ, or blebs. The serous infiltration of tissue spaces is an inflammatory œdema. On mucous surfaces serous exudates may contain a large percentage of mucin derived from mucous degeneration of the epithelium (mucous catarrh); or a loosening of the epithelium into the exudate may occur (desquamative catarrh). If flakes of fibrin are formed in the exudate it may be styled sero-fibrinous; if the number of leucocytes is so great as to make the fluid slightly turbid, sero-purulent.

Fibrinous exudates occur either upon mucous or serous surfaces, into the lung alveoli, or into tissue spaces. On mucous membranes they form whitish or grayish croupous or diphtheritic membranes which are either loosely or firmly adherent to the tissues beneath. These membranes are made up chiefly of granular or fibro-granular fibrin, occasionally in coarse bands or hyaline masses. In fibrinous effusions large masses of stringy fibrin may float in the exudate, while the serous surface may be covered with a thick layer of stringy fibrin, or in mild cases only small strings or flakes may be scattered over the surface. In the lung the alveolar spaces may be completely filled with a network of fine fibrin fibrillæ enclosing leucocytes, red blood cells, and desquamated epithelial cells in its meshes. In the kidneys fibrillar or hyaline fibrin may be found in the tubules. In the follicles of the spleen and lymph glands the spaces between the cells may be filled with a fibrinous exudate. The intercellular spaces in tubercles are also commonly filled with an exudate of fibrin. According to Neumann the fibrinous material found in certain inflammations of serous membranes is not an exudate, but the result of a "fibrinoid degeneration" of the superficial connective tissue of the membrane. This theory is not supported by the actual findings, and has not been generally accepted.

If the inflammatory exudate contains a large number of leucocytes, but not in a sufficient number to cover up the structure of the tissue, it is spoken of as a small-celled infiltration. When the leucocytes in the exudate are so numerous as to give it a white or creamy appearance it is called pus; such an exudate on mucous membranes is a purulent catarrh; in the body cavities a purulent effusion or empyema. Purulent vesicles are styled pustules; deep-seated purulent exudates, abscesses. Seropurulent exudates may infiltrate the tissues (purulent œdema). Fibrin is a very frequent accompaniment of purulent exudates (fibrino-purulent exudate); and the inflammations of serous membranes usually produce exudates of this kind. Usually with an increase of pus formation the amount of fibrin decreases and the fibrin masses present in the exudate begin to dissolve. Fibrin coagula infiltrated with leucocytes become white and friable. The presence of large numbers of red blood cells (hemorrhagic exudate) and blood plates is found usually in association with fibrinous exudation, but they may also be present in serous inflammations.

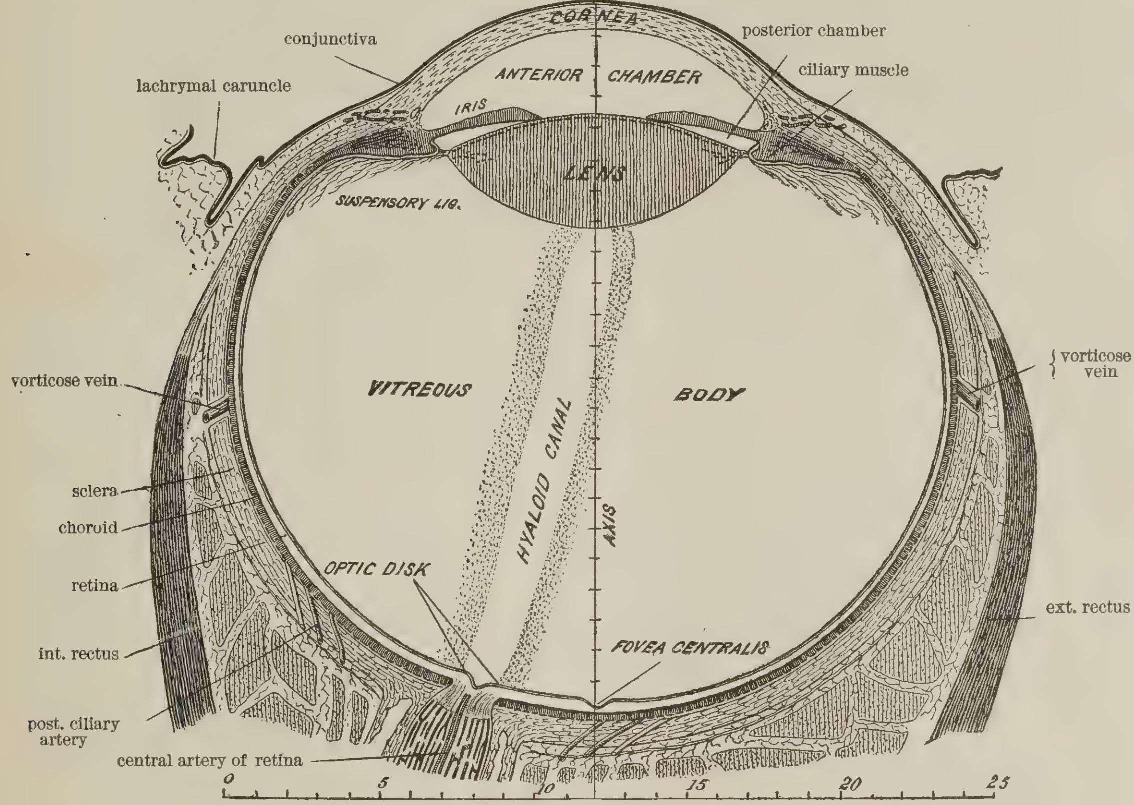
The exciting causes of pathological exudation are those of inflammations in general. Serous, sero-fibrinous, and fibrinous exudates may be caused by thermal and chemical means; but are most frequently due to infection with the Diplococcus pneumoniæ, Bacillus diphtheriæ, and the Streptococcus pyogenes. Purulent exudates may also be caused by chemical action, but are most frequently the result of infection by the Streptococcus pyogenes, the staphylococci, gonococcus, etc. After the causes which have produced them cease to operate exudates are discharged from the body, absorbed, organized, or under certain conditions encapsulated and calcified. In the processes of repair and organization it is possible that the exudate may serve as a source of nutriment for the new-formed tissue cells.

The significance of pathological exudations is practically that of inflammation in general. The old view, and the one still commonly accepted by clinicians, is that they are essentially harmful. From the pathological side, however, inflammation must be regarded as a reaction on the part of the body to local injuries, having for its purpose protection and repair. Though both protective and reparative measures may be imperfectly carried out and even many times in themselves cause further damage, it must be granted that inflammation is essentially an attempt at self-preservation. In this attempt the constituents of the exudate, both cellular and fluid, play the chief part. The leucocytes of the exudate act as phagocytes and as sources of bactericidal and antitoxic substances, or may even furnish nutriment to formative tissue. The fluids of the exudate likewise possess important germicidal and antitoxic powers; they serve further as diluting and irrigating agents; and may also carry nutriment to the newly forming cells. Even fibrinous exudates may serve a beneficial purpose in limiting the action of bacteria. Masses of leucocytes may also form mechanical barriers to the spread of germ growth.

In the exudate we therefore find the means of counteracting or destroying harmful agents, neutralizing their poisons, protecting the organism, and aiding in healing. But in the attempt to fulfil these functions exudates may in themselves create new conditions that may damage the body. The pressure upon the brain of meningeal exudates, the disturbance of respiration and heart's action by pleural and pericardial effusions, the closure of the glottis from inflammatory infiltration, etc., are examples of the imperfect adaptation of the process, which though in the main intended to be beneficial may often overreach its aim.

(See also *Inflammation.*) *Aldred Scott Warthin.*

EYE.—General Arrangement.—The eyeball (see Fig. 1952) is a spheroidal expansion attached to the end of the optic nerve, optically equivalent to a camera obscura and filled with fluid or semifluid contents. It has three concentric envelopes or coats: an outer one, protective in character, formed of fibrous tissue, called the *sclera* behind, where it is white and opaque, and the *cornea* in front, where it is clear and transparent; a middle one, nutritive in character, composed of vascular tissue intermingled with pigment, called the *choroid* behind, in front assisting to form the *iris* or diaphragm which regulates the admission of light through a central aperture, the *pupil;* an inner one, percipient in character, formed of nervous elements and called the *retina.*



Scale of millimetres.

Fig. 1952.—Diagram of Horizontal Section of Eyeball Drawn to an Accurate Scale. (Flemming.)

The rays of light that pass through the pupil are focussed dioptrically by the refractive action of a clear, lenticular body, the *crystalline lens,* which is set behind the iris and divides the cavity of the eyeball into two compartments or chambers: the *aqueous chamber,* situated in front and containing a watery fluid called the *aqueous humor,* and the *vitreous chamber* behind, containing the semifluid *vitreous humor* or *body.* The aqueous chamber is subdivided by the iris; the space in front of that curtain being known as the *anterior chamber,* that between it and the lens as the *posterior chamber.*

In describing the eye terms applicable to a spheroid are used (see Figs. 1953 and 1954). The antero-posterior diameter is termed the *axis,* the ends of that diameter the *poles.* The *equator* is a line on the surface equidistant from these poles; circles and directions parallel to it are

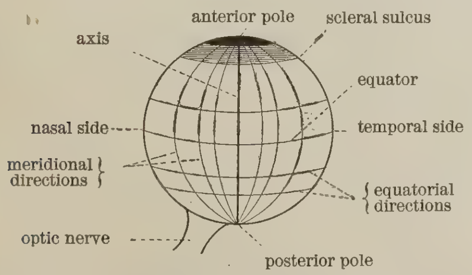


Fig. 1953.—Diagram of Right Eye, as Seen from Above, to Illustrate Terms of Orientation.

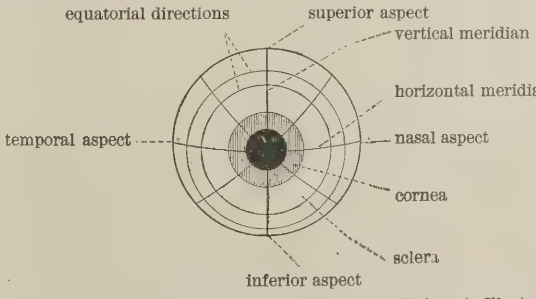

Fig. 1954.—Diagram of Right Eye, as Seen from Before, to Illustrate Terms of Orientation.

termed *equatorial.* Circles drawn from pole to pole are termed *meridians,* directions along these are *meridional.* Any half of the ocular globe is called a *hemisphere,* any fourth a *quadrant.* The lateral aspects of the globe are distinguished as *temporal* and *nasal.*

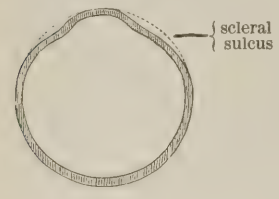

FIG. 1955.—The Eyeball Compared with a Sphere.

The eyeball is not a perfect sphere. Its antero-posterior diameter averages 24.2 mm., its transverse diameter 23.6 mm., and its vertical diameter 23.2 mm. The radius of curvature of the cornea is considerably less than that of the sclera and a slight groove, the *scleral sulcus,* separates the two (see Fig. 1955). Individual variations may lead to visual defects. An examination of the annexed figures (Figs. 1956, 1957, and 1958) will show that a lengthening of the axis of the ball may cause the rays from distant objects to focus in front of the retina, while a shortening of that axis may focus them behind it. The average weight of the eyeball is about 7 gm., its specific gravity about 1.077. At birth its weight as compared with the rest of the body is as 1 : 419; at maturity it is as 1 : 4,832.

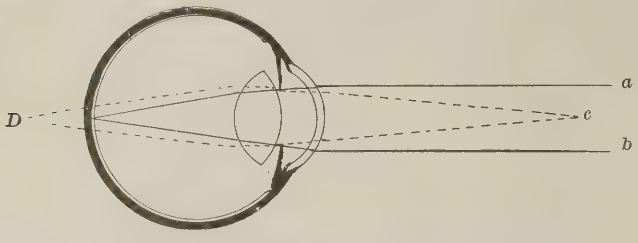

FIG. 1956.—An Emmetropic or Normal Eye. Parallel rays, *a b,* are focussed upon the retina; while divergent rays, as those proceeding from the point *c,* come to a focus *behind* the retina, as at *D.*

RELATIONS.—The eye is placed just within the margin of the pyramidal cavity of the orbit, 16 to 18 mm. from the optic foramen (Figs. 1959 and 1960), usually a little nearer to the upper margin and to the temporal side, though equidistant from the upper and lower walls at the equator (Fig. 1961). It fills about one-fifth of the cavity, the remainder being occupied by the ocular vessels, nerves and muscles, the lachrymal gland and the bulbar fascia, loose orbital fat lying in the interstices. The edge of the orbit retreats somewhat on the temporal side so that the eyeball is there somewhat more accessible for operation.

In front the eye is protected by two movable folds of integument, the eyelids, or *palpebræ,* which, when open (Fig. 1962) form an aperture known as the *rictus palpebrarum* or palpebral opening that exposes nearly the whole of the cornea and a considerable portion of the sclera. About 30 mm. in length and 12 to 15 mm. high, it is curved above and below, uniting internally and externally at the *angles* or *canthi* of the eye. The external angle is sharp, the internal rounded, forming a slight recess known as the *lachrymal bay.* It is here that are found passages for the removal of the lachrymal fluid (Fig. 1963). Two small openings, the *puncta lachrymalia,* lead into the short lachrymal ducts which discharge through the nasal duct into the inferior meatus of the nose. With horizontally directed vision the upper lid impinges slightly upon the cornea, the lower falls near its inferior edge; when looking upward a strip of sclera is visible below. The axis of the palpebral opening is slightly higher at the outer angle, but when the eyes are closed (Fig. 1964) the outer angle descends.

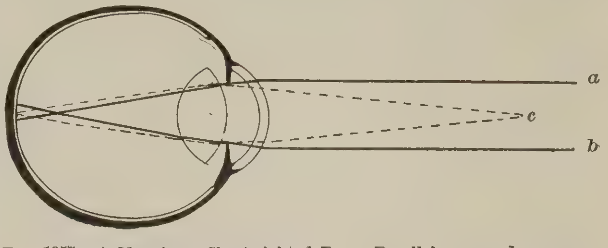

FIG. 1957.—A Myopic or Short-sighted Eye. Parallel rays, *a b,* converge before reaching the retina. Rays must be *divergent* in order to focus there.

The lids are lined by a thin epithelial membrane, the *conjunctiva,* which extends from them over the anterior surface of the ball (Fig. 1965). The

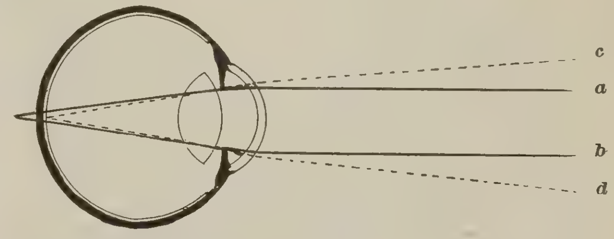

FIG. 1958.—A Hypermetropic or Far-sighted Eye. Parallel rays converge *behind* the retina. Rays must be *convergent* in order to focus there.

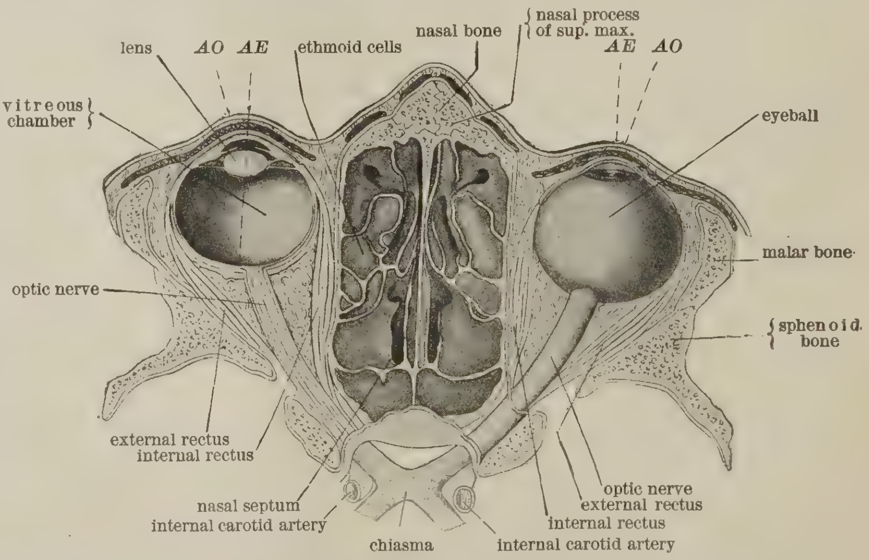

FIG. 1959.—The Eyes and Optic Nerves Seen from Above after Removal of the Roof of the Orbit. *AO,* Axis of Orbit; *AE,* axis of eye.

place of reflection is known as the *fornix* of the conjunctiva and is situated 13 mm. from the upper lid, 9 mm. from the lower one when the eyes are open. Its distance from the cornea is 10 mm. above, 8 mm. below, 14 mm. at the outer angle, and 7 mm. at the inner angle (Testut).

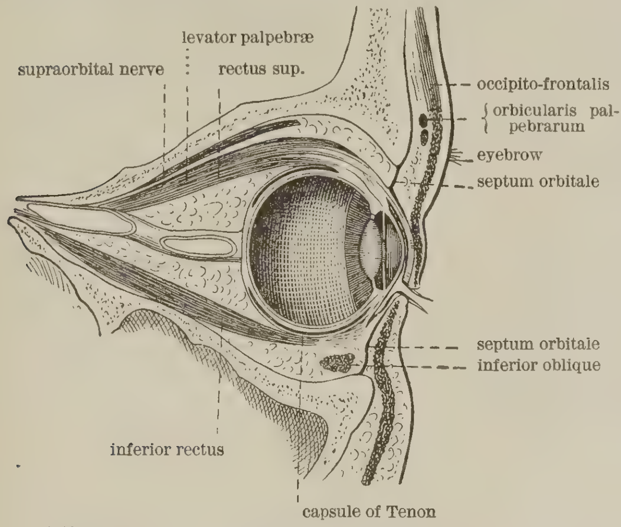

FIG. 1960.—Sagittal Section of the Visual Apparatus Through the Summit of the Cornea and the Optic Foramen. (Merkel.)

Within the orbit a thin aponeurotic sheet, the *bulbar fascia* or capsule of Tenon, separates the eyeball from the orbital fat (Fig. 1966). This invests the posterior part of the ball with two layers, one closely adherent to the sclera and sometimes called the *episclera*, the other reflected over the orbital contents. The two layers are united by fine trabeculæ, and there is between them a loose lacunar interval, the *periscleral space*, that communicates with the perineural space of the optic nerve. Processes from the bulbar fascia invest the structures that pass to the eyeball. Those that extend upon the ocular muscles are of considerable surgical importance. Extensions also pass to the fornix of the conjunctiva, to the eyelids, and to the edges of the orbit. As the latter assists to retain the contents of that cavity, it is known as the *orbital septum*.

DEVELOPMENT.—The percipient portion of the eye is, like the essential part of other organs of sense, derived, either directly or indirectly, from the ectoderm. In its simplest form, as seen in invertebrates, it consists merely of tegumentary cells, forming eye spots or retinas, surrounded by pigment and communicating by filamentous processes with nervous ganglia. Often, by a thickening of the epidermis, one or more lenses are developed in connection with these.

In vertebrates the ectodermal integument becomes infolded to form the central nervous system, and the development of the eye is more complicated. In Amphioxus there appears, toward the close of the embryonic period, on the swollen anterior end of the simple tube that forms its central nervous system, a pigmented spot that is believed to represent an eye. To this spot rays of light pass through the pellucid jelly that covers the animal externally, and, arrested by the pigment, excite directly the cells of the neural tube and apparently impart an obscure sensation of vision. In this primitive form, therefore, vision appears to be a direct function of a specialized portion of the central nervous system.

An examination of the visual organs of higher vertebrates, including man, shows that here too the essential element was primitively a portion of the central nervous system which, extending peripherally, became separated and associated with other elements to form a complicated apparatus. The retina may be regarded as a specialized portion of the cortex of the brain, the optic nerve as a fibre tract, the lens as an epithelial invagination, the cornea, sclera, choroid, and contents of the eyeball as connective-tissue derivatives.

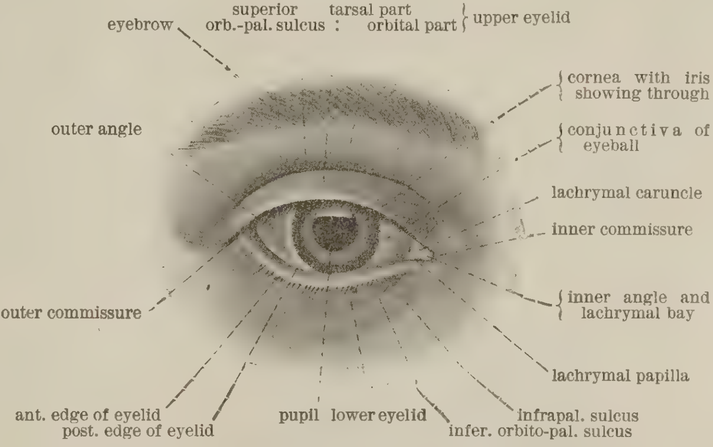

FIG. 1962.—The Eye as Seen with Lids Open. (Toldt.)

In the human embryo of three weeks (corresponding to the chick of two or three days) the central nervous system is also tubular, being formed by the approximation and gradual concrescence of the edges of a groove. The area that is to form the retina lies at first along the outer edges of the groove, in the region known as the neural crest, from which also originate the cells for the sensory nerves. The retinal cells differ from the latter in that, as the edges of the groove fold over to form the tube, they are gradually drawn in until they lie along the sides of the cavity (Fig. 1967, A, B, C, D).

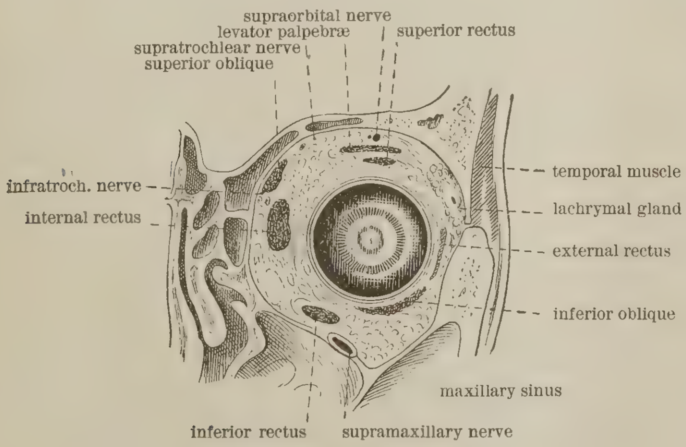

FIG. 1961.—Frontal Section of the Eyeball in the Orbit. (Merkel.)

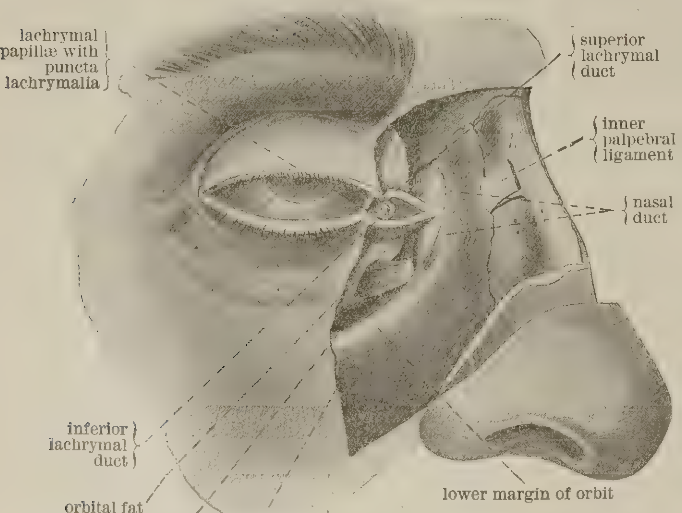

Fig. 1963.—The Lachrymal Passages.

This peculiar displacement of the cells of the retinal area is made possible by delay in the concrescence of the edges of the groove. If this occurs prematurely the fœtus develops but a single orbital cavity, a teratological phenomenon known as *cyclopia*, which differs according to the stage at which union takes place. If early, the two retinas may be fused together to form a single eye; somewhat later, the two are imperfectly united; still later, two eyes exist in a single median orbit.

At the period we are considering the neural tube shows at its cephalic end three bulbar enlargements, the primary cerebral vesicles. It is from the anterior of these, the forebrain, that are formed the parts immediately concerned with vision: the retinal areas, the optic nerves, the corpora geniculata, and the optic thalami. The forebrain now widens out laterally, forming two hollow protrusions, whose bulbar extremities, containing the retinal areas, are called the primary ocular vesicles, the constricted pedicles, from which the optic nerves are formed, being known as the optic stalks. The cavity of each still communicates freely with that of the forebrain (Figs. 1968, 1969).

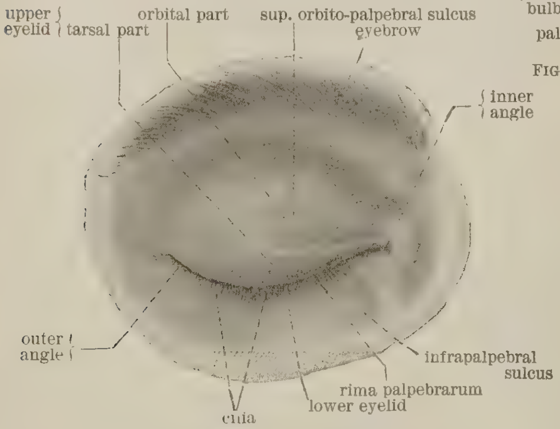

Fig. 1964.—Eyelids of Right Eye when Closed.

The ocular vesicles in their outward growth soon reach the epithelium or ectoderm of the side of the head which, at the place of contact, becomes thickened and cupped. This cupping or invagination continues until another vesicular structure is formed, the lenticular vesicle, from which develops the crystalline lens. The intrusion of the lens upon the growing end of the ocular vesicle causes the latter to assume a shape like that of a thin hollow rubber ball with a marble somewhat smaller in size pressed against its surface (Fig. 1970). Because of this change of form it is henceforth called the optic cup (secondary ocular vesicle). The successive changes are shown diagrammatically in Figs. 1971 to 1975. The edge of the cup is the future margin of the pupil; its walls are double, the inner or retinal layer being much thicker than the outer one in which pigment is deposited; they are at this stage deficient below where growth is less rapid and a fissure is thus formed, known as the choroidal cleft, through which

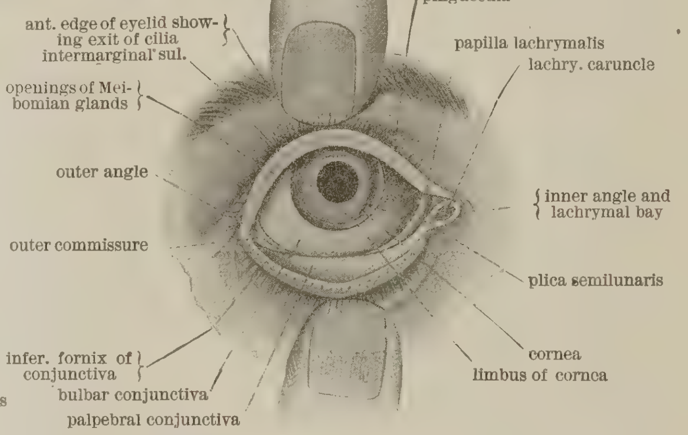

Fig. 1965.—Widely Opened Eye of an Elderly Person; Lower Lid Everted.

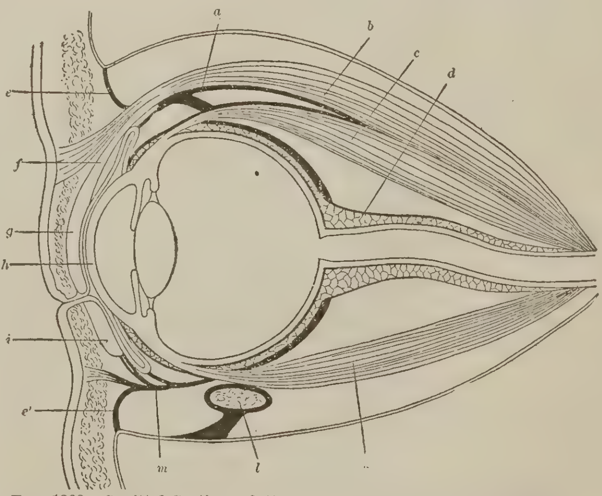

Fig. 1966.—Sagittal Section of the Eye, showing the Bulbar Fascia and its Attachments. *a*, Prolongation of bulbar fascia; *b*, levator palpebræ; *c*, rectus superior; *d*, perineural space; *e*, *e'*, septum orbitale; *f*, tendon of levator; *g*, tarsus superior; *h*, cornea; *i*, tarsus inferior; *k*, inferior rectus muscle; *l*, inferior oblique muscle; *m*, prolongation of bulbar fascia.

wandering mesenchymal cells penetrate between the retina and the lens to form the vitreous body. The interval between the layers is soon obliterated. The central artery of the retina enters the cleft back of the cup, upon the optic stalk, thus becoming finally enclosed within the optic nerve. The cleft closes early but a trace of it may often be found in the adult. If the closure is incomplete the ocular defect known as coloboma occurs, causing distortion of the pupil or a defect of the visual field.

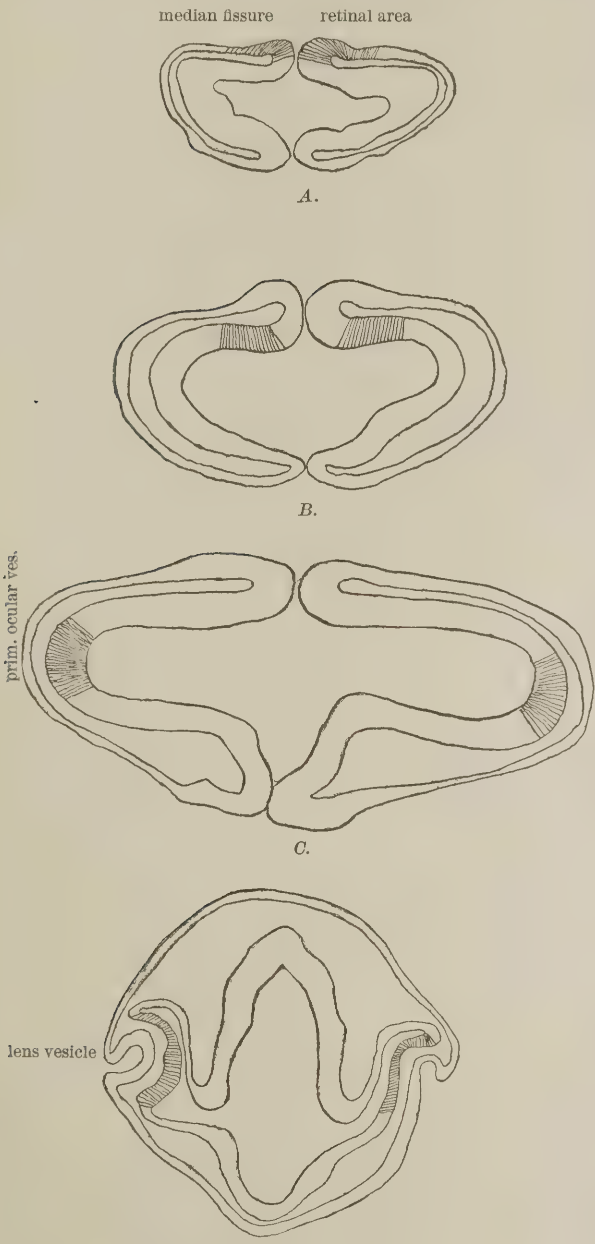

FIG. 1967.—Diagrams showing the Displacement of the Retinal Cells and their Relation to the First Cerebral Vesicle. (Dejerine.) *A* and *B* show the early development of the first primitive cerebral vesicle; *C*, the primitive ocular vesicle; *D*, the secondary ocular vesicle and the lens vesicle.

The retina develops like a part of the cerebro-spinal axis. Spongioblasts and neuroblasts arise in it, the former developing into the supporting tissue of the retina or fibres of Müller, of which the expanded bases form the internal limiting membrane, the distal, arborescent extremities the external limiting membrane in which spaces are left which eventually enclose the rods and cones. The neuroblasts appear first in the area centralis, afterward extending peripherally as far as the ora serrata. Beyond this, in the retinal layer of the ciliary region and the iris, spongioblasts alone occur. The neuroblasts develop axis-cylinder processes that grow inward along the optic stalk, gradually obliterating its cavity and constituting the optic nerve. The percipient elements (rods and cones) are the last to develop, not appearing until the fifth month in man and after birth in kittens and rabbits.

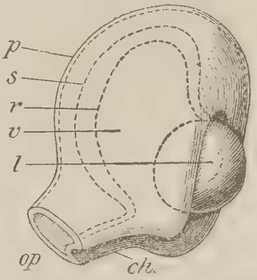

FIG. 1970.—Model showing Reconstruction of the Optic Cup. (Hortwig.) *p*, Outer wall of cup, which becomes the pigmented layer of the retina; *r*, its inner wall, which becomes the retina; *s*, temporary space between the two walls; *v*, vitreous chamber; *l*, lens; *ch*, choroid fissure; *op*, hollow stalk of cup which becomes the optic nerve.

In its early stages the lenticular vesicle is proportionately larger than at birth, filling the cavity of the optic cup so that there is but little space left between it and

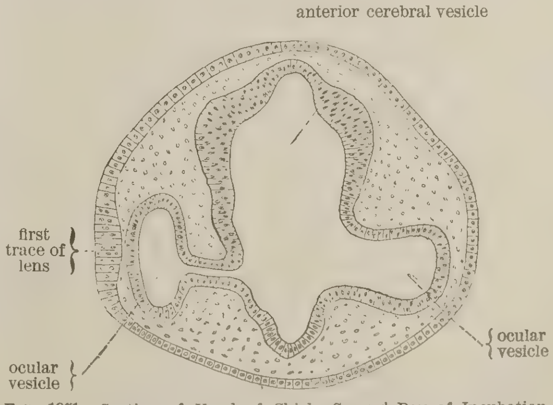

FIG. 1971.—Section of Head of Chick, Second Day of Incubation. (Duval.)

the retina. Its cells are soon arranged in a single layer, those on its outer aspect remaining cubical and forming the so-called lens epithelium; while those on the inner or retinal aspect become greatly lengthened and form the lens fibres (Fig. 1976). By this process the cavity of the vesicle is finally obliterated. At the equator or edge of the lens there is a transition region where proliferation is most active. The lens increases in size by the addition of successive layers of fibres which extend from the anterior to the posterior surface. The structureless capsule of the lens is now believed to be a product of the cells themselves and not of mesoblastic origin.

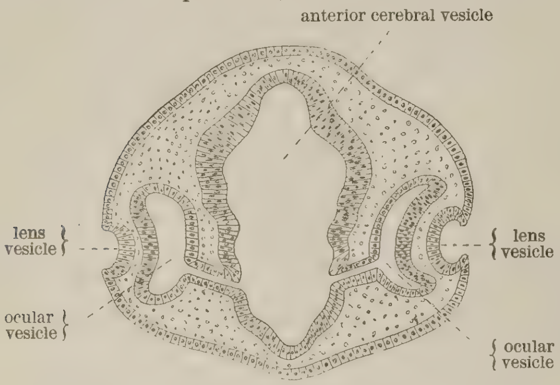

FIG. 1972.—Section of Head of Chick, Third Day of Incubation. (Duval.)

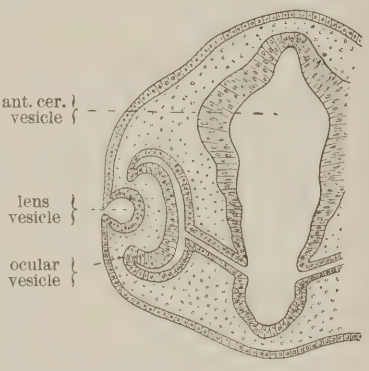

FIG. 1973.—Further Development of Retina and Lens. The lens vesicle is still attached to the epidermis. (Duval.)

Besides the capsule proper the lens is invested during fœtal life by a vascular membrane, the *tunica vasculosa lentis*. The vessels that supply this are derived from the hyaloid artery, a branch of the central artery of the retina, and from the long and short ciliary arteries that supply the iris (Fig. 1977). The supply is especially great around the equator of the lens where proliferation is active. The portion of this membrane that lies in front of the lens stretches over the pupil or mouth of the optic cup, and is known as the pupillary membrane. The tunica vasculosa begins to disappear about the seventh month, but vestiges often remain after birth.

Around the optic cup and the lens the mesoderm forms a complete investment in which two layers may be distinguished: an inner, more vascular one, which becomes the choroid coat, the choroidal part of the iris and the pupillary membrane; and an outer, less vascular one, which forms the sclera and cornea. In front of the lens a cleft appears which enlarges to become the aqueous chamber (Fig. 1978).

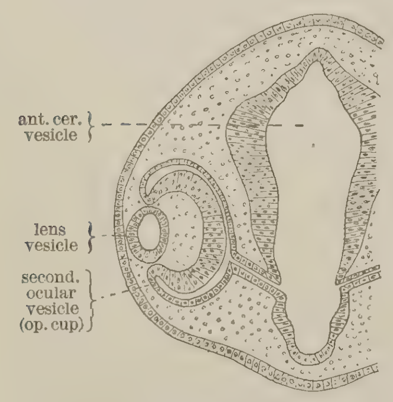

FIG. 1974.—Further Development of Retina and Lens. The lens vesicle has become entirely detached and lies at the entrance to the optic cup. The inner layer to the optic cup has begun to thicken.

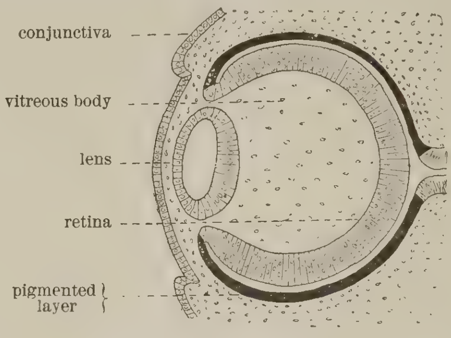

FIG. 1975.—Further Development of the Retina and Lens. The posterior wall of the lens has begun to thicken; the external layer of the optic cup is charged with pigment. (Duval.)

The eyes have first a lateral position like those of fishes, but the growth of the superior maxillary and nasal processes causes them to assume their adult situation. At first the cornea is entirely uncovered, the lids develop as folds of integument.

The nasal duct is formed in the fold between the superior maxillary and nasal processes by the canalization of a cord of infolded ectodermic cells.

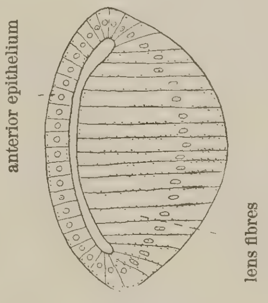

FIG. 1976.—Final Stages of Development of Lens. The cavity of the lens vesicle almost wholly disappears. (Duval.)

The Outer or Fibrous Coat.—Analogous to the dura mater of the brain, this tunic completely invests the eyeball except where penetrated by vessels and nerves. It is composed of fibrous tissue irregularly arranged behind, producing the white, opaque sclera, more regularly in front, forming the clear, transparent cornea. It is very scantily supplied with vessels and nerves, but has numerous lymph channels that appear to afford it nutrition. Associated with these and lying in the interstices of the tissue are various specific forms of corpuscles. The density and hardness of the coat efficiently protect the eye and contribute to its shape, which essentially depends, however, upon the tension produced by the enclosed contents.

The Sclera.—Four-fifths of the surface of the eyeball

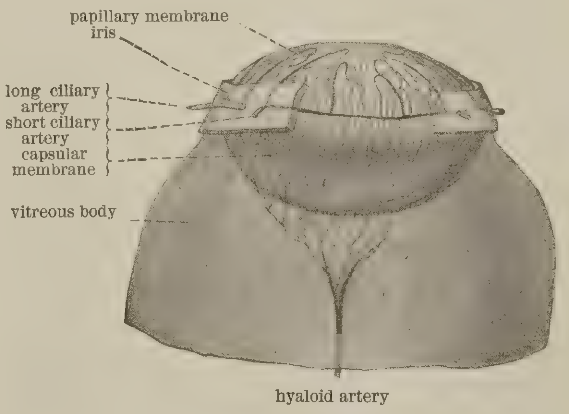

FIG. 1977.—The Vascular Tunic of the Lens in the Fœtus. (Kollman.)

is formed by the dense, opaque structure known as the "white of the eye." Its dead white appearance is due to the interference of light occasioned by the irregularly interwoven bundles of its fibres. In children and the darker races the underlying pigment shows through it slightly, giving it a bluish cast. In old persons it is yellowish from the deposit of fat within it.

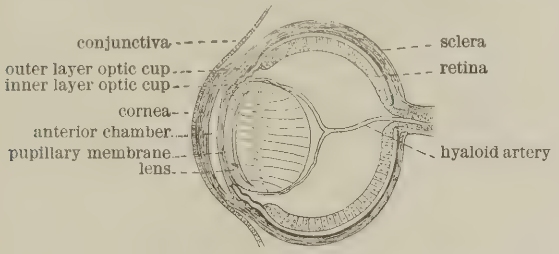

FIG. 1978.—Formation of the Anterior Chamber.

Two principal openings occur in the sclera: one in front, where the transparent cornea is set into it like the crystal of a watch into its frame, the fibres of the two mutually interblending; one behind, where the optic nerve enters at the so-called *optic canal* (optic foramen, porus opticus). Strictly speaking the sclera is not wholly deficient in the latter situation, as it is represented by a perforated sheet of connective tissue, the *lamina cribrosa*, through which the fibres of the optic nerve pass. The canal is situated about 3 mm. from the posterior pole on the nasal side and 1 mm. below the horizontal meridian. Since the fibres of the optic nerve lose their medullary sheaths as they pass forward, the canal contracts funnel-wise from without inward, terminating within in a crest-like ridge, the *pecten scleræ*. Other perforations for vessels and nerves occur, viz.: a posterior ciliary set, arranged about the optic nerve (Fig. 1979), together with those for the long ciliary vessels and nerves lying a short distance farther forward; a middle set, comprising the vorticose veins; and an anterior ciliary set a short distance behind the corneo-scleral junction.

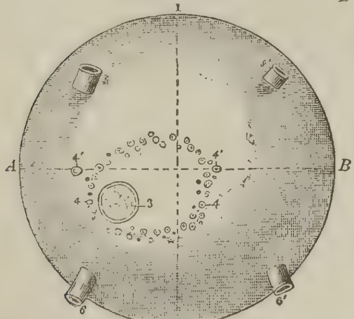

FIG. 1979.—Posterior View of Right Eye, showing Entrance of Optic Nerve. (Testut.) *A*, Nasal side; *B*, temporal side; 1, vertical meridian; 2, horizontal meridian; 3, optic nerve; 4, 4, ciliary vessels and nerves; 4′ 4′, long ciliary arteries; 5, 5′, superior vorticose veins; 6, 6′, inferior vorticose veins.

The sclera attains its maximum thickness of about 1 mm. in the vicinity of the optic nerve entrance where it is required to support the most sensitive part of the retina. It grows gradually thinner forward until, just behind the insertion of the recti muscles, it is but 0.35 mm. thick. The tendons of those muscles reinforce it to some extent and at the corneo-scleral junction it measures 0.60 mm.

The recti muscles are inserted by means of flattened expansions that blend intimately with the sclera. The adjoining sketch (Fig. 1980) shows that their insertions follow a spiral line running at a distance of 5 mm. from the corneal margin for the rectus internus, to 8 mm. for the rectus superior. The oblique muscles are inserted in the posterior hemisphere, their lines of insertion being diagonal to the meridians. The striated fibres of the inferior oblique are inserted directly upon the sclera without the intervention of a tendon.

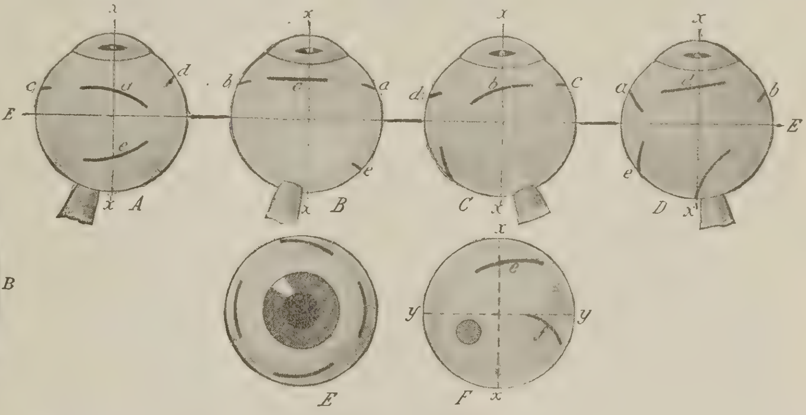

FIG. 1980.—Insertion of the Ocular Muscles upon the Sclera of the Right Eye. Drawn from the determinations of Fuchs. *A*, View from above; *B*, from nasal side; *C*, from below; *D*, from temporal side; *E*, from the front; *F*, from behind; *a*, rectus superior; *b*, rectus inferior; *c*, rectus internus; *d*, rectus externus; *e*, obliquus superior; *f*, obliquus inferior; *E E*, equator; *xx*, axis. In *F*, *y y*, horizontal meridian; *xx*, vertical meridian.

The density of the sclera is considerable, its weight being at least one-sixth that of the entire eye.

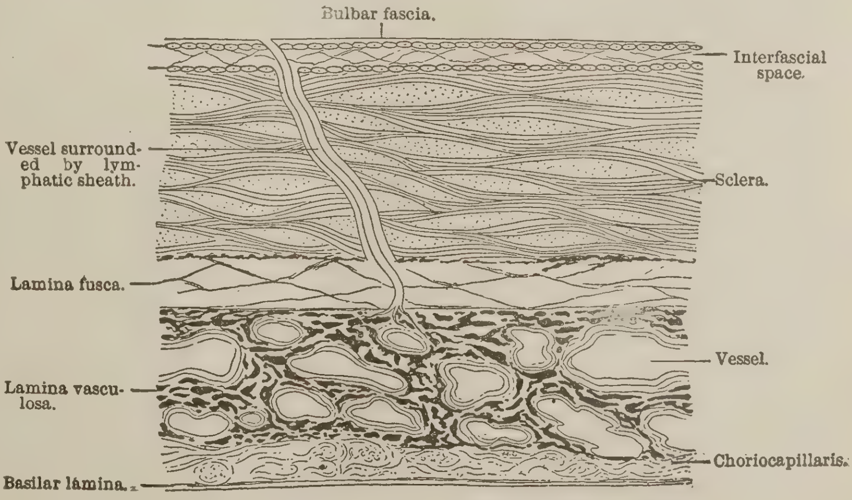

FIG. 1981.—Transverse Section of the Sclera and Choroid. (Testut.)

The sclera is a typical connective-tissue structure, being composed of white fibrous tissue with a few yellow elastic fibres intermingled (Fig. 1981). On boiling it yields gelatin. The bundles are in all parts of it irregularly arranged, though equatorial bands are more common near the corneo-scleral junction. The interstitial spaces are small and cleft like. In their walls are found fixed cells, the scleral corpuscles, in their cavities wandering leucocytes. Pigmented connective-tissue cells occur, especially in the deeper layers, where their aggregation gives a dark-brown color to the tissue, called for this reason the *lamina fusca.* Perivascular and perineural lymph channels extend from the periscleral space into the tissue along the interpenetrating vessels and nerves and communicate with a lymph space, the *perichoroidal space,* that occurs between the sclera and the choroid. It is mostly by the lymphatic circulation that the sclera is nourished, as its blood-vessels are very few.

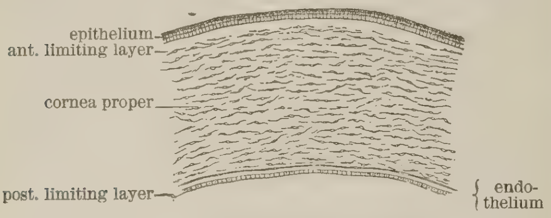

FIG. 1982.—Transverse Section of Cornea Slightly Magnified. (Gerlach.)

Near the corneo-scleral junction there occurs an equatorially extending channel called the *scleral sinus* or canal of Schlemm, that is now considered to be of a venous character. It is probably by this avenue that the aqueous humor is removed from the eye and the proper interchange of fluids effected. It appears to have no direct communication with the chambers, and the action of removal must be by intercellular filtration (Leber).

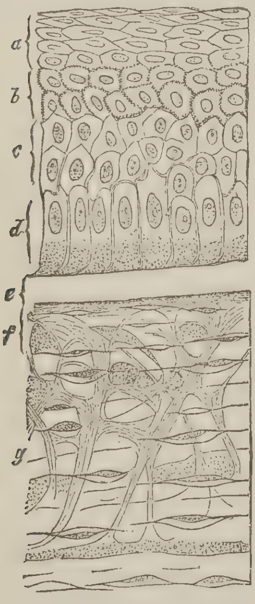

FIG. 1983.—Section through the Anterior Portion of the Cornea of the Calf. (Waldeyer.) *a*, Flattened epithelial cells; *b*, prickle cells; *c*, polymorphous cells; *d*, basal layer of club-shaped cells; *e*, anterior limiting membrane; *f* and *g*, substantia propria of cornea.

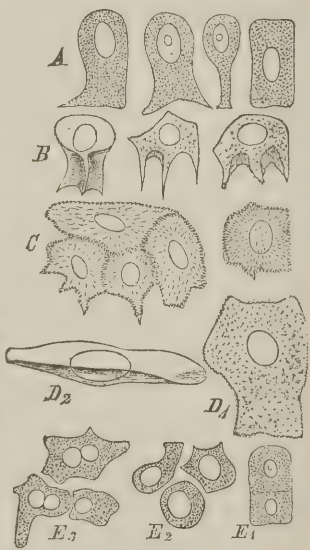

FIG. 1984.—Isolated Cells from the Corneal Conjunctiva. (Waldeyer.) *A*, From the basal layer; *B*, polymorphous cells; *C*, prickle cells; *D*, flattened cells; D_1, plane view; D_2, side view; *E*, young cells from the middle layers; E_1, cell undergoing division; E_2, cells with one nucleus; E_3, multinucleate cells.

The nerves supplying the sclera are few in number and are derived from the ciliary nerves.

The Cornea.—This is also a connective-tissue structure formed of superposed and anastomosing lamellæ, closely applied to each other and with no substance intervening that can vary the refractive force of its fibres. Although composed of many different units—epithelium, limiting membranes, successive layers of connective tissue, lymph channels, corpuscles and nerves—all have the same index of refraction and the membrane is perfectly transparent. A slight disturbance tending to derange its mechanical adjustment, such as compression or other strains, the absorption of fluids, etc., at once beclouds it.

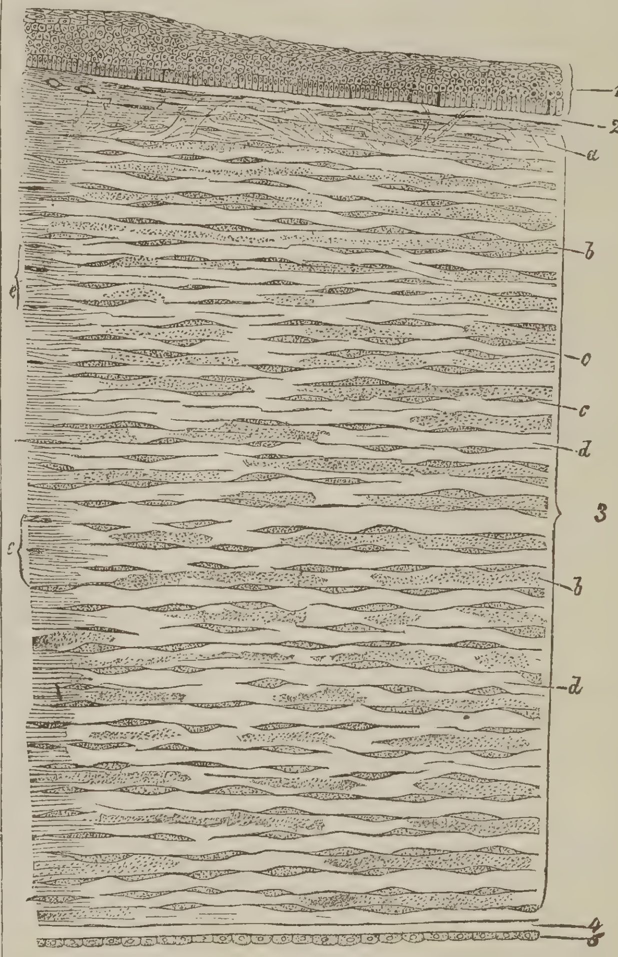

FIG. 1985.—Section through Human Cornea. (Waldeyer.) 1, Conjunctival epithelium; 2, anterior limiting membrane; 3, substantia propria; 4, posterior limiting membrane; 5, endothelial layer; *a*, fibres from anterior limiting membrane entering substantia propria; *b*, fibres cut transversely and fasciculi; *c*, corneal corpuscles; *d*, fasciculi cut lengthwise and therefore appearing homogeneous; *e*, *e*, corneo-scleral junction.

The history of its development shows that its layers may be classified according to their sources: (1) *conjunctival*, forming the exterior layer of epithelium, derived from the ectoderm; (2) *scleral*, forming the main portion of the structure together with its anterior limiting membrane, derived like the sclera from the mesoderm (mesenchyme); (3) *choroidal*, forming the endothelium lining the anterior chamber together with the posterior limiting membrane, also of ectodermic origin but correlated with the middle tunic of the eye.

Set like a window in the frame of the sclera its outline is slightly elliptical, its horizontal diameter being 11.6

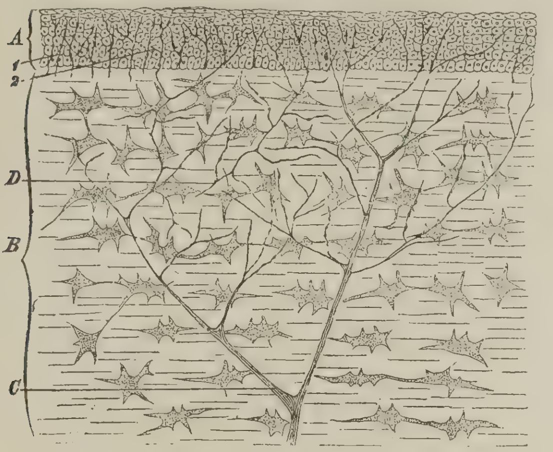

FIG. 1986.—Section of Human Cornea Stained with Chloride of Gold, showing the Corneal Corpuscles and Nerve Endings. (Waldeyer.)

mm., while its vertical one is but 11 mm. The outer and inner surfaces are unequally curved, the inner one having nearly the curvature of a sphere with a radius of 6 mm., while the outer one has that of an ellipsoid with a horizontal radius of 7.8 mm., and a vertical one of 7.7 mm., even greater variations being frequently observed. The surfaces therefore are not parallel, and the thickness of the cornea varies from 1.1 mm. at its periphery to 0.9 at the ocular axis. It attains its permanent dimensions early; its weight averages 180 mgm., one-fortieth that of the entire eye; and its specific gravity is 1.076 (Davy). Its index of refraction is 1.3523, that of distilled water being 1.3358 (Krause). When boiled it yields a form of chondrin instead of gelatin as does the sclera. Its percentage of water is 72.75.

The main substance of the cornea is a lamellated connective tissue lined both without and within by clear structureless limiting membranes, then clothed without by the epithelium of the conjunctiva, within by the endothelium of the anterior chamber. Thus there are five varieties of tissue to be considered (Fig. 1982).

The corneal conjunctiva is an epithelium corresponding with that of the general surface of the body, but having fewer layers of cells and no corneous layer. The deeper cells are expanded at the base and show signs of mitotic division (see Figs. 1983, 1984). Those of the middle layer ("prickle cells") are surrounded by intercellular passages that permit the circulation of lymph.

The anterior limiting membrane (Bowman's membrane, anterior elastic lamina) is a clear anhistous sheet that lines the cornea under the conjunctiva up to near the margin, sending down into the deeper layers fibres of a similar character. It behaves with reagents like the spiral fibres that encircle connective-tissue bundles, not dilating when treated with acetic acid, and resembles the subepithelial basement layer of many membranes.

The proper tissue of the cornea presents from sixty to sixty-five lamellæ (Fig. 1985) composed of flattened bundles of white fibrous tissue arranged nearly at right angles to each other. Between these is an intricate system of interfascicular spaces or lymph lacunæ connected with each other by fine canals and containing fixed cells, the corneal corpuscles (Fig. 1986). These have a resemblance to the osteoblasts of bone in that they occupy interstitial spaces and apparently send fine branching processes along delicate canals that communicate with other spaces. Wandering cells are also found in the passages of the cornea. At the corneal margin these passages communicate with similar ones in the sclera.

The posterior limiting membrane (membrane of Descemet, of Demours, of Duddell, posterior elastic lamina) is also an anhistous layer but apparently quite different in character and origin from the anterior limiting membrane. Its increase with age, and certain irregularities found on its surface lead to the conclusion that it is produced by the endothelial cells which it supports. At the margin of the cornea it becomes thickened into a ring-like zone, the *annular ligament*, beyond which it can be traced over to the insertion of the iris, as a series of distinct bundles of fibres, the *pectinate ligament*, separated by minute clefts, the *spaces of Fontana* (Fig. 1987).

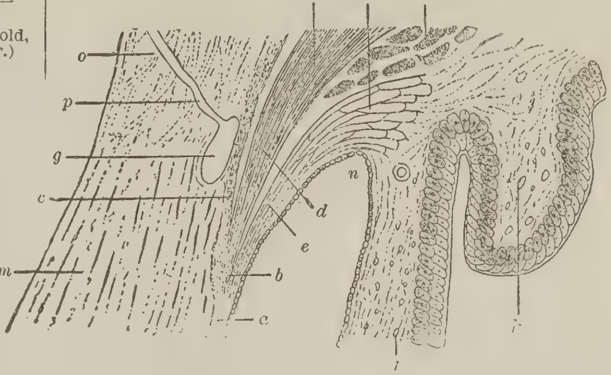

FIG. 1987.—Meridional Section Showing the Connection Between the Cornea and the Middle Coat of the Eye. (Testut.) *a*, Posterior limiting layer; *b*, annular ligament; *c*, scleral fibres; *d*, ciliary fibres; *e*, posterior fibres forming the pectinate ligament; *f*, Fontana's space; *g*, scleral sinus; *h*, meridional fibres of the ciliary muscle; *i*, annular fibres of same; *k*, ciliary process; *l*, iris; *m*, cornea; *n*, angle of the iris; *o*, sclera; *p*, scleral vein.

The endothelium that forms the posterior boundary of the cornea is a flattened single layer of cells similar to those usually lining serous cavities. It is continuous

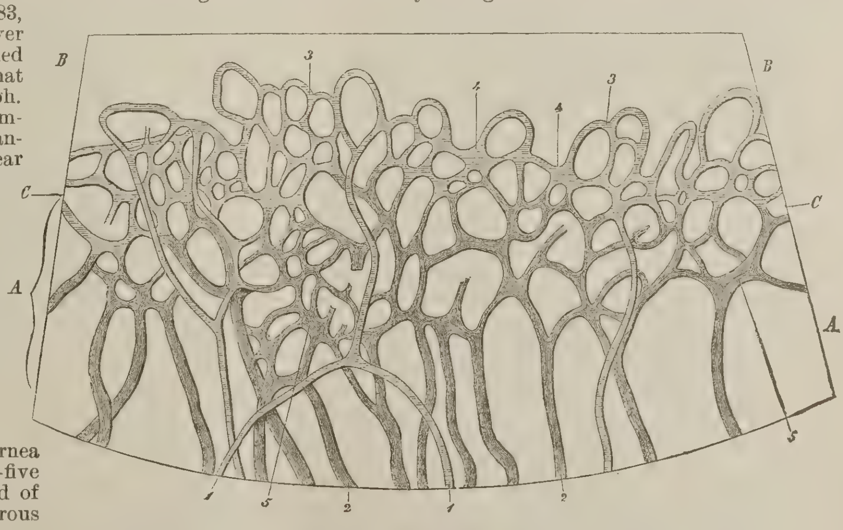

FIG. 1988.—The looped Marginal Plexus at the Periphery of the Cornea. (Waldeyer.)

over the acute peripheral portion of the anterior chamber (known as the *angle of the iris*) with the endothelium lining the anterior surface of the iris.

In the healthy cornea there are no blood-vessels, except just at the margin where vessels from the sclera form a looped network (Fig. 1988). Notwithstanding this wounds of the cornea heal rapidly, nutrition being afforded by the copious supply of lymph.

The nerves that supply the cornea are derived from the anterior ciliary set which form, near the corneoscleral junction, a close-meshed plexus, the *plexus annularis*, from which sixty to eighty nerves, containing both medullated and non-medullated fibres, pass to the cornea, two-thirds going toward the anterior surface. They soon lose their medullary sheaths and form a second plexus, the *deep stroma plexus* (primary plexus, fundamental plexus) (Fig. 1989). Reaching the anterior limiting membrane, perforating fibres from this plexus penetrate that layer and unite to form a third or *subepithelial plexus* from which again fibres pass between the epithelial cells, forming a fourth, or *intra-epithelial plexus*. From this as well as from the subepithelial plexus terminal filaments are given off on which are formed end organs shaped like rounded bulbs, hooks, loops, and platelets. So rich is this supply that it appears probable that every epithelial cell is in actual contact with a nerve fibre or its terminal.

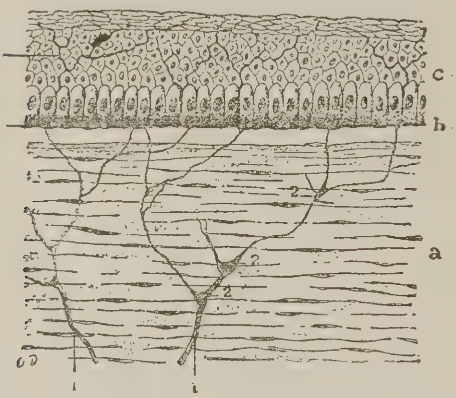

FIG. 1989.—Nerve Plexuses of the Cornea. (Testut.) 1, 1, Two afferent nerve trunks; 2, deep stroma plexus; 3, subepithelial plexus; 4, intra-epithelial plexus; *a*, cornea proper; *b*, anterior limiting membrane; *c*, anterior epithelium.

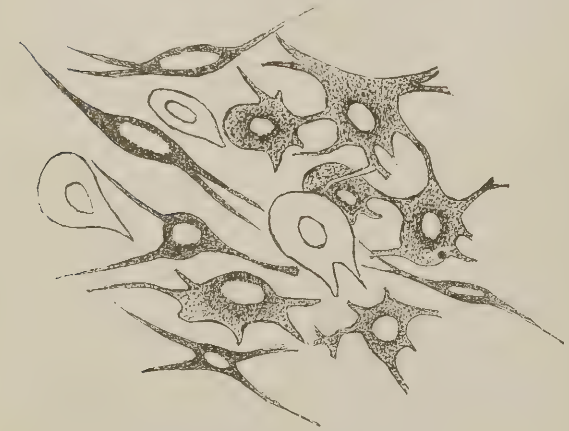

FIG. 1990.—Branched Cells of the Choroid.

The Middle or Vascular Coat.—Considered from an embryological point of view this coat is properly divided into four regions: (1) The choroid proper, comprising the pigmented vascular membrane that extends from the optic-nerve entrance as far as the boundaries of the visual retina where it is limited by a crenulate line called the *ora serrata;* (2) the ciliary choroid, or ciliary body, a thickened portion containing muscular fibres and vascular plexuses; (3) the choroidal part of the iris, comprising the greater portion of the colored curtain which is stretched in front of the lens; (4) the corneal choroid, comprising the corneal endothelium lining the anterior chamber and its product, the posterior limiting membrane. These last have already been described.

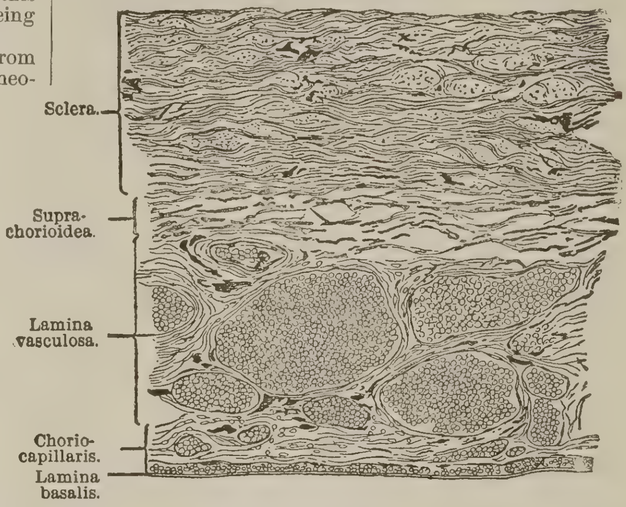

FIG. 1991.—Section of the Human Choroid. (Böhm and von Davidoff.)

This coat generally offers a marked contrast to the other two by its vascular and pigmented character, and has been compared to the pia mater of the brain. Its function is essentially nutritive, and it supplies the fluids that fill the eyeball and preserve its tension. It is soft, yielding, and easily torn or injured.

The Choroid Proper.—This portion of the middle coat, covering about two-thirds of the eyeball, is a loose, vascular, extensible tunic about 0.1 mm. in thickness at the optic-nerve entrance, thinning gradually to about half that at the ora serrata. It is imperfectly separated from the sclera by the suprachoroidal space, intervening bands of fibrous tissue as well as numerous perforating vessels and nerves uniting the two. Its inner surface is smooth and closely applied to the pigmented layer of the retina.

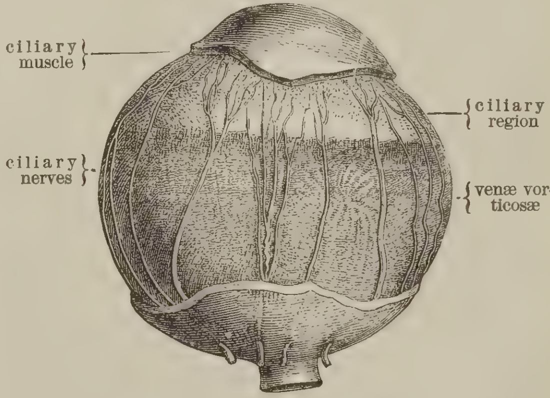

FIG. 1992.—The Choroid Viewed from its Outer Surface. (Merkel.)

Its color, depending on the pigment deposited in its cells and the amount of blood in its vessels, is a dark or reddish-brown, somewhat lighter in the old than in the young.

The general substance or *stroma* of the choroid is composed of interwoven trabeculæ of connective tissue, both white and elastic, supporting a large number of blood-vessels and containing many irregularly branched, pigmented cells (Fig. 1990). The outer layer, being more loosely woven and containing fewer vessels, is known as the *lamina suprachoroidea;* that next to it, containing the largest vessels, is the *lamina vasculosa;* the next layer having an extremely rich network of capillaries is the *lamina choriocapillaris;* while the anhistous limiting membrane that separates this from the retina is the *lamina basalis* (Fig. 1991).

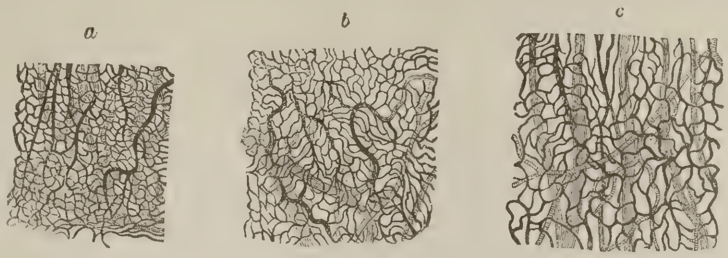

FIG. 1994.—The Capillary Network of the Choroid. *a*, Near the optic-nerve entrance; *b*, about the equator of the eyeball; *c*, near the ora serrata. The veins are striated longitudinally, the arteries transversely, the capillaries are black. The latter are only half as broad as they ought to be.

While the suprachoroidea is not itself remarkably rich in vessels and nerves, its loose tissue affords an avenue by which they readily penetrate to their ultimate destinations. The long ciliary arteries and nerves lie almost wholly in this layer in their transit forward to supply the iris and neighboring structures (Fig. 1992).

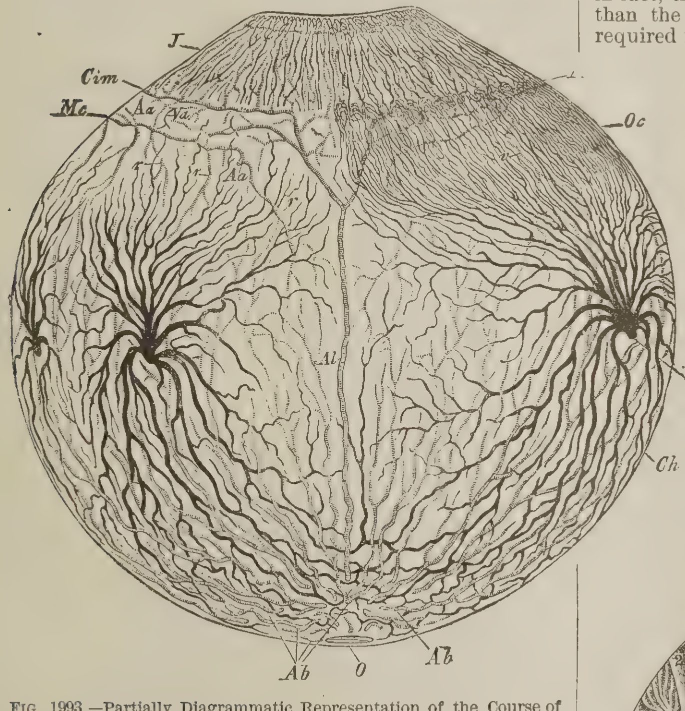

FIG. 1993.—Partially Diagrammatic Representation of the Course of the Vessels in the Choroid. (Leber.) *Ch*, choroid; *J*, iris; *Mc*, ciliary muscles; *Pc*, ciliary processes; *Oc*, ciliary ring; *O*, optic nerve entrance; *Ab*, short posterior ciliary arteries; *Al*, long posterior ciliary arteries; *Aa*, anterior ciliary arteries; *Cim*, greater arterial circle of iris; *Vv*, vorticose veins; *r*, *r*, recurrent arteries.

The arteries of the lamina vasculosa (Fig. 1993) are derived mainly from the short ciliary set that penetrate the ball by about twenty small branches in the vicinity of the optic nerve. The main vessels of this layer are, however, the vorticose veins, from four to eight large trunks formed by converging whorls of vessels. They are usually arranged in a nearly symmetrical manner in four sets nearly ninety degrees apart, and penetrate the sclera obliquely near the equator. Owing to this oblique penetration their discharge is liable to be interfered with by pressure from without, particularly from the action of the ocular muscles. In the deepest part of this lamina are found wavy bundles of elastic tissue, a vestige of the *tapetum* that causes the metallic sheen observed in the eyes of many lower animals under certain conditions of reflected light.

The choriocapillaris or membrane of Ruysch (Fig. 1994) is a close-meshed network of capillaries, so close, in fact, that the space occupied by the vessels is greater than the intervals between them. This appears to be required for the nourishment of the closely contiguous percipient layer of the retina, *i.e.*, the rods and cones, to which the proper arteries of the retina do not penetrate. The vorticose veins begin in this layer by capillary whorls, sometimes called the *stars of Winslow* (Fig. 1995).

The basilar lamina, also known as the vitreous membrane, or the membrane of Bruch, is structureless or nearly so, and appears to be analogous to the basement membrane of epithelium.

The long and short ciliary nerves send vaso-motor twigs to the choroid, and lymphatics gather fluid from its numerous interspaces.

The Ciliary Body.—The wavy line of the ora serrata marks the limit of the layer of rods and cones of the retina and of its trophic layer, the choriocapillaris (Fig. 1995). From this line to the border of the iris curtain the middle tunic of the eye is marked by finely radiate striæ resembling cilia, hence the name that has been applied to this region. The posterior portion,

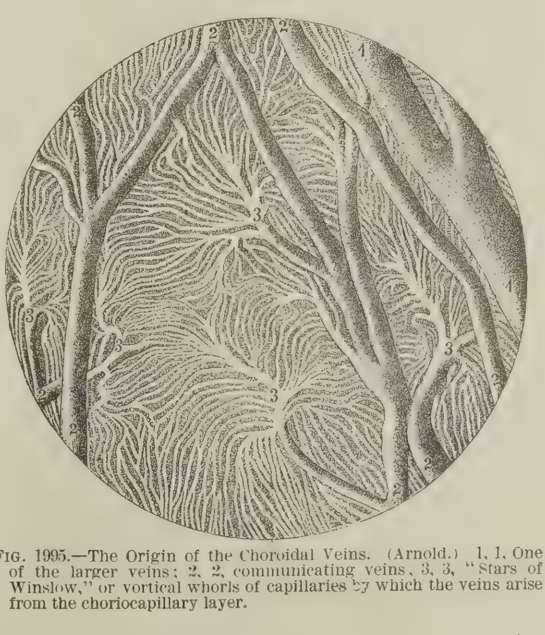

FIG. 1995.—The Origin of the Choroidal Veins. (Arnold.) 1, 1, One of the larger veins; 2, 2, communicating veins, 3, 3, "Stars of Winslow," or vortical whorls of capillaries by which the veins arise from the choriocapillary layer.

comparatively smooth, is known as the *ciliary ring* or orbiculus ciliaris; the anterior portion, thickened and plicated in a meridional direction, is known as the *corona radiata.* Between these and the sclera, in the more superficial portion of the middle coat, lies an annular band of muscular tissue, known collectively as the *ciliary muscle.*

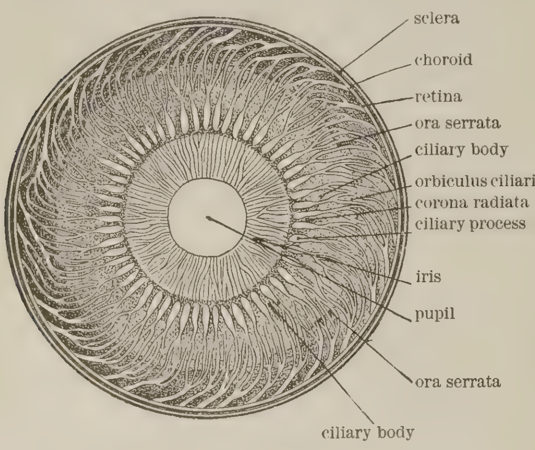

FIG. 1996.—The Ciliary Body as Seen from Behind. × 3.

The ciliary ring, about 4 mm. broad, is formed of nearly straight, unbranched vessels for conveying blood either forward to the corona radiata or backward to the vorticose veins, united by a loose stroma like that of other portions of the middle coat. The basilar layer is continued forward and is even somewhat thickened.

The corona radiata is the zone lying between the margin of the ciliary ring and the outer margin of the iris. It derives its name from the radiate arrangement of its characteristic features, the *ciliary processes,* club-shaped plications from 2 to 3 mm. in length and 0.12 mm. wide, that lie in a meridional direction (Fig. 1997). They resemble the glomeruli of the kidney in containing convoluted blood-vessels, and doubtless assist in the production of the aqueous humor. The suspensory ligament of the lens (zonula ciliaris) extends backward over them as far as the ora serrata, some of its fibres springing directly from the stroma of the processes. A marked interval separates the corona from the iris.

The ciliary muscle (Fig. 1998) occupies a zone 6 to 7 mm. in width and triangular in meridional section, reaching a maximum thickness of 0.8 mm. It takes its origin from the annular ligament and the sclera in the neighborhood of the scleral sinus and is inserted upon the stroma of the middle coat in the region of the ciliary body and beyond. Its most superficial fibres are directed meridionally and constitute the *tensor choroidea* of Brücke; those next succeeding approach more and more a radial direction as they get deeper; and the deepest of all are arranged equatorially, constituting the *compressor lentis* of H. Müller. The office of the muscle is to draw the choroid forward and thus relax the suspensory ligament of the lens, which, being no longer held tense, assumes a more convex shape suitable for the refraction of diverging rays from objects near at hand. In myopic eyes the circular fibres are fewer in number or wanting, while in hypermetropic eyes they are greatly increased.

Many ancient anatomists (Eustachius, Scheiner, Plempius, Descartes) suspected that this structure was muscular, but the first to demonstrate it from actual microscopic examination appears to have been an American oculist, William Clay Wallace of New York City, who, in 1835, published in the *American Journal of Sciences and Arts* an article "On the Accommodation of the Eye to Distances," saying:

"At the base of the ciliary processes, upon the inner surface of the choroid coat, there is a range of muscular fibres. In the sheep the fibres of the upper portion run transversely to the ciliary processes; those of the lower portion run parallel to them."

Brücke, to whom the credit of the discovery of the meridional fibres is usually given, did not describe the muscle until 1846, and H. Müller, usually credited with the discovery of the equatorial fibres, published first in 1855.

The muscle is supplied by the long ciliary nerves from the nasal branch of the ophthalmic and by the short ciliary from the ciliary ganglion. These form within the substance of the muscle a ring-like plexus, the *ciliary plexus* (orbiculus gangliosus), from which pass fibres of apparently motor function, ending free between the muscle cells, vaso-motor fibres, and also sensory fibres with terminal end organs. Some of the latter are believed to impart an accurate appreciation of the contraction of the muscle.

The Iris.—This colored diaphragm, pierced with its central aperture, the pupil, hangs freely but not quite vertically in the aqueous chamber, its outer or ciliary border attached just behind the corneo-scleral junction, and its free or pupillary border resting a little anterior to the other upon the lens. Behind, its tissue is continuous with that of the ciliary body, in front with that of the pectinate ligament and the angle of the iris.

Its diameter is from 10 to 12 mm., its thickness 0.4 mm. when lax, increasing to double that amount when contracted. The pupil, slightly eccentric toward the nasal side, varies from 1 to 8 mm. in diameter, according to the state of contraction of the iridial muscles.

It will be remembered that the pupillary border of the iris forms the edge of the optic cup, which here doubles back upon itself and becomes invested by the vascular, mesodermal layer that produces the choroid. Hence the iris is composed of two genetically distinct portions: a retinal one, secondarily derived from the ectoderm, belonging to the optic cup proper; and a choroidal one, mesodermic in origin (Fig. 1999). Since the retinal portion contains no percipient elements it will be convenient to consider all together.

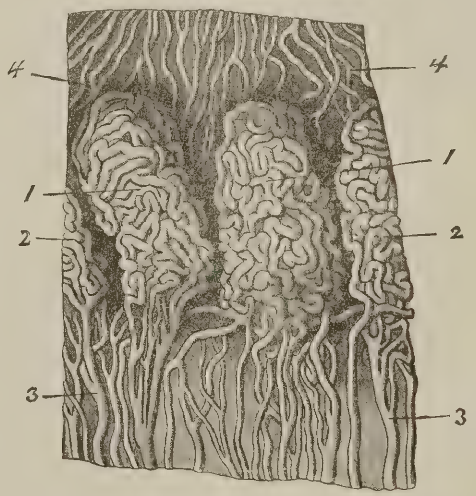

FIG. 1997.—Injected Ciliary Processes Viewed from Behind. (Sappey.) 1, 2, Venous plexuses composing the bulk of the projections; 3, 3, efferent trunks tributory to the vorticose veins; 4 4, venous radicles from the iris. × 40.

Viewed closely, the anterior surface will be seen to present two concentric zones, *pupillary* and *ciliary,* separated by a festooned line, the *lesser arterial circle,* that indicates the former attachment of the pupillary membrane (Figs. 2000 and 2001). Both zones are marked by radial striæ, caused by vessels and nerves: those of the pupillary zone being fine and close, *radii minores;* those of the ciliary zone larger, *radii majores.* The pupillary border shows a thin black line slightly beaded where the striæ reach it. In the pupillary zone there are found between the striæ minute clefts that penetrate the stroma and communicate with lymph spaces. The ciliary zone is furrowed by concentric ridges that indicate where folds are formed during dilatation.

Pigmented cells scattered through the stroma impart color. When these are scanty the pigment of the posterior epithelium shows through, producing the color characteristic of blue or gray eyes according to the thickness of the translucent stroma. The stroma pigment is scattered in flecks, producing various tints of green, yellow, or brown which when very deep is called black. In albinos pigment is absent even in the posterior epithelium and the iris appears reddish from the hue of its blood-vessels.

The posterior surface (Fig. 2002) presents a series of radial ridges cut by concentric lines into rectangular spaces. Within the pupillary zone these ridges (*contraction folds*) are increased in number. The color of the posterior surface is normally uniform and dark from the pigmented retinal epithelium.

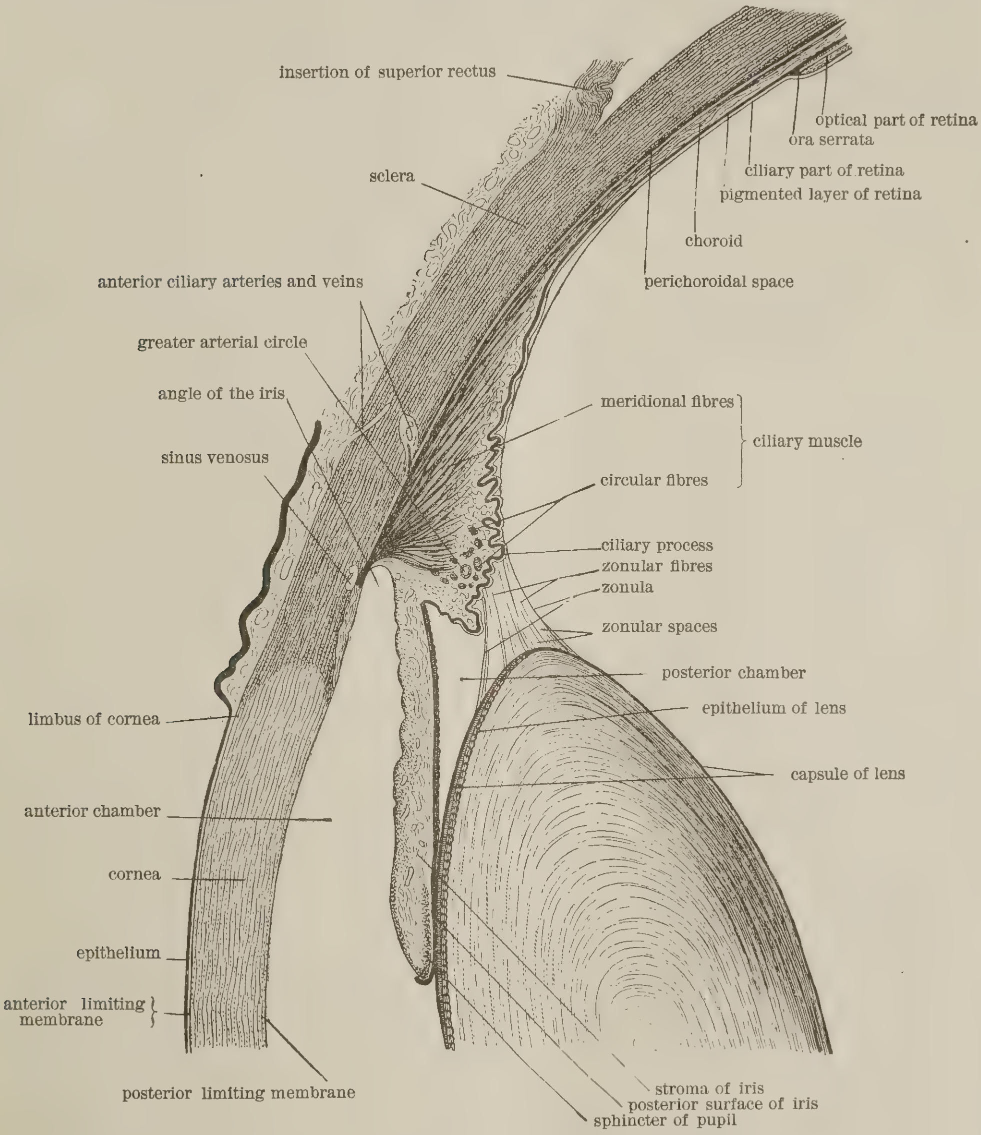

FIG. 1998.—Meridianal Section of a Portion of the Anterior Part of the Eyeball. (Toldt.)

In minute structure the iris consists of a choroidal portion, composed of a loose stroma condensed both externally and internally to a boundary membrane and clothed also anteriorly with the endothelium of the anterior chamber, and of a retinal portion, composed of two layers of pigmented cells corresponding to the doubled margin of the optic cup.

The anterior epithelium, clear and transparent, is like that lining the posterior surface of the cornea.

The anterior boundary layer is composed of delicate interlacing bundles essentially similar to the connective tissue of the stroma.

The stroma is much like that of the choroid, being composed of numerous vessels and nerves united by loose connective tissue, with interstitial lymph spaces and muscular fibres. The latter are condensed near the pupillary margin to an annular band, the *sphincter pupillæ,* while an imperfect layer of radially arranged bundles stretching from the sphincter to the pectinate ligament constitutes the *dilatator pupillæ*. The long controversy regarding the existence of these fibres, which are very difficult to demonstrate in the pigmented iris, may now be regarded as settled. The sphincter appears to be controlled by the oculo-motor nerve, the dilatator by the sympathetic.

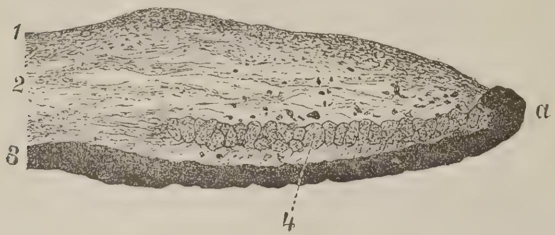

FIG. 1999.—Meridional Section through the Pupillary Zone of the Human Iris. *a*, Pupillary border formed of epithelium, arranged in bead-like processes; 1, anterior limiting layer; 2, stroma or vascular layer; 3, pigmented epithelium, continuous behind with the retina; 4, sphincter pupillæ.

The posterior boundary layer is a continuation of the basilar lamina of the choroid and like it is a very thin structureless membrane formed by condensation of the connective tissue of the stroma.

The epithelium of the retinal portion of the iris is in two layers, of which the outer is composed of fusiform cells, the inner of columnar cells. Both of these are densely crowded with pigment.

A vascular network, the greater arterial circle (Fig. 2003), formed by branches of the anterior and long ciliary arteries, lies at the ciliary border of the iris between the two portions of the ciliary muscle. From this arterioles pass radially toward the pupil and on reaching the sphincter unite in another anastomosis, the lesser arterial circle, from which are given off vessels that supply the pupillary zone and the pupillary membrane of fœtal life. Venules from these networks pass radially outward and finally discharge into trunks that reach the vorticose veins.

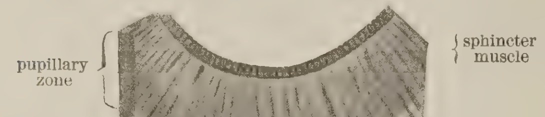

FIG. 2000.—Segment of Anterior Surface of Iris with Pupil Contracted. × 20. (Fuchs.)

There are abundant lymph spaces within the stroma of the iris, but no lymphatic vessels properly speaking.

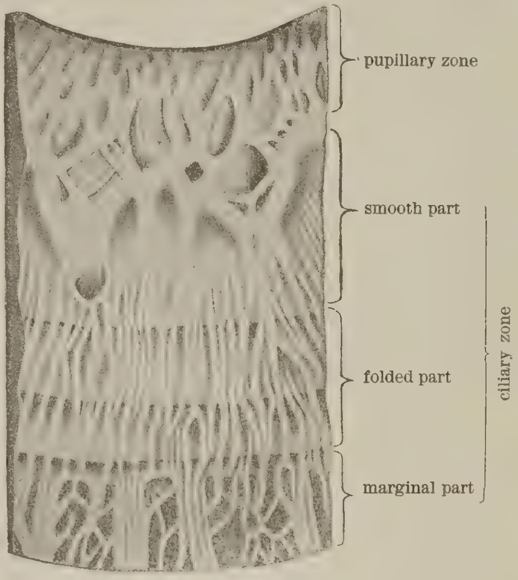

FIG. 2001.—Segment of Anterior Surface of Iris with Pupil Dilated. × 20. (Fuchs.)

The nerves of the iris are derived from the ciliary plexus. Their fibres, as they proceed toward the pupillary border, form a coarse meshwork from which are derived motor nerves with ultimate filaments that supply muscle cells, vaso-motor nerves, and sensory nerves that lie immediately under the anterior endothelium.

The Inner or Nervous Coat.—Being formed from the duplicate, invaginated layers of the optic cup, originally an outgrowth from the brain, the structure of this coat bears some analogy to that of the cerebral cortex. As the ventricles of the brain are lined with epithelium (ependyma), so the lining of the cavity of the optic vesicle, originally continuous with them, retains an epithelial character. By the invagination of the optic cup this cavity becomes obliterated, but the boundary lining remains as the two outer layers of the retina. The outermost of these is a single layer of highly pigmented epithelium; the inner one becomes, for a region extending from the optic-nerve entrance to the ora serrata, a highly specialized neuro-epithelium reinforced by a large number of nervous elements, while over the ciliary region and the iris it too

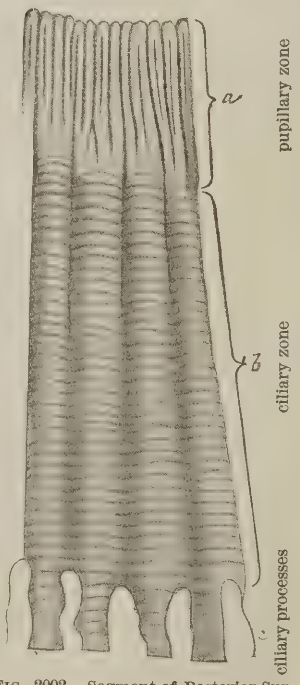

FIG. 2002.—Segment of Posterior Surface of Iris, Medium Dilatation of Pupil. × 25. (Fuchs.)

is reduced to a single layer of simple epithelium, non-pigmented in the former, pigmented in the latter region.

We may therefore distinguish three retinal regions: (1) The retina proper, or percipient retina; (2) the ciliary retina; and (3) the iridian retina. The last has already been described.

The Retina Proper is a smooth tunic that covers the posterior two-thirds of the interior of the eyeball, reaching to about 5 mm. from the attachment of the iris. When the interior of the eye is viewed by the ophthalmoscope it appears reddish from the blood-vessels that ramify in the innermost layers. Its thickness varies from 0.4 mm. behind to half that near the ora serrata. Its outer epithelial layer is deeply pigmented, the remainder perfectly transparent unless deprived of light, when it assumes a purplish hue due to a diffused coloring matter known as the visual purple. Its transparency ceases after death and sometimes during life from pathological causes. It is also normally obscured where the fibres of the optic nerve enter—the *optic disc*, and in an elliptical area lying in the optical axis—the *yellow spot*.

The optic disc (optic papilla, porus opticus), situated 1 mm. below the horizontal meridian and 3 mm. to the nasal side of the vertical meridian, is nearly circular in form with a diameter of from 1.4 to 1.7 mm. As the optic fibres pass through the lamina cribrosa they lose their medullary sheaths and diverge, causing a depression near the centre of the disc, termed the *excavation*. The myelin of the deep fibres shining through its transparent surface gives a whitish appearance to the disc and the free edges of the sclera and choroid are seen as boundary rings. The central artery of the retina entering at the excavation ramifies upon its surface. There being no percipient elements in this area it is insensible to light, and is hence sometimes called the punctum cæcum or blind spot.

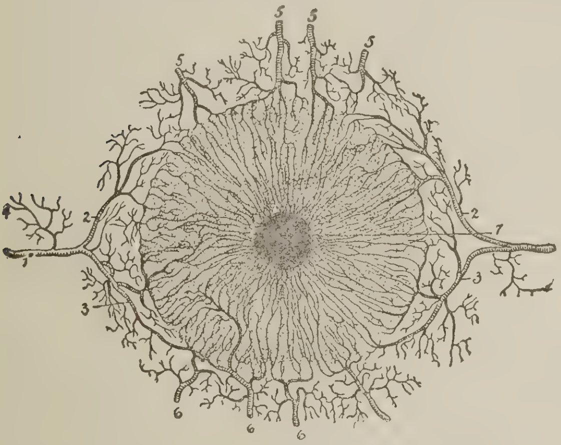

FIG. 2003.—Arteries of the Iris. (Sappey.) 1, 1, long posterior ciliary arteries; 2, 3, their branches of bifurcation; 4, recurrent arteries destined for the choroid; 5, 5, 6, 6, anterior ciliary arteries anastomosing with the long ciliary to form the greater arterial circle of the iris; 7, the lesser arterial circle of the iris.

The yellow spot (macula lutea, spot of Sömmering) is a reddish-brown area nearly circular in form, about 2 mm. in diameter. Near its centre it has a depression termed the central fovea (fovea centralis), 0.02 to 0.4 mm. in diameter, which is the seat of the most acute vision. The percipient elements have here a special arrangement which will be hereafter explained.

The retina being the only sense organ directly derived from the cerebral cortex, shows combined within it structures usually widely separated. Its cells are arranged in three layers that communicate with each other in a chain-like series: (1) collective, comprising the neuro-epithelium of the rods and cones that receive the primary impulses leading to vision; (2) transmittive, bipolar cells sometimes collectively called the ganglion of the retina; (3) liminal, large multipolar cells lying near the inner surface of the retina and sending fibres brainward through the optic nerve.

Similar members exist in other sense organs; thus, in the organs of common sensation we have: (1) the epithelium surrounding the nerve terminal in the skin; (2) the cells of the spinal ganglia, conveying the impulses to the nervous centres; (3) the cells of the receptive nuclei in the spinal cord or the medulla oblongata.

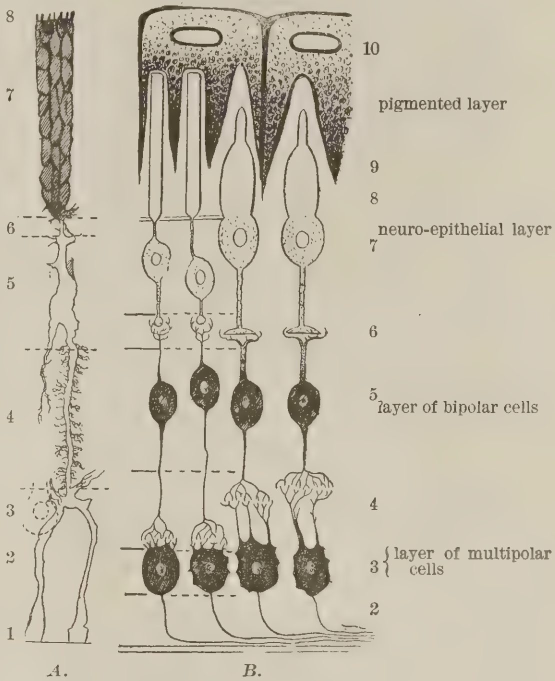

FIG. 2004.—Schema Showing the Arrangement of the Structural Elements of the Retina. A, Fibre of Müller; B, nerve and epithelial cells. 1, Membrana limitans interna; 2, layer of nerve fibres; 3, ganglionic layer, 4, inner molecular layer; 5, inner nuclear layer; 6, outer molecular layer; 7, outer nuclear layer; 8, membrana limitans externa; 9, layer of rods and cones; 10, pigmentary layer.

Besides the elements of the retina already mentioned, which are doubtless the main apparatus by which visual sensations are conveyed, there are certain associative cells that probably serve to correlate and co-ordinate the action of the separate neural chains.

All these may be considered active elements. There are also, in the central nervous system, certain passive or sustentacular elements. These, known in other regions as neuroglia cells, are in the retina called the fibres of Müller.

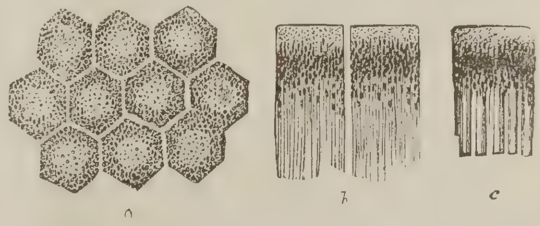

FIG. 2005.—Cells of Pigment Epithelium from the Human Retina. (Max Schultze.) *a*, Surface view; *b*, side view showing fringe-like processes that extend toward the layer of rods and cones; *c*, a cell to which the outer portions of some rods are attached.

The retina is often described as consisting of from nine to eleven layers. There seems to be no good reason for this, as some of the appearances described as layers are caused by the intermingling processes of cells, while others, the so-called limiting membranes, are expansions from the supporting cells or fibres of Müller. Morphologically speaking there are but four layers, the three already mentioned and the external layer of pigmented epithelium. The accompanying diagram presents both the older and the more recent nomenclature (Fig. 2004). The layers will be described in succession from without inward.

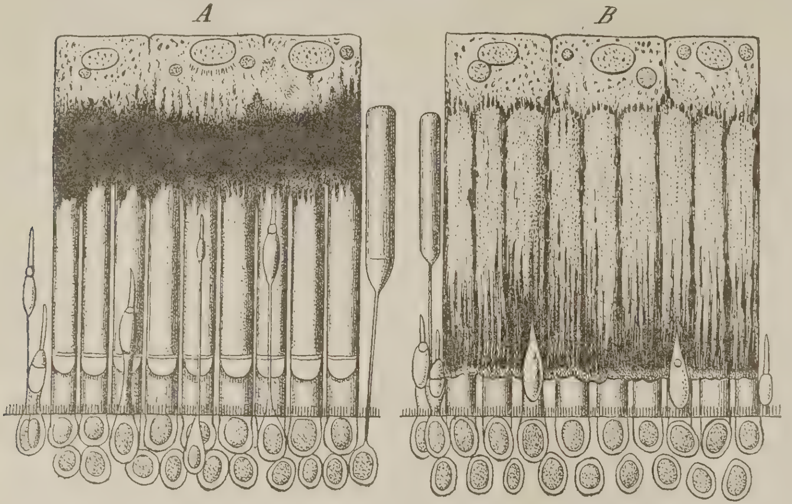

FIG. 2006.—Sections of Frog's Retina Showing the Action of Light upon the Pigment Cells, and upon the Rods and Cones. (von Gendesen—Stort). *A*, From a frog which had been kept in the dark for some hours before death; *B*, from a frog which had been exposed to light just before being killed. Three pigment cells are shown in each section. In *A* the pigment is collected toward the nucleated part of the cell, in *B* it extends nearly to the basis of the rods. In *A* the rods, outer segments, were colored red (the detached one green), in *B* they had become bleached. In *A* the cones, which in the frog are much smaller than the rods, are mostly elongated, in *B* they are all contracted.

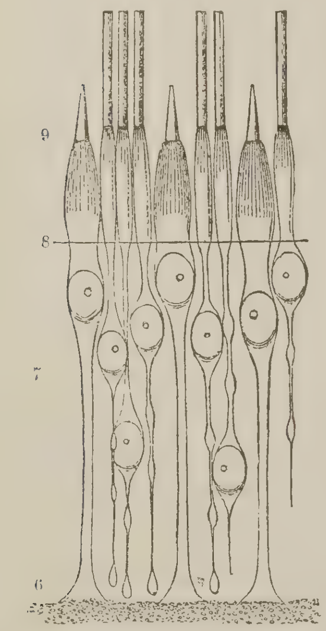

FIG. 2007.—Neuro-epithelium of the Human Retina. (Max Schultze.) 6, Arborescent processes, forming the appearance known as the "external molecular layer"; 7, nuclei of the epithelial cells, forming the "external nuclear layer"; 8, grillwork formed by processes of the fibres of Müller, forming the "membrana limitans externa"; 9, specialized processes of the epithelium, forming the layer of rods and cones.

The pigmented layer comprises the entire outer lamella of the optic cup, the part not invaginated in the course of its development, and is composed of a single layer of tesselated polygonal cells (Fig. 2005), whose protoplasm is crowded with colored granules (the fuscin of Kühne), which have the form of minute crystals with long axes perpendicular to the retinal surface. They are somewhat more deeply colored near the ora serrata. The outer surface of the cells, applied to the basilar lamina of the choroid, is smooth and devoid of pigment; the inner surface is not well defined, for it consists of fringe-like filaments loaded with pigment that extend down between the outer segments of the rods and cones which are applied directly against it. Experiments have shown that the distribution of the coloring matter in these cells varies with exposure to light, for during prolonged darkness it is withdrawn into the cell bodies, while after the stimulus of light it descends like a curtain into the fringe between the rods and cones (Fig. 2006). The visual purple found in the outer segments of the rods appears to be derived from the pigmented layer.

The neuro-epithelial layer, or layer of visual cells proper, comprises two distinct elements, the rod cells and the cone cells (Fig. 2007), set in a framework (external limiting membrane) formed by processes from the fibres of Müller, and projecting into the pigmented fringe already described. These cells are bipolar in form, having elliptical cell bodies (rod and cone granules) with large nuclei surrounded by a small amount of protoplasm from which processes extend radially in either direction. The outer one of these expands into the peculiar bacillary forms known as the rods and cones; the inner one extends inward for a short distance and ends either in a rounded knob (rod cells) or an expanded foot (cone cells) embraced by the filamentous terminals of the ganglion cells of the next layer.

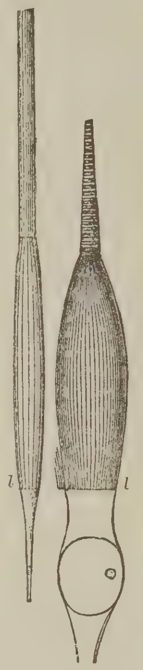

FIG. 2008.—A Rod and a Cone from the Human Retina. *l*, Situation of the membrana limitans externa.

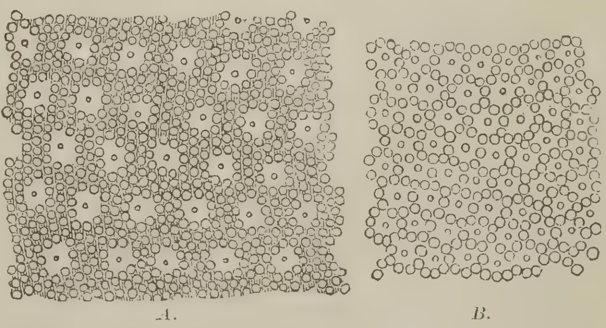
The bodies of the rod cells, which lie at various levels, show when stained under favorable conditions dark and light bands. The rods themselves are divided into two nearly equal segments: an outer, cuticular, doubly refracting one, and an inner, protoplasmic singly refracting one; the former being cylindrical, staining but slightly and having a tendency to break up into superimposed discs; the latter slightly elliptical in outline, staining readily and showing at its outer end a fibrillated area called the ellipsoid, more apparent in the lower animals



A. *B*.

FIG. 2009.—Distribution of the Rods and Cones. *A*, From the peripheral portion of the retina; *B*, from the region of the macula lutea.

than in man (Fig. 2008). The outer segments are purplish-red in tint, owing to the diffusion through them of *visual purple* or rhodopsin, the peculiar coloring matter of the retina, which quickly bleaches in the presence of light.

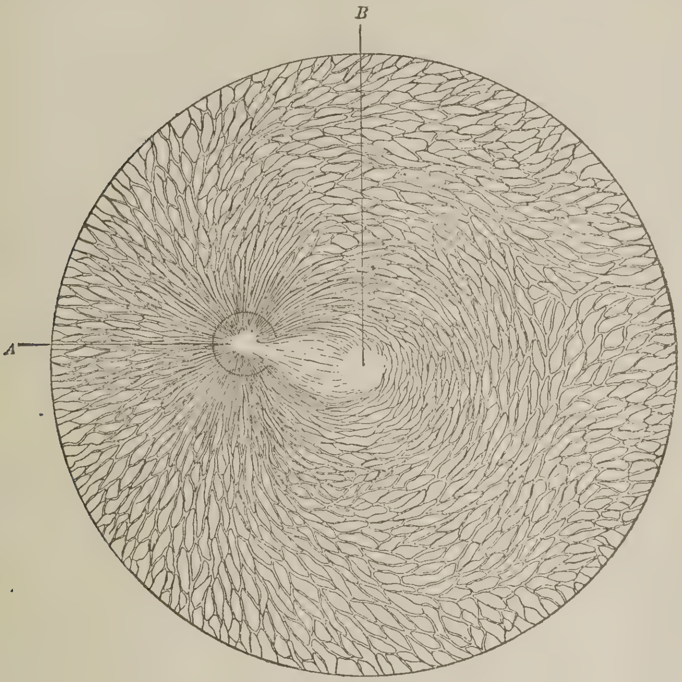


FIG. 2010.—Radiation of the Optic Nerve Fibres upon the Retina. (Michel.) *A*, Optic disc; *B*, macula lutea.

The bodies of the cone cells (Fig. 2007) are contiguous to their bacillary processes or cones. The latter also have an outer and an inner segment. The outer segment, apparently similar in intimate structure to that of the rods, is, however, much shorter, ending in a blunt point. The inner one, thick and flask-shaped, contains also an ellipsoid. During prolonged darkness the cones appear to stretch outward toward the pigmented layer (Fig. 2006). They do not contain rhodopsin.

The distribution of the rods and cones varies in different parts of the retina and in different animals (Fig. 2009). In the central fovea, the region of the most acute vision, cones only are found, but from this point forward the proportion of rods gradually increases, until at the ora serrata cones are almost wholly absent. It is estimated by Krause that there are in the retina about seven million cones, or seven to each fibre of the optic nerve, and that the number of rods is about 130,000,000. While in fishes the rods far exceed the cones in number, in birds and reptiles the reverse is the case, lizards possessing cones alone.

In the layer of bipolar cells the characteristic elements are fusiform with protoplasmic processes that surround the inner terminals of the visual cells. They may therefore be distinguished as rod bipolars and cone bipolars according as they are related to the rod or to the cone cells. The rod bipolars have protoplasmic processes with vertical arborizations, embracing from three to twenty bases of rod cells, and long axis-cylinder processes that penetrate centrally as far as the bodies of the multipolar cells, around which they ramify. The cone bipolars have protoplasmic processes, with horizontal arborizations that interblend with twigs from the feet of several cone cells, probably including also in their contact area some of the terminations of the rods. Their axis-cylinder processes are much shorter than those of the rod bipolars and terminate on five different and quite determinate levels by blending with the ascending processes of the cells of the next layer.

The layer of multipolar cells consists of large, irregularly oval elements with protoplasmic processes that intertwine with arborescences of cells from the outer layers, and whose axis-cylinder processes turn toward the optic disc and become fibres of the optic nerve (Fig. 2010). The cells of this layer are classified according to the arrangement of their protoplasmic processes: (1) monostratified, those whose processes ramify in but one level; (2) multistratified, those whose processes ramify in more than one level; (3) diffuse, those whose protoplasmic arborescences are not limited to definite levels.

At two different levels of the retina associative cells are found: (1) in relation to the rod and cone cells; (2) in relation to the layer of bipolar cells (Fig. 2011). The first class run parallel to the layers of the retina and hence are often called *horizontal* cells, three varieties of which are distinguished: one small, flattened, stellate, *cone associatives*, connecting cone-terminals with each other; another larger and placed somewhat deeper, *rod associatives*, connecting by means of long axis-cylinder processes rod terminals; a third, large, pyriform in shape, having descending processes that pass centralward as far as the internal ramifications of the bipolar cells.

The second class of associative cells is situated in the internal portion of the layer of bipolar cells, constituting there what some authors recognize as a distinct layer of the retina. W. Müller, supposing them to be of a sus-

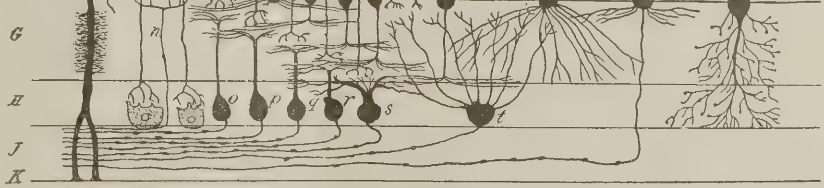

FIG. 2011.—Diagram Illustrating the Relation of the Retinal Elements. (Kallius.) *A*, Layer of rods and cones; *B*, limitans externa; *C*, outer nuclear layer (bodies of visual cells); *D*, Henle's external fibrous layer (composed principally of rod fibres); *E*, outer plexiform layer; *F*, inner nuclear layer (rod and cone bipolars); *G*, inner plexiform layer; *H*, layer of large ganglion cells; *J*, fibre layer; *K*, limitans interna; *a*, supporting fibre of Müller; *b*, *c*, rod and cone visual cells; *d*, bipolars belonging to rod cells; *e–i*, bipolars belonging to cone cells; *k–m*, horizontal nerve cells; *n*, centrifugal nerve fibre; *o–t*, ganglion cells connected with optic fibres; α–ϵ, amacrines arranged in layers; ζ–ϑ, diffuse amacrines; η, nervous amacrine.

tentacular character, called them spongioblasts. It seems desirable to discontinue the use of this name as it has been applied by His to totally different structures, the primitive cells of the medullary plate from which neuroglia is formed. Ranvier, who regarded these elements as undoubtedly nervous, designated them as unipolar cells. Cajal, having in view the fact that they do not show any axis-cylinder process of the typical form, called them *amacrine* cells, from *a*, privitive; *μακρός*, long; *ἴς*, *ἰνός*, nerve—*i.e.*, having no long process. The name is not wholly satisfactory, as homologous structures in reptiles and birds undoubtedly possess a distinct axis-cylinder process, and in man a considerable difference is noted in the ramifications on two sides of the cells.

These cells are large and pyriform with arborescent processes extending inward, and may be subdivided into *diffuse* amacrines that send ramifications throughout all levels where the terminals of the bipolars branch, and *stratiform* amacrines that confine their ramifications to one of the five levels at which the cone bipolars terminate. Their terminal filaments appear to embrace the inosculations of the bipolar and multipolar cells.

It will be remembered that the greater part of the fibres of the optic nerve originate as outgrowths from the cells of the retina. Some "centrifugal" fibres do, however, occur, probably for conveying impulses from the brain to the retinal cells (Fig. 2012). Some of these end by ramifications about the amacrine cells, others at various levels by horizontal arborescence.

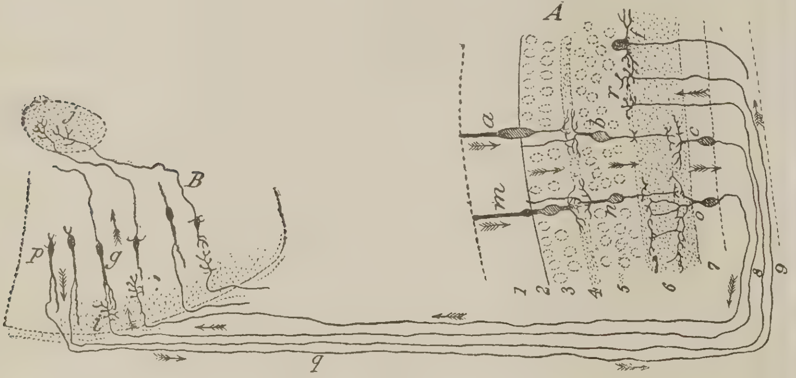

FIG. 2012.—The Course of Nerve Fibres Between Retina and Brain. (Ramon y Cajal.) *A*, Retina; *B*, corpus geniculatum; *j*, central ganglion; *a*, *b*, *c*, a cone system composed of a rod, a bipolar cell, and a multipolar cell; *m*, *n*, *o*, a rod system composed of a rod, a bipolar cell, and a multipolar cell; *g*, cells of the corpus geniculatum that receive excitations from the retina through the optic nerve; *p*, *q*, *r*, a centrifugal current originating in the brain and passing to the retina.

During the early development of the neural tube certain cells, called by His spongioblasts, become shaped into rods extending throughout the entire thickness of the wall of the tube and constituting, by interlacing processes, an efficient framework for supporting the delicate protoplasmic nerve cells that they surround. These elements remain as the neuroglia of adult nervous tissue. The retina shows its genetic relation to the medullary tube by the possession of similar sustentacular elements which are known as the *fibres of Müller* and the *spider cells.*

The fibres (Fig. 2011) extend radially throughout all portions of the percipient retina, being especially well marked near the ora serrata and in the macula lutea. They are greatly modified and elongated cells, whose nuclei lie at the level of the layer of bipolar cells. At the internal surface of the retina they commence by broad and often forked bases that unite with each other to form a continuous boundary known as the *internal limiting membrane*, which, however, cannot in any way be considered to be an independent structure. At their distal or external ends they unite to form a grillwork around the rods and cones which project beyond them. This fenestrated structure is inaptly called the *external limiting membrane.* Septa from the fibres closely invest the bodies of the visual cells, and delicate lateral processes are also given off by them for the support of the terminals of the bipolar, multipolar, and amacrine cells.

Stellate neuroglia or spider cells are found near the inner surface of the retina between the bundles of nerve fibres and among the multipolar cells.

The structure of the retina in the macula lutea and fovea centralis varies somewhat from that already described (Fig. 2013). In the fovea the cones are the only visual cells found, being there much narrower and longer than in other regions. The conical depression of the fovea causes the fibres of the cells to be drawn out obliquely. The bipolar and multipolar layers disappear at the centre of the fovea, but immediately about it, within the macula, become increased in thickness.

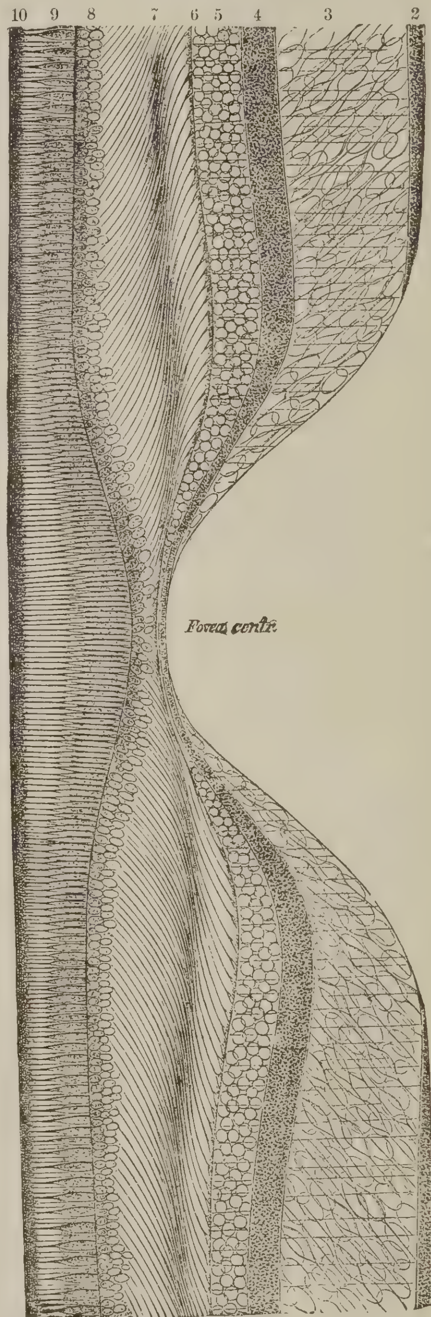

FIG. 2013.—Diagrammatic Section of the Macula Lutea and Fovea Centralis. 2, Layer of nerve fibres; 3, layer of multipolar cells; 4, internal molecular layer, composed of intertwining arborescent processes; 5, layer of bipolar cells, or internal granular layer; 6, external molecular layer, composed of intertwining arborescent processes; 7, nuclei of epithelial cells, or external granular layer; 8, frillwork formed by processes from fibres of Müller, often called the "external limiting membrane"; 9, layer of rods and cones; 10, layer of pigment epithelium.

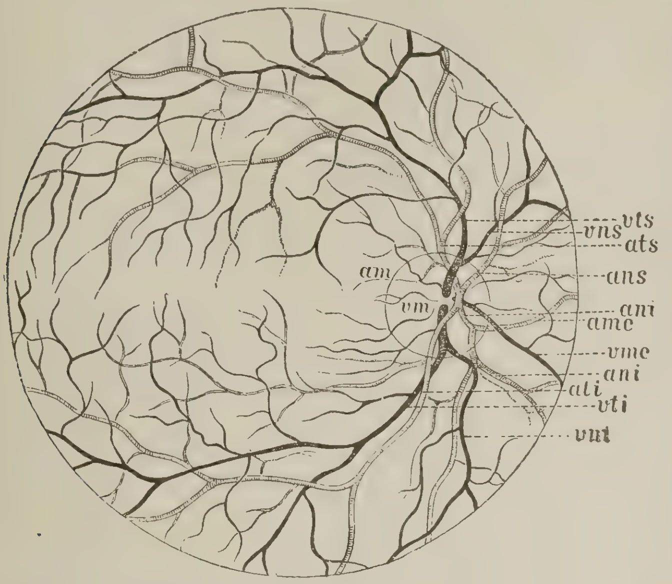

FIG. 2014.—Diagram of the Blood-vessels of the Human Retina. (Leber, after Jaeger.) *ans*, *vns*, Superior nasal artery and vein; *ats*, *vts*, superior temporal artery and vein; *ani*, *vni*, inferior nasal artery and vein; *ati*, *vti*, inferior temporal artery and vein; *am*, *vm*, macular artery and vein; *ane*, *vme*, median artery and vein.

The Ciliary Retina.—As we approach the ciliary region the highly specialized structures that characterize the fundus of the retina become changed. The cones become more scanty, the multipolar cells are fewer, the rods are shortened and disappear. Finally the elements are abruptly reduced to a simple layer of columnar epithelium. This sudden diminution leaves a line of demarcation known as the ora serrata, well seen by the unassisted eye.

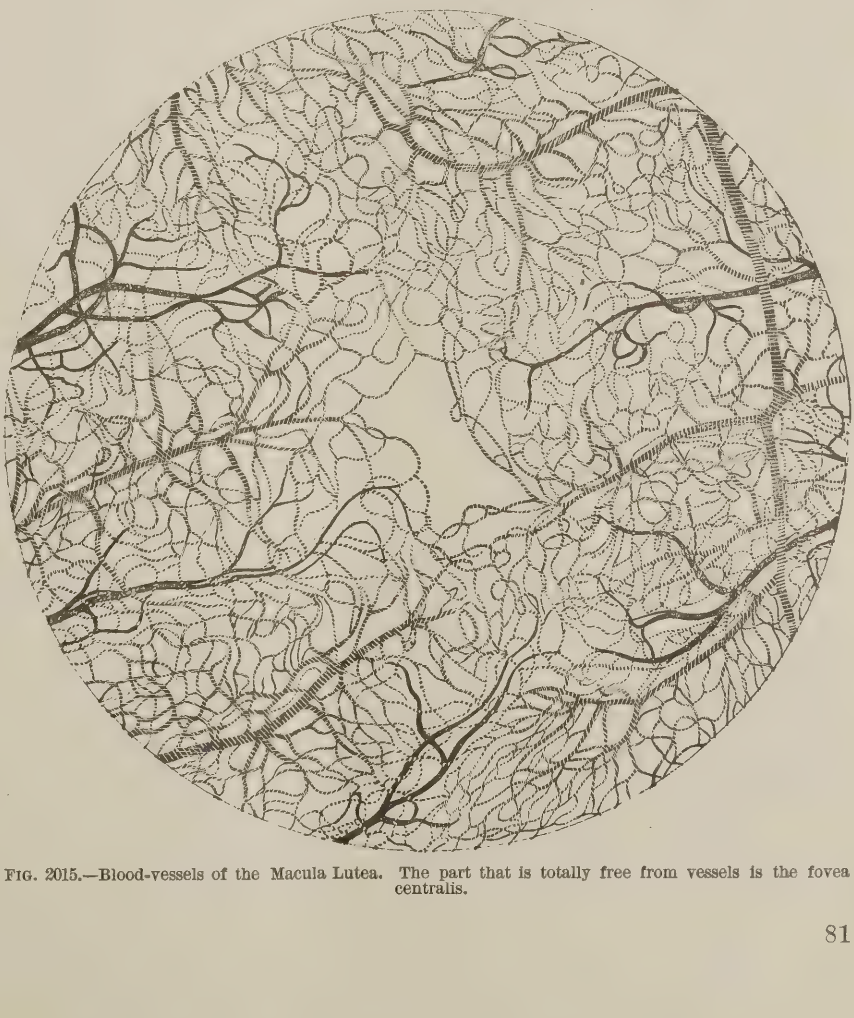

FIG. 2015.—Blood-vessels of the Macula Lutea. The part that is totally free from vessels is the fovea centralis.

The retinal blood-vessels (Fig. 2014) are derived from the central artery of the retina, which, as already stated, pierces the nerve at from 15 to 20 mm. behind the eyeball and appears on the disc at the bottom of the excavation. It immediately breaks up into two branches, the *superior* and *inferior papillary arteries*, each of which subdivides into a temporal and a nasal branch. The papular arteries also send small twigs, the *macular arteries*, toward the region of the yellow spot. Except at the optic-nerve entrance, where a capillary anastomosis occurs with twigs from the posterior ciliary arteries, all these vessels form a system independent of that of the choroid. They ramify mainly in the layer of multipolar cells and do not anastomose with each other. At the central fovea the vessels from this system are wanting (Fig. 2015), as might be expected from the absence of the inner layers at that place.

The *crystalline lens* (Figs. 2016, 2017, 2018), is a transparent biconvex body with a circular margin, applied to the opening of the pupil, touching the iris in front and resting behind in a shallow depression of the vitreous, known as the *hyaloid fossa.* Its margin is from 0.5 to 0.6 mm. from the ciliary processes to which it is united by a suspensory ligament called the *zonula.* Its diameter is from 9 to 10 mm., and, having the unique property of changing its form under the influence of the ciliary muscle for adaptation to vision of near or remote objects, its thickness varies from 3.7 to 4 mm. While not mathematically exact, its curved surfaces are nearly those of spheres, the radius of the anterior one varying from 10 to 6 mm., that of the posterior one from 6 to 5 mm., according as the lens is accommodated for distant or near objects. The fœtal lens is nearly circular; in old age it becomes flattened.

The weight of the adult lens is from 0.20 to 0.25 gm., specific gravity 1.121, volume 0.25 c.c. The central core or *nucleus* is more condensed and less elastic than the peripheral part or *cortical substance,* though its histological structure is the same. This difference does not exist in the fœtus and increases with age, depriving the lens of its elasticity, so that the eyes of elderly persons do not readily accommodate for distance. The nucleus refracts more than the cortical substance, the indices being 1.4541 and 1.4053 respectively, that of distilled water being

1.3342 (Krause). The lens is completely enveloped by a structureless elastic capsule thicker in front than behind, which resembles in its reactions the sarcolemma of muscle or the membrana propria of glands.

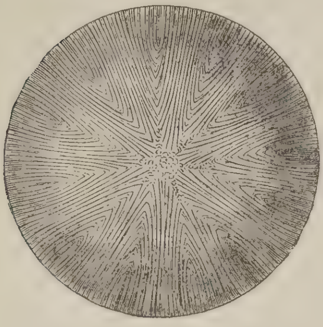

FIG. 2016.—Anterior Surface of Adult Lens. (Arnold.)

The development of the lens is the key to its structure. It will be remembered that it is formed from an invagination of the external epithelium that becomes isolated as the lenticular vesicle and that the cells of the anterior wall retain their epithelial characters, becoming more and more columnar toward the margin or equator of the lens, while those on the retinal aspect become lengthened into flattened fibres that vary in size and length in the central and the peripheral portions (Fig. 2019). The superficial fibres are from 0.010 to 0.012 mm. wide, 0.005 mm. thick, and 8 mm. long, while those of the deeper portion are 0.0075 wide, 0.0025 thick, and 4 mm. long. In the middle and interior portions of the lens the edges of the fibres are finely serrated (Figs. 2020, 2021), but these serrations do not fit into each other and there are thus left between the fibres fine spaces that serve for the passage of lymph. As the lens has no blood-vessels such a provision seems necessary for its nutrition. Between the epithelium and the lens fibres is the original cavity of the lenticular vesicle reduced to a narrow slit filled with semifluid material. This rapidly liquefies after death and becomes the so-called *liquor Morgagni.*

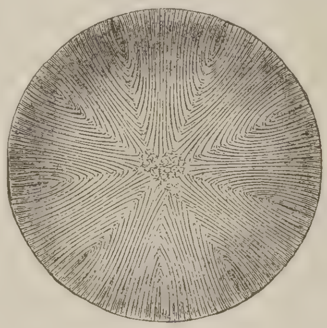

FIG. 2017.—Posterior Surface of Adult Lens. (Arnold.)

When treated by appropriate reagents the fibres of the peripheral third of the lens may be separated into concentric layers like those of an onion (Fig. 2022). In each layer the fibres have approximately the same length and terminate along nearly regular radiating lines called the *lens stars* (Fig. 2023). In the young lens these have behind an arrangement like a Y, in front that of the same letter reversed (⅄). They are more complicated in the adult.

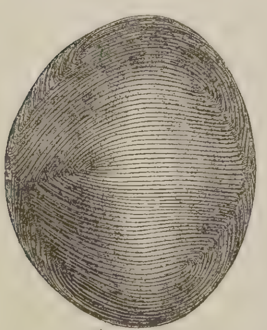

FIG. 2018.—Lens of a Child at Birth Seen from the Side. (Arnold.)

The *zonula,* formerly thought to consist of two folds of a tenuous membrane enclosing a triangular canal (canal of Petit) that encircles the lens, is now known to be a system of delicate fibrillæ that extend from the ciliary region and the hyaloid membrane to be implanted upon the capsule of the lens. The origin and exact nature of these fibrillæ is still under discussion. It seems probable that they originate like the vitreous from mesenchymal connective tissue. They form an annular structure about 6 mm. wide that completely encircles the lens, serves to hold it in position and to keep the capsule tense.

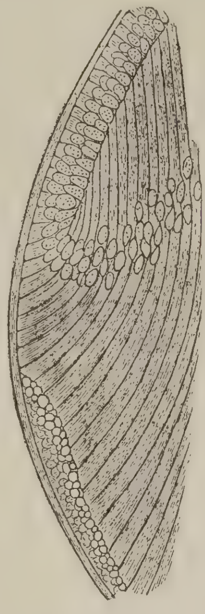

FIG. 2019.—Meridional Section Through Lens of Calf. (Arnold.)

The anterior chamber has the character of a lymph space developed in the connective tissue that primitively separates the lens from the external epithelium. This cavity is filled by the *aqueous humor,* a sparkling, transparent fluid containing 98.71 per cent. of water and having a considerable similarity to lymph. The quantity of this is from 231 to 323 c.mm. and remains nearly constant during life, being sufficient to maintain an intraocular tension equal to that of a column of mercury 26 mm. in height. Its specific gravity is 1.0053 and its index of refraction 1.3420, that of distilled water being 1.3342 (Krause). Apparently it is constantly renewed by a secretion from the vessels of the choroid, particularly those of the ciliary processes, and removed from the chamber by infiltration through the spaces of Fontana into the scleral sinus and perhaps by the lymph crypts of the iris. Normally it contains no morphological elements.

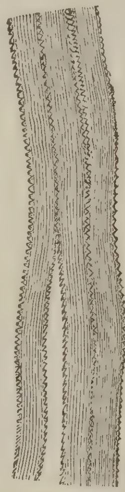

FIG. 2020.—Isolated Fibres from Lens. (Arnold.)

Behind the lens the cavity of the eyeball is filled with the *vitreous humor* or *body,* a transparent, jelly-like material that has the characters of a primitive form of very watery connective tissue, showing widely scattered cells embedded in a matrix of gelatinous material in which appropriate reagents develop a rich fibrillary network. Leucocytes are also found in it, especially where it is in contact with the retina. It has a very delicate envelope, the *hyaloid membrane,* adherent to the retina at the optic disc and the ciliary region where arteries enter during fœtal life. This membrane does not pass down into the intervals between the ciliary bodies, but spans them over, forming thus small meridional spaces, the *recesses of the posterior chamber,* which are filled with aqueous humor infiltrated through the zonula from the anterior chamber. In front the vitreous has a depression, the *hyaloid* or *patellar fossa,* into which the lens is received. The hyaloid membrane appears to be lost upon the zonula in front and not to

be continued over the hyaloid fossa, the consistence of the vitreous at that place being maintained by a condensation of its substance. From the optic disc forward there runs in fœtal life a small vessel, the *hyaloid artery,*

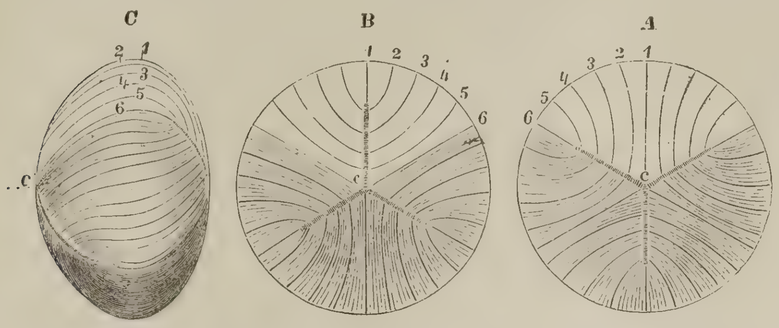

FIG. 2023.—Arrangement of the Fibres of the Lens in the Fœtus and at Birth. *A*, Posterior surface; *B*, anterior surface; *C*, side; *c*, centre of the lens stars, being the anterior and posterior poles of the lens; 1 to 6, course of fibres taken at equal distances.

for the nourishment of the lens. This is represented in the adult by a central lymph space, the *hyaloid canal* (Fig. 1952). Just in front of the disc this canal enlarges to a space known as the *area Martegiani.*

The refractive index of the vitreous body is nearly that of distilled water, its weight is from 6.7 to 8.3 gm. and its specific gravity is 1.005. Its reaction is alkaline, and the proportion of water found in it is very high, being 98.40 to 98.64 per cent. *Frank Baker.*

EYE, DIOPTRICS OF.—REFRACTION.—1. The term refraction refers in physics to the deviation of a ray of light from its straight path on passing from one transparent medium into another of different nature. In physiological optics, however, this term is used with a special significance, denoting the relation of the focal length of the eye to the position of the retina. The eye has a normal, or emmetropic (from ἔμμετρος, according to measure, and ὤψ, eye), refraction, if images of distant objects are sharply defined on the retina; the refraction is myopic, or near-sighted, if distant objects form images in front of the retina; while hypermetropia is that refractive state in which images of distant objects can be sharply defined only behind the actual place of the retina. Any refractive state other than emmetropia is referred to in general as ametropia (from ἄμετρος, disproportionate, and ὤψ, eye).

The eye of all vertebrates is an optic instrument, the principle of which is illustrated by the photographer's camera obscura. By means of a convex lens, the rays of light coming from the different points of external objects are so reunited as to form inverted, but geometrically correct, images of those objects on a screen. The screen is the retina, while the convex lens is constituted by all the transparent media of the eyeball.

A correct knowledge of the optic properties of the eye is not possible without some familiarity with the laws of physical dioptrics. Hence we must begin with a résumé of the laws of the refraction of light. In order to keep this article within the allotted space, we will not attempt to follow out the mathematical deduction of all the various formulæ of which we must make use. For the complete mathematical proof of all the statements the reader must consult some of the works mentioned in the bibliography, especially those of Helmholtz and Donders.

The paths of the rays of light entering the eye, and the influence of the different media upon them, can be deduced from the following optic principles:

2. *Law of Refraction.*—From every point of a luminous or illuminated object there proceed rays of light in all directions. Every ray pursues a straight course as long as it passes through a uniform medium. When a ray passes from one transparent medium into another of different optic properties, it is refracted or deflected from its straight path, except when its original direction is vertical to the surface of the second medium. The extent of deflection depends on a specific property of each medium, viz., its refractive power. The relation of the refractive power of any one medium to that of another is termed the refractive index, and is usually designated by the letter n. Air is taken as the standard of comparison, and its index of refraction is called 1. Compared with air the refractive index of water is 1.334; of crown glass, 1.533; of flint glass, 1.664. A medium having the greater refractive index is said—in a somewhat loose manner—to have a greater optic density than another rarer medium.

The extent to which a ray of light is deflected from its straight path, by refraction, depends on the angle at which it strikes the surface, as well as on the refractive indices of the media.

Let A, in Fig. 2024, be air, with the refractive index $= n$, and B be glass, with the index $= n'$, the two being separated by the surface $s\,s'$. A ray of light, having the direction $a\,c$ in the air, will be bent in the direction $c\,d$ on entering the glass. If we erect the normal $b\,c\,e$ vertical to the surface at the point c, the angle $a\,c\,b$ is the angle of incidence of the ray $a\,c$; the angle $e\,c\,d$ is the angle of refraction. The latter is here smaller than the former, for, in the denser medium, the refracted ray is bent toward the perpendicular. The relation of one angle to the other depends on the relation of the refractive indices of the two media, so that the sine of either angle is to the sine of the other inversely as the index of the corresponding medium is to that of the other, or

$$\frac{\text{sine } a\,c\,b}{\text{sine } e\,c\,d} = \frac{n'}{n} \tag{1}$$

Since the sine of an angle zero is likewise zero in value, it follows that when the incident ray is itself perpendicular to the refracting surface, it continues to be perpendicular after its entrance into the second medium, *i.e.*, it is not deflected at all from its course.

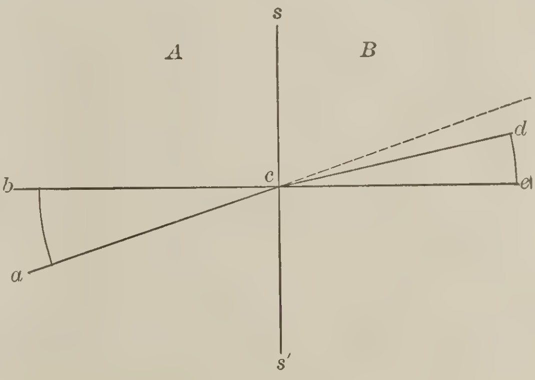

FIG. 2024.

The path which a ray describes in passing through one or more refracting surfaces is the same, whether that ray travels forward or backward from any given point in its course.

3. If the denser medium is in the form of a plate bounded by parallel surfaces and surrounded by the same rarer medium on both sides, a ray, after passing through the plate, follows a direction parallel to its original course, but is displaced laterally.

For in Fig. 2025, where *A* represents the air, and *B* the plate of glass, the ray *a c* on entering the glass is bent toward the perpendicular *d c* to an extent exactly counterbalanced by its deflection from the perpendicular *e f* on leaving the glass. Hence the ray *e b* after passing through the glass is parallel to the prolonged direction of the original ray *a c*.

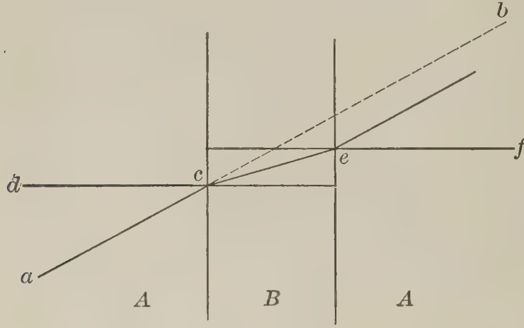

FIG. 2025.

4. *Refraction by a Single Refracting Surface.*—When the denser medium is bounded by a convex spherical surface, all rays (except one) coming from any point in the rarer medium are deflected in such a manner as to be less divergent after their refraction than they were before. The one ray not deflected is the one striking the surface vertically, hence coinciding in the radius or axis of that point of the surface. It is hence termed the *axial ray*.

In Fig. 2026 let *a* be a point in the air from which rays proceed toward the convex surface *b c* separating the air from the glass. Let *o* be the centre of curvature of the refracting surface *b c*. Let the ray *a c* be vertical to the surface, *i.e.*, coinciding with the direction of the radius *o c;* it will hence not be deflected from its course. The ray *a b* is, however, refracted. If *o b* is the radius of the surface, and is hence vertical to the point *b*, the angle of refraction *f b o* can be found by the formula:

$$\text{sine } f\,b\,o \;:\; \text{sine } a\,b\,d = n \;:\; n'$$

It is evident from Fig. 2026, that if the point *a* be not too near to the refracting surface, the refracted ray *b f* will verge toward the undeflected axial ray, and will meet it in some point which we will designate *f*. It can be shown by a mathematical analysis, that not only this one ray, but that all rays proceeding from the point *a* toward the convex surface *b c* are so refracted as to meet the axial ray at the point *f*, provided we limit our analysis to those rays only which are not very oblique to the axis, and do not strike the surface far from the axis. With this provision, the point *f* is the collecting point of all rays coming from *a;* the point *f* is therefore the image of the point *a*. If we trace, however, the course of the rays which are very oblique to the axial ray, or which strike the surface far from its axis, we shall find that they meet the axial ray at various points different from *f*. Such a want of exact reunion of all the rays, when too large an extent of the refracting surface is exposed, constitutes the fault of optic instruments known as *spherical aberration*. The refraction of such very oblique rays is represented, in a somewhat exaggerated manner, in Fig. 2027.

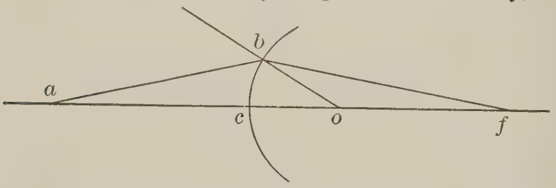

FIG. 2026.

5. *Focal Length.*—When the luminous point is situated in the rarer medium at a distance infinitely great compared with the dimensions of the refracting surface, the different rays emanating from that point strike the refracting surface with so little divergence as to be practically parallel to each other. These parallel rays are rendered convergent by their refraction. The point where these refracted rays meet is called the principal posterior focus, and its distance from the refracting surface is the posterior focal length. This distance, designated usually as F'', depends on the relative indices of refraction of the first and second media and on the radius of curvature of the refracting surface. If we call this radius r, the formula for the posterior focal length is:

$$F'' = \frac{n'\,r}{n' - n} \qquad (2)$$

The plane drawn through the posterior focus vertical to the axis of the refracting surface is called the posterior focal plane.

As the luminous point moves nearer to the refracting surface, so as to make the incident rays more and more divergent, their focal reunion recedes farther from the surface, until a certain point in front of the convex surface is reached, the rays proceeding from which are so divergent that they can no longer be rendered convergent by their refraction, but only parallel. Their point of focal reunion may then be considered as infinitely far behind the surface. The point in front of the surface from which these rays proceed is the principal anterior focus, and its distance from the surface, which we will call F', is the anterior focal length. A vertical plane laid through it is the anterior focal plane. F' can be found by the formula:

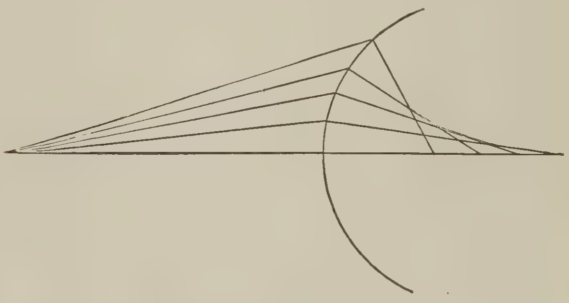

FIG. 2027.

$$F' = \frac{n\,r}{n' - n} \qquad (2a)$$

A comparison of formulæ (2) and (2a) shows that the anterior and posterior focal lengths are not alike under the circumstances, but that

$$F' : F'' = n : n' \qquad (2b)$$

Remembering that the path of the rays is the same, whether they travel forward or backward, we may also define the anterior focus as the point in which rays unite, which proceed parallel to each other in the denser medium toward the refracting surface.

6. The distance of the focal reunion from the refracting surface can be calculated for any set of rays, coming from any point, if we know the distance of that point from the surface, and also the anterior and posterior focal lengths of the refracting surface. If f' be the known distance of the luminous point, the distance of the corresponding focal reunion f'' will be:

$$f'' = \frac{F''\,f'}{f' - F'} \qquad (3)$$

Conversely, the distance of a luminous point f' can be found, if we know the distance of its corresponding focal reunion or image f'', according to the formula:

$$f' = \frac{F'\,f''}{f'' - F''} \qquad (3a)$$

A very convenient formula for finding the place of the focal reunion of rays coming from a point at a known distance can be obtained by the transformation of (3) and (3a). If we designate the distance from the luminous point to the anterior focus, viz.: $f' - F'$ as l' (counting l' negative if f' is nearer to the surface than F'), and the distance from the posterior focus to the point of focal reunion of the rays in question, viz.: $f'' - F''$ as l'', then

$$l' \, l'' = F' \, F'' \tag{3b}$$

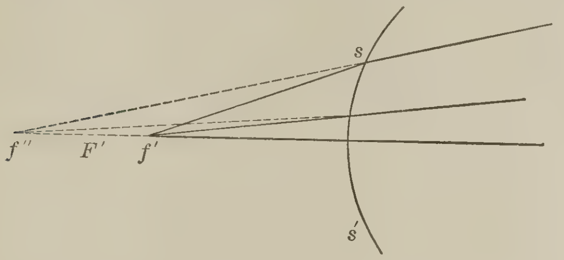

FIG. 2028.

In all these instances the relation of luminous point and corresponding image can be reversed without change of position; in other words, if the point x is the image of the point a, then for rays proceeding in the reverse direction, a is also the image of the point x. Any two points having such a relation of luminous point and corresponding image are called *conjugate points.*

7. *Virtual Image.*—When the rays, coming from a point nearer than the anterior focus, strike the refracting surface, their divergence is too great to be entirely overcome by the refraction. They cannot therefore be united to form an actual image; but if their direction, after the refraction, be prolonged backward, their prolongations meet to form a *virtual* image. The focal reunion of such rays is therefore negative.

Thus, in Fig. 2028, if F' be the principal anterior focus of the refracting surface $s\,s'$, and f' the luminous point, the rays proceeding from f' will have a divergence after their refraction, as if they came from the point f'', which is therefore the image of f'. Since f'' is on the same side of the surface as f', its distance is counted negative. It can be determined by formula (3a) or (3b).

8. *Formation of Images.*—Since an object is made up of an infinitely great number of points, and since of every such point in front of the refracting surface an image is formed somewhere behind the surface, therefore an image must also be formed of the entire object. From every point of the object there proceeds one ray, which is not bent from its course by refraction, viz.: the ray which strikes the surface perpendicularly, and hence coincides in direction with the radius of the point of the surface. Such rays are termed *rays of direction.* Since all other rays proceeding from any one point of the object meet the ray of direction at the corresponding distance of focal reunion, the image of every point of the object is situated somewhere in the path of the ray of direction coming from that point. Since every ray of direction coincides with one of the radii of the refracting surface, the rays of direction must, therefore, like the radii, intersect at the centre of curvature of the surface. Since the focal length of a refracting surface is always greater than its radius, according to formulæ (2) to (3a), therefore the actual images of objects farther off than the anterior focus are formed somewhere beyond the point of intersection of the rays of direction, and are hence inverted. This is illustrated by Fig. 2029.

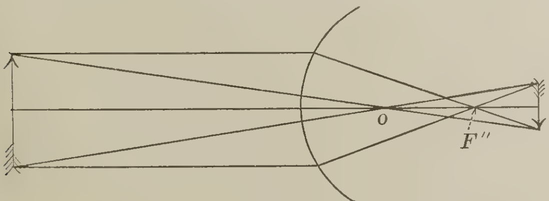

FIG. 2029.

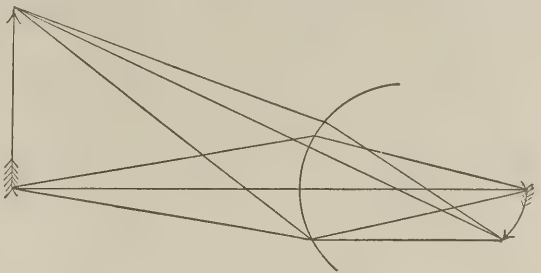

FIG. 2030.

The point where the rays of direction cross, viz.: the centre of curvature of the surface, is also called the *optic centre.*

9. When the object lies in a plane vertical to the axis of the refracting surface, all points of the object near the axis are sensibly at the same distance from the refracting surface, as measured by the length of the rays of direction. Their images are therefore likewise situated at equal distances behind the surface, and hence lie in a plane vertical to the axis. But this is true only as long as the angle included between the ray of direction coming from that point of the object, and the axis of the refracting surface is so small as to permit the substitution of its chord for its arc without practical error. In the case of objects of dimensions exceeding this limit, the images lie in a curved line, with the concavity toward the refracting surface, as shown in Fig. 2030.

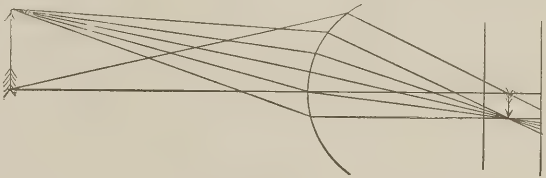

FIG. 2031.

Such extensive images are blurred, on account of spherical aberration. (See Section 4.)

10. *Circles of Diffusion.*—An image is sharply defined only in the plane of focal reunion of the rays. In any plane anterior to this the rays are not yet united; in any plane posterior to this the rays diverge again. Hence a screen placed in front or in the rear of the focal reunion receives a blurred image, since every point of the object is represented—not by a single point—but by a circle of diffusion. The size of the circles of diffusion increases with the distance of the screen from the point of focal reunion in either direction, and with the extent of the refracting surface through which rays pass. This is evident from Fig. 2031.

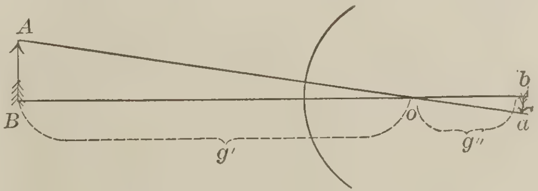

FIG. 2032.

11. *Size of Images.*—The size of the image is to the size of the object as the distance of the image from the optic centre is to the distance of the object from the same point. If we designate, in Fig. 2032, the distance of the

object AB from o, the optic centre, as g', and the distance of the image ab from o as g'', we can express the relation of size by the formula:

$$ab : AB = g'' : g' \qquad (4)$$

the truth of which is evident from the similarity of the two triangles ABo and abo. For certain calculations the relation of size can be more conveniently stated as

$$ab : AB = f'' - F'' : F'' \qquad (4a)$$

in which formula F'' is the principal posterior focal length, and f'' the distance of the image from the surface. The derivation of this formula is shown in Fig. 2033.

For if we draw in this figure the ray Ad from the point A parallel to the axis, it is refracted as if it were a ray coming from some point in the axis at an infinite distance, that is to say, it is deflected to F'' the posterior focus, and proceeds beyond F'' until it meets the other rays coming from A in the point of focal reunion a. Thereby are formed the two similar triangles dcF'' and abF''. Hence,

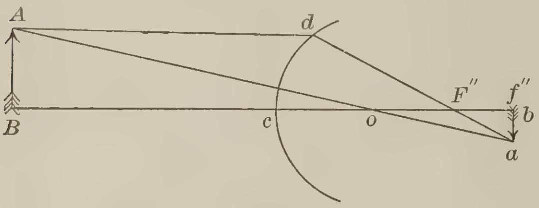

FIG. 2033.

$$ab : dc = f''F'' : cF''$$

Since the line Ad has been drawn parallel to Bc, the side dc is equal in size to the object AB. If we substitute the term F'' for the line cF'', and the term $f'' - F''$ for the line $f''F''$ according to our premises we get the equation:

$$ab : AB = f'' - F'' : F''$$

12. *Virtual Images.*—When the object is nearer to the refracting surface than the principal anterior focus, there is no real image, but only a virtual image is formed on the same side of the surface as the object is itself. In this case f'' is hence negative, otherwise the same formulæ apply as above. Since the rays of direction do not cross, this virtual image is erect, and since it is always farther from the optic centre than the object, it is larger than the object. The amplification of the image diminishes as the object approaches the refracting surface, for when the object has just passed through the anterior focus the image is at an infinitely great distance, and is therefore most enlarged, while when the object touches the refracting surface, object and image coincide in position and size. The formation of virtual images is shown in Fig. 2034.

13. All the facts above stated with reference to images formed in the denser medium of objects situated in front of the refracting surface, are equally true conversely of images formed in the rarer medium of objects situated behind the refracting surface.

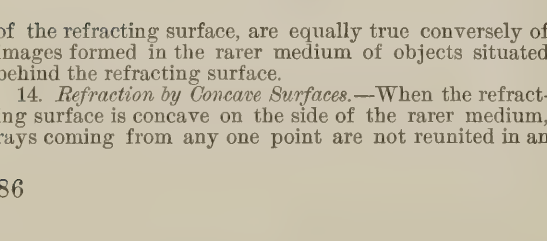

FIG. 2034.

14. *Refraction by Concave Surfaces.*—When the refracting surface is concave on the side of the rarer medium, rays coming from any one point are not reunited in an actual focus. But if the direction which they assume after their refraction be prolonged backward, the prolonged rays will meet in a point representing the focus. This focal length is therefore always negative, that is to say, the focus is always on the same side of the surface as the object itself. The position of the principal foci or any conjugate point of focal reunion can be found by the same formulæ as in the case of a convex surface, but these values are always negative, because the radius of curvature of the concave surface is negative in direction. The images formed by a concave refracting surface are hence always on the same side as the object, that is to say, they are not real, but virtual, and can only be smaller than the object, as is shown in Fig. 2035.

15. *Refraction by Successive Surfaces.* — When light passes through a number of surfaces of different media, the above-developed formulæ apply to the refraction through each surface. Thus the focus of the first surface forms the luminous point for the second refraction, its distance being counted positive when it is in front of the second surface, and negative when it happens to be behind that surface. Similarly the image formed by the second surface is the object for the third surface, and so on. But such calculations become very cumbersome if we try to follow actually the course of the rays through their successive refractions. The matter is simplified by treating the series of surfaces as one system having certain fixed points, the position of which determines the path of all rays. These are called the cardinal points. Their position remains constant in any given system, and can be calculated, if the refractive indices of the media, the radii of curvature of all the surfaces, and the distances of all the surfaces from each other are known, provided the centres of curvature of all the surfaces lie in a straight line, the axis of the system. If the latter condition is fulfilled, the system is said to be centred. The cardinal points are the two foci, the two principal points and the two nodal points.

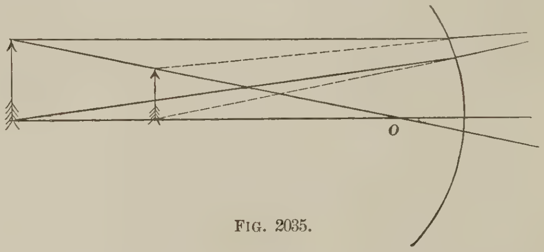

FIG. 2035.

16. *The Foci.*—The foci, anterior or first, and posterior or second, are the two points—one on either side of the system—at such distances that rays coming from the focus are rendered parallel to each other by their last refraction. Conversely parallel rays, entering the system from either side, are united in a point in the focus on the other side, as has been shown to occur in the case of a single refracting surface. The distance of either one of the foci of a compound system from the surface next to it may be computed in the following manner: Let n be the refractive index of the first medium, n_1 of the second, n_2 of the third, and so on. Let S_1 be the first refracting surface, and r_1 its radius of curvature; S_2 the second surface, and r_2 its radius, and so on. The value of r is positive if the surface is convex on the side of the luminous point; negative if it is concave. Let d_1 be the distance from the first surface to the second, d_2 from the second to the third, and so on. Determine the foci of each surface by itself, without reference to the other surfaces. According to formulæ (2) and (2a), we get for the first surface,

$$F_1' = \frac{nr_1}{n_1 - n} \text{ and } F_1'' = \frac{n_1 r_1}{n_1 - n}$$

and for the second surface,

$$F_2' = \frac{n_1 r_2}{n_2 - n_1} \text{ and } F_2'' = \frac{n_2 r_2}{n_2 - n_1}$$

The posterior focus for the first and second surfaces taken together will now be found by considering F_1'' as the luminous point for S_2; and, on applying the formula (3), viz., $f'' = \frac{F'' f'}{f' - F'}$ we get the equation:

$$F(_1 + _2)'' = \frac{F_2'' \; (d' - F_1'')}{(d' - F_1'') - F_2'} \qquad (5)$$

which states the distance of the posterior focus of the system of surfaces S_1 and S_2 from S_2 The distance of the anterior focus of S_1 and S_2 together, from S_1, is similarly found by the application of formula (3a), viz., $f' = \frac{F' f''}{f' - F''}$ and following the light in the reverse direction, hence

$$F(_1 + _2)' = \frac{F_1' \; (d_1 - F_2')}{(d_1 - F_2') - F_1''} \qquad (5a)$$

By treating the surfaces S_1 and S_2 as one system, we can then proceed to determine the foci for $S(_1 + _2)$ and S_3, and so on.

The foci of an optic system having been determined, the focal length is now measured by the distance of each focus from its corresponding principal point. If we call the anterior or first principal point H', and the posterior or second principal point H'', then F' H' is the anterior focal length, and H'' F'' is the posterior focal length.

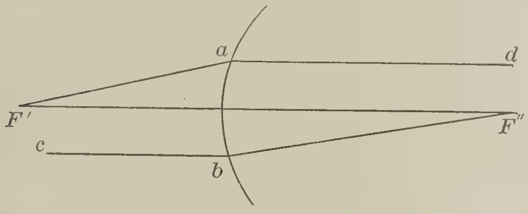

FIG. 2036.

17. *The Principal Points.*—The principal points are the two points where the axis of the system is cut by the two principal planes. The significance of the principal planes can be best explained on comparing the refraction by a single surface with the course of rays through a compound system. In the case of the single surface *a b*, Fig. 2036, the ray *F' a*, coming from the anterior focus, is, by its refraction, made parallel to the axial ray *F' F''*. Incident and refracted rays intersect here in the plane of the refracting surface. The same is true of the ray *F'' b* coming from the posterior focus, and its continuation, *b c*, after refraction. In Fig. 2037, however, where there are two refracting surfaces, *a b* and *a' b'*, the ray, *F' a*, coming from the anterior focus, is twice bent from its course, viz., at each surface, so as to finally assume the direction *a' d*, parallel to the axial ray. In this case the incident ray, *F'' a*, and the refracted ray, *a' d*, do not intersect, being separated by the space between *a* and *a'*; but if we prolong them through this space, their prolongations intersect at the point *h'*. A plane, *h' H'*, laid through this point, vertical to the axis, is the first principal plane. Similarly, if we prolong the ray *F'' b'*, which proceeds from the posterior focus to the surface *a' b'*, it will cut the backward prolongation of the refracted ray *b c* at the point *h''*, which point determines the position of the second principal plane. It is evident, from Fig. 2037, that the ray which before entering the system is directed toward the point *h'* in the first principal plane, has a direction after its last refraction as if it came from a point in the second principal plane at the same distance from the axis as the point *h'*. Likewise the ray which proceeds in the opposite direction from *F''* toward the point *h''* has a direction, after its last refraction, as if it came from a point in the first principal plane at the same distance from the axis as the point *h''*. This mutual relation of the two principal planes is the same for all rays, not merely those coming from *F'* or *F''*; and it is true also for any distance at which the points *h'* and *h''* may be from the axis within the limitations of Section 4. In other words, any ray which is directed toward a given point in the principal plane on the side from which it comes, apparently emerges from the other principal plane at the same distance from the axis. We can thus determine by construction the direction of any ray after its refraction through a compound system, and thereby find the places of the image formed by such rays, if we know the position of the foci and the two principal planes. In Fig. 2038, let *a a'* be the first, and *X X'* be the last refracting surface of a compound system; let *H'* be the first, and *H''* be the second principal point, *F'* the anterior, and *F''* the posterior focus. Draw the axis *F' F''*. From the point *B* there proceeds the ray *B a*, parallel to the axis, and verging toward the point *m'* in the first principal plane. Hence, after its last refraction, that ray has a direction as if it came from the point *m''* in the second principal plane, going through the posterior focus *F''*. Another ray convenient to follow is the one coming from *B* and passing through *F'*. This verges toward the point *n'* in the first principal plane. Hence, by its refraction, it is turned in the direction *n'' b*, as if coming from *n''* and proceeding parallel to the axis. Where the two refracted rays meet, at the point *b*, is the image of the luminous point *B*.

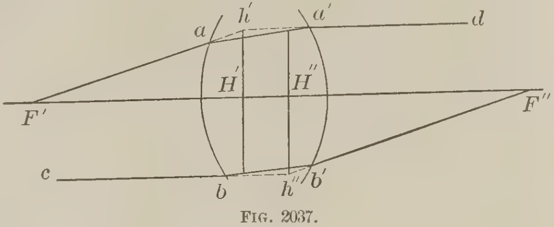

FIG. 2037.

Since the course of rays is determined by their relation to these imaginary principal planes, the focal lengths of a system must be measured by the distance of each focus from its corresponding principal point, and not by the distance of the foci from the refracting surfaces. Indeed, for all subsequent purposes, we can practically ignore the position of the refracting surfaces of any system, after we have once determined the position of the foci and of the principal planes. For now all the problems relative to the position of object and image can be solved by the same formulæ as in the case of a single refracting surface, by measuring the focal lengths from the principal planes.

18. The position of the two principal points is determined by the position of the two planes in which the images of a certain other plane are of equal size and direction. In every refracting system there exist only two such planes, and these are the principal planes; and there exists, moreover, only one plane of which two images of equal size and direction are possible. Hence, in order to find the principal points, we must determine where a line must be in order to form two images of the same size and direction, and then learn the place of these two images.

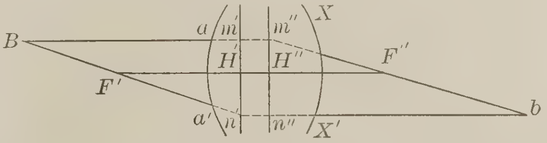

FIG. 2038.

This proposition can be demonstrated by means of Fig. 2039, in which we have a refracting system bounded by the surfaces *s' S'* and *s'' S''*. *F'* is the first and *F''* the second focus. Draw the ray *F' c*, which is deflected toward *s''* by the surface *s' S'*, and is made parallel to the axis by the surface $s'' S''$. By the intersection of the prolonged incident and refracted rays the point h' determines the position of the first principal plane. Similarly a reverse ray going from F'' to e is bent twice, so as to follow ultimately the direction $s' b$ parallel to the axis. The prolongations of the ray before entering and after leaving the system give us the point h'', and thereby the position of the second principal plane. If we draw a line $d d'$ vertical to the axis from the point d, where the rays coming from each side intersect after their first refraction, the virtual image of $d d'$ produced by the surface $s' S'$ coincides with the first principal plane $h' H'$, while the image formed by the surface $s'' S''$ coincides with the second principal plane $h'' H''$, as is evident from the refraction of the rays according to the construction; and these two images are alike in size. The distance of d' from each surface is determined by the equation (4a).

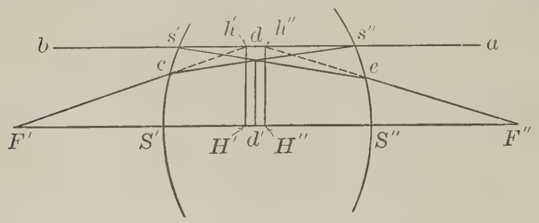

FIG. 2039.

$$a\, b\ (\textit{image}) : A\, B\ (\textit{object}) = f'' - F'' : F''$$

or more conveniently, on account of the erect position of the virtual image,

$$a\, b : A\, B = F'' - f'' : F''$$

Each surface is here considered independently of the other. Hence it can be deduced that the distances of d' from each surface must be to each other as the focal lengths of the surfaces, in order to have the images formed by the two surfaces of equal size. This is shown in Fig. 2040, where $P' S''$ is the focal length of the surface $s'' S''$ in the medium between the two surfaces and $P'' S'$ of the surface $s' S'$.

A consideration of the two triangles $P' S'' s''$ and $P'' S' s'$ and their segmentation by the line $d d'$ proves that

$$d' S' : d' S'' = P'' S' : P' S'' \qquad (6)$$

Hence, in order to find the principal planes of a system, determine the position of a point in the axis, the distances of which from the two refracting surfaces are to each other as the focal lengths of these surfaces in the medium between them. Then calculate the place of the images of this point formed by each surface independently of the other, according to formula (3).

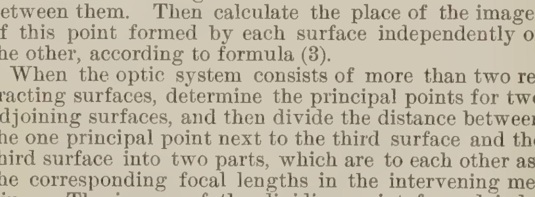

FIG. 2040.

When the optic system consists of more than two refracting surfaces, determine the principal points for two adjoining surfaces, and then divide the distance between the one principal point next to the third surface and the third surface into two parts, which are to each other as the corresponding focal lengths in the intervening medium. The images of the dividing point formed independently by the third surface, and by the system of the other two surfaces, are then the principal points of the system of three surfaces.

19. *The Nodal Points.*—The nodal points of a compound system replace the optic centre of a single refracting surface. For while all rays of direction pass undeflected through the optic centre of a single surface, a second surface will deflect all rays with the exception only of the axial ray. Hence a single optic centre cannot exist in a compound system. But there exist two points in the axis, viz., the nodal points, of such properties that a ray directed toward the first before entering the system pursues a course after its final refraction as if it had passed through the second nodal point parallel to its original direction.

That a pair of points of such properties must exist in any compound system is evident from Fig. 2041, where F' is the first and F'' the second focus, and $m' H' n'$ the first and $m'' H'' n''$ the second principal plane. A ray $B m'$, coming from the luminous points B, forms with the refracted ray $m'' b$ any angle of less than 180° as seen from below, while the ray $B n'$ forms with its refracted prolongation $n'' b$ an angle greater than 180° as seen from below. Somewhere between m' and n' there must be a level where the incident ray includes with its continuation beyond the second principal plane an angle of 180° exactly, in other words, where the two are parallel. Let this be at the level l'. If we prolong the incident ray $B l'$, the points where this prolonged ray and the refracted ray $l'' b$ cut the axis, viz., K' and K'', answer the requirements of the nodal points. The position of the nodal points relative to the principal points is made evident in Fig. 2042.

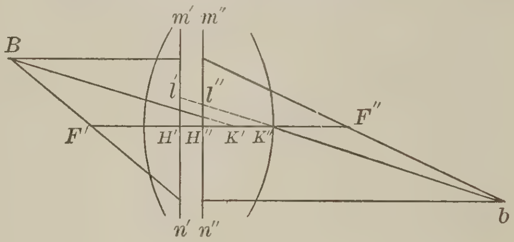

FIG. 2041.

In this figure we will draw the line $B F'$ on F' vertical to the axis. From the point B there proceeds a ray of direction $B K'$ to the first nodal point K'. According to our premises the ray $K'' b$ must be parallel to $B K'$ and in the direction $K'' b$ lies the image of B, at an infinite distance from the optic system. Since the point B lies in the anterior focal plane, every ray proceeding from it is rendered parallel by its refraction to the ray of direction coming from B. Hence the ray $B h'$ parallel to the axis is continued after passing through the second principal plane, as $h'' F''$ parallel to $K'' b$, and hence also to $B K$. From the similarity of the triangle $B F' K'$ and $h'' H'' F''$ it is evident that the distance

$$F' K' = H'' F'' \qquad (7)$$

and by reversing the figure and constructing the course of rays coming from the posterior focal plane, we can similarly learn that the distance

$$F'' K'' = H' F' \qquad (7a)$$

and that hence

$$H' H'' = K' K'' \qquad (7b)$$

which latter corollary is also apparent from Fig. 2041. The position of the nodal points can hence be at once learned by formulæ (7) and (7a), after knowing the position of the principal points and of the foci. And thus we have all data necessary to follow the course of rays through any compound optic system.

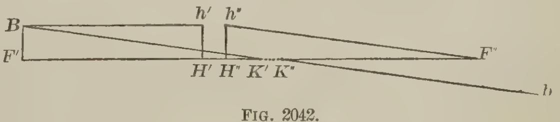

FIG. 2042.

20. *Lenses.*—It will be best to refer briefly to the optic properties of glass lenses before we proceed to the eye

itself. According to the curvature of their surfaces and the distance between them, lenses either reunite into one point all the rays coming from one point, or disperse them. The former, or collecting lenses, have a positive focal length. They form inverted actual images of distant objects, and erect, virtual, and enlarged images of objects nearer than their focus. The latter, or diverging lenses, have a negative focal length, and can form only erect, virtual images, smaller than their object. When both surfaces of a lens are convex, or one is convex and the other plane, the lens belongs to the former variety; when one surface is concave and the other plane, or when both are concave, we have a diverging lens with negative focus. When one surface is convex and the other concave, the positive or negative value of the resulting focal length depends not only on the curvature of the two surfaces, but also on the distance between them.

The refractive index of the glass used for spectacles is so near 1.5 that we can calculate on that basis without important error, at least for spectacles. Taking this index we find that in a plano-concave, or plano-convex lens, the focal length is twice the length of the radius of the curved surface, measuring from the curved surface, according to formula (2) or (2a). The first and second focal lengths are of course equal to each other, when the lens is surrounded by the same medium on both sides, according to (2b). The distance of the foci from the plane surface is, however, not the same as from the curved surface, for the focal lengths are measured from the principal points, one of which coincides with the curved surface, while the other is between the two surfaces. But for most of our purposes we can ignore the thickness of the glass lenses, as long as this is slight compared with the other dimensions, and practically measure the focal length from the surface, or, indifferently, from the centre of the lens. If, hence, we express the focal length of a plano-convex lens as

$$F' = F'' = 2\,r$$

we get for a biconvex lens the formula

$$F = \frac{r' + r_2}{2}$$

If the radii of curvature of the two surfaces are alike, we find the focal length equal to the radius, provided the index of refraction is practically 1.5. This applies similarly to biconcave lenses, F being, however, negative. In lenses with one convex and one concave surface, the measurement of the focal length is not quite so simple, because the thickness of such a lens cannot be ignored without error, and the principal points can in such a combination be outside of the substance of the lens.

The so-called strength of lenses is measured differently, according to the unit which we adopt. Formerly a lens of the focal length of one inch—either negative or positive—was taken as the standard and called 1. Any lens of longer focal distance could be named only in fractions, $\frac{1}{2}$ being one-half of that strength; that is to say, having a focal distance of two inches, and $\frac{1}{12}$ having twelve inches focal length, while a stronger lens, greater than 1, had a corresponding shorter focal distance. Since the adoption of the metric system in ophthalmology, the opposite way of enumeration has been employed. A lens of the focal length of 1 metre is now taken as unit, and called one dioptric, or 1 D. Any lens of longer focal length is expressed in a decimal fraction, thus, 0.25 D means a lens of 4 metres focal length. The stronger lenses, on the other hand, are measured by several dioptrics; thus, 10 D, being a lens of $\frac{1}{10}$ metre, or 10 c.c. focal length. Since both systems of measurement are yet in use, it is best to become familiar with both. As regards the convenience in calculation, for which purpose the dioptric system was introduced, there is really not much difference between them. In order to convert the number of a lens from one system into another, it is to be remembered that the metre is equal to 39.37 English inches, or 36.94 French inches. On account of inaccuracies in grinding glasses, the whole numbers, 40 (English), and 36 (French), are close enough for practical purposes. Hence, to get the dioptric equivalent of an English number, divide that number into 40, and to translate a certain number of dioptrics into the French inch system, divide the number into 36.

21. In order to examine the refraction in the eye we must determine the refractive indices of the different media, the curvature of the surfaces, and the distances between the separate surfaces.

22. *Refractive Indices of the Media of the Eye.*—The refractive indices have been measured by various observers in dead eyes by means of different physical methods. On account of less perfect methods former results must be taken with some caution. Even the more recent determinations made with Abbe's refractometer have yielded not inconsiderable discrepancies among different observers, which may perhaps be attributed to individual variations. The table of refractive indices, given below, is copied from Zehender and Matthieson.[1] It is the most complete of all recent determinations.

The indices of cornea, aqueous humor, and vitreous body are so nearly alike that an average index of the three can be used as a basis for calculation without appreciable error. Helmholtz assumes 1.3365 as the most nearly correct average in his latest publication. While the index of the capsule of the lens is considerably above this figure, this membrane is so thin and its surfaces are so nearly parallel to each other that its influence on the rays can be neglected without error. The index of the lens itself increases from the external layer to the nucleus, so that the lens really consists of a large number of layers of increasing optic density. By reason of this stratified arrangement the total refractive power of the lens is greater than it would be were the entire lens of the refractive index of its nucleus. For each layer, as we proceed toward the nucleus, increases not only in refractive

index but also in convexity. This is evident when we compare the following two lenses, the thickness of which must not be more than a small fraction of the focal length. Let one of these lenses, *A*, be homogeneous and have the refractive index *n''*, the index of the surrounding medium being *n*, while the other lens, *B*, has only a core or nucleus more convex than the surface of the lens of the index *n''*, the superficial layer having an index *n'*, intermediate between *n* and *n''*. If *n'* is now very nearly equal to *n*, we have practically a lens of the same index as that of the lens *A*, but of shorter radius of curvature, and hence of shorter focal length. If *n'*, however, is very nearly equal to *n''*, the lens *B* will be practically of the same strength as the lens *A*, but never less. Hence, no matter in what ratio the index increases as we proceed toward the nucleus, the lens gains thereby in strength. The special advantages of this stratification over a homogeneous lens is the more regular refraction of rays very oblique to the axis, as has been shown mathematically by Hermann.[2] Thereby the images of objects situated laterally from the axis of the eye are not distorted as they would be when projected by a glass lens. The actual refraction of the excised human lens was found by Helmholtz in two measurements to be equal to that of a homogeneous lens of the same curvature, but with a refractive index = 1.4519 and 1.4414. But in his latest estimate (1874) he adopts 1.4371 as the more nearly correct average total refractive index of the lens in its normal attachment during life.

23. *Curvature of the Ocular Surfaces.*—The curvature of the surfaces cannot be measured with accuracy in the dead eye, on account of the altered tension of the eyeball. In the living eye the curvature can be calculated from a measurement of the size of images reflected from the surfaces. The cornea, for instance, acts as a polished convex mirror, producing diminutive images, apparently behind its surface. The size of such an image is to half the radius of curvature of the mirror as the size of the object is to the distance of the object from the cornea. The size of the image is most conveniently measured by means of Helmholtz's ophthalmometer. This consists of a telescope, in front of which there is a thick plate of glass with parallel surfaces, which has been cut in two, so that the line separating its two halves exactly bisects the field of the telescope. The two plates can be turned on an axis vertical to the line of separation. As long as the two plates are practically one, that is to say, lie in one and the same plane, objects are seen through them in their natural shape; but when the two plates are turned in opposite directions, the objects appear split into two halves, which are displaced laterally in opposite directions, in proportion to the rotation of the plates. The explanation of this displacement has been given in Section 3. For actual use the ophthalmometer is directed toward the observed eye, at a distance of several metres, and the images of two lights, one placed on either side of the telescope, or, rather, the ideal line uniting the two lights, are observed as reflected from the cornea. The two lights are, of course, placed in the prolongation of the line separating the two glass plates of the instrument. These plates are then turned by a screw until the image is doubled; that is to say, until the two halves are displaced laterally through the open space occupied by the image. From the observed degree of rotation, and the thickness of the plates, the extent of displacement, and hence the size of the image, can be calculated, and thereby the radius of curvature of the cornea be determined.

The radius of curvature, measured by reflection from the middle portion of the cornea, has been found to vary in different eyes from 7 to 8.2 mm., an average near 7.8 mm. being the most common. No definite relation has been found between this radius and any existing ametropia. On observing the reflection from the marginal portion of the cornea, it can be seen, even with the unaided eye, that the images are larger than in the centre; that is to say, that the convexity of the cornea diminishes from the centre toward the periphery. The cornea is therefore a segment of a sphere, only in its central area, while toward the periphery its shape approaches that of an ellipse, the major and minor axes of which are to each other in the ratio of about 9 to 10 or 11. The posterior surface of the cornea is found in the dead eye to be nearly concentric with the anterior surface. This fact, in connection with the rather slight difference in the indices of cornea and aqueous humor, allows us to regard the cornea, aqueous humor, and vitreous body as one optically homogeneous medium, bounded by a single surface.

The radius of curvature of the anterior surface of the lens has been found to vary between 9 and 12, and exceptionally even 14 mm.; and that of the posterior surface between 5.5 and 6.5. The images reflected from these surfaces are so faint, on account of the small difference in the refractive indices of aqueous humor and lens, that the ophthalmometer can be used to advantage only with sunlight. The apparent size of these images requires a correction, for the cornea and aqueous humor act as a magnifying lens, interposed both in the path of the rays from the object to the reflecting surface, and, again, between the latter and the ophthalmometer. In the case of the images reflected from the posterior surface of the lens, the substance of the lens must also be taken into account as part of the magnifying system. It is necessary hence to know the distance from the cornea to the anterior surface, and from the latter to the posterior surface of the lens in order to calculate the radii of curvature. The posterior surface of the lens acts as a concave mirror, giving an inverted and very small image.

24. *Distances between the Refracting Surfaces.*—The distance of the anterior surface of the lens from the cornea has been determined according to various methods by Helmholtz and his pupils. By means of a focussing microscope with graduated screw, or by means of the ophthalmometer with the aid of movable lights, it was learned how far the rim of the iris appears behind the cornea and the true position of the pupil was then calculated from the known refractive power of cornea and aqueous humor. Values between 3.2 and 4 mm. have been found in different eyes. Helmholtz adopted 3.6 mm. as a sufficiently accurate average to use in his diagrammatic eye. The distance of the posterior surface of the lens from the cornea can be measured only by complicated methods based on the observation of the parallax between the reflection from the cornea and that from the posterior surface of the lens, and by taking into account the influence of cornea, aqueous humor, and lens substance on the rays. It has been found to approximate very closely to 7.2 mm., which gives 3.6 mm. as the average thickness of the lens (while the eye is not accommodating). The lens taken out of the eye increases in thickness on account of elastic retraction, as will be explained in the section on Accommodation.

25. *Diagrammatic Eye.*—We learn thus that there are noticeable differences in the optic constants of normal eyes, so that two eyes, both emmetropic, are not necessarily identical in construction. But within the latitude of emmetropic eyes the deviations of the different figures from the average counterbalance each other, so that the object, the formation of sharp images of distant objects in the plane of the retina, is equally attained in all. From numerous measurements made by himself and others, Helmholtz has constructed the following diagrammatic eye, corresponding to the average figures of human emmetropic eyes:

	Millimetres.
Refractive index of cornea, aqueous, and vitreous humor	1.3365
Refractive index of the lens as a whole	1.4371
Radius of curvature of the cornea	7.829
Radius of curvature of the anterior surface of the lens.	10.
Radius of curvature of the posterior surface of the lens.	6.
Distance from the anterior surface of the cornea to the lens	3.6
Thickness of the lens	3.6

From these data are computed:

Anterior focal length of the cornea, aqueous and vitreous humor	23.266
Posterior focal length of the cornea, aqueous and vitreous humor	31.095

	Millimetres.
Focal length of the lens (in place)	50.671
Distance of first principal point of the lens from its anterior surface	2.12
Distance of second principal point of the lens from its posterior surface	1.274
Distance of the first principal point H' of the entire eye behind the cornea	1.750
Distance of the second principal point H'' of the entire eye behind the cornea	2.115
Distance of the first nodal point K' of the entire eye behind the cornea	6.966
Distance of the second nodal point K'' of the entire eye behind the cornea	7.331
Anterior focal length of the entire eye	15.508
Posterior focal length of the entire eye	20.719

This latter figure plus the distance of H'' from the cornea gives us 22.834 mm. as the optic axis from the anterior surface of the cornea to the sensitive plane of the retina and adding to this number the thickness of the sclerotic coat, viz., 1.3 mm., we obtain about 24.1 mm. as the length of the eyeball. Anatomical measurement has shown the eyeball to vary between 22.5 and 27 mm. in length, 24 to 24.6 mm. being the most common limits. Unfortunately these anatomical measurements refer mostly to eyes the refractive state of which was not determined during life. The diagrammatic eye of Helmholtz and the position of its cardinal points are illustrated by Fig. 2043, amplified twice.

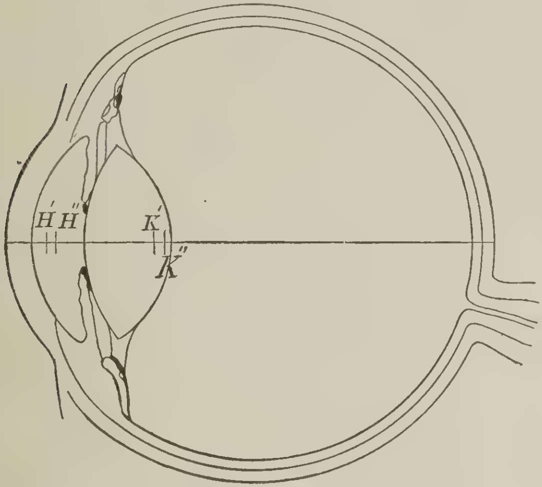

FIG. 2043.

26. In the calculation of the size of retinal images and of the influence of glasses on sight in fact, in almost all the problems not relating to the changes during accommodation, we can arrive at results sufficiently accurate by taking as a basis the simplified diagrammatic eye of Donders, in which the lens is omitted. It consists of a single refracting surface, representing the cornea with a radius of curvature of 5 mm. The single internal medium, optically identical with the cornea, has a refractive index of 1.333 ($\frac{4}{3}$). Thereby we deal with but one principal point, viz., in the plane of the cornea and but one nodal point, the centre of curvature of the cornea. The first focal length is 15 mm., the second 20 mm., which latter figure represents likewise the length of this eye.

The human eye has some advantages not possessed by artificial optic instruments, but also various faults which a skilful optician can avoid.

27. *Visual Field.*—There exists no instrument which has as extensive a field as the eye, since images are depicted on the retina of objects situated as far as 55° to 65° from the line of direct sight, and on the temporal side even as far as 90° to 100°. The fact that images formed near the periphery of the retina are not seen distinctly, is due principally to the relative dulness of sensibility of the peripheral portion of the retina. The images themselves are quite sharp, as we can learn by examining the periphery of the retina in the eye of another person with the ophthalmoscope. When the refraction is emmetropic in the centre of the retina, it is very nearly so also in the extreme periphery. This is due to the curvature of the rear of the eyeball and of the retina (compare Section 9). Moreover, the elliptical curvature of the cornea, and still more the stratified structure of the lens prevent the distortion of images, which ordinary spherical, homogeneous lenses would produce in the case of objects situated far laterally from the axis of the system.

28. *Spherical Aberration.*—Spherical lenses do not collect in the common focus those rays which are very oblique to the axis or strike the refracting surface far from its centre. This spherical aberration is shown in Fig. 2027. In the eye it is almost wholly obviated by the elliptical shape of the cornea and the stratification of the lens. The iris, moreover, serves the purpose of a diaphragm, so that the extreme marginal rays cannot ordinarily pass through the pupil.

29. *Chromatic Aberration.*—The chromatic aberration of lenses gives rise to colored rings around images otherwise well defined. It is due to the fact that the index of refraction is not the same for waves of light of different length. Hence there is necessarily a slight separation of the different colors when mixed or so-called white light is refracted by a lens. The eye is not free from this defect; it possesses it to about the same extent as if it consisted of water. If either end of a sharply defined spectrum be observed through an achromatic telescope the other end appears diffuse until the adjustment of the telescope (or of the eye) is altered. The difference in adjustment corresponds to about 1.5 to 2 dioptrics; that is to say, an eye forming a sharp image of an object emitting violet light, requires an additional convex lens of some 75 to 50 c.c. focal length, in order to bring the less refrangible red rays into a focus upon the retina. Ordinarily we are not conscious of this defect, because the eye is adjusted for the middle and brightest portion of the spectrum, viz., yellow and green to blue, while the red and violet rays form circles of diffusion around the image, which blend, and thereby diminish in distinctness of color, being, moreover, much less bright than the sharply defined image which they surround. But we can see these colored circles of diffusion quite distinctly on looking at some bright object, while covering one-half of the pupillary aperture with an opaque screen, for by thus cutting off half of the pencil of light, we prevent the blending of the color rings, and the object shows then a blue edge on one side and a yellow margin on the other. The chromatic aberration is also quite noticeable on observing a luminous point through a violet glass, which absorbs the middle part of the spectrum, whereupon we see either a red point surrounded by a blue halo, or a red margin around a blue point of light, according to the refractive state of the eye.

30. *Imperfect Centring.*—The optic system of the eye is not perfectly centred. The centre of the cornea coincides, indeed, with the vertex of its ellipse; but the major axis of this ellipse forms an angle with the visual line, or line of direct sight; that is to say, the line of the ray of direction passing from an observed point through the nodal points to the centre of the retina. The visual line deviates toward the nasal side of the corneal axis (proceeding outward) to an extent of from 4° to 8°. This relatively oblique direction of the corneal axis, when extreme, may give some eyes a false appearance of divergent squint. Still no noticeable deficiency of sight can be attributed to this want of centring.

31. *Astigmatism.*—More serious defects are those due to irregularities in the curvature of the refracting surfaces. We have so far considered only the refraction of rays which lie in one plane, with the tacit assumption that our refracting surfaces are the surfaces of true bodies of rotation, that is to say, that the radii of curvature are equal in all meridians. For, in this case, any of the figures illustrating the course of rays in the plane of the paper may be supposed rotating on their axis in order to illustrate the course of rays in all planes. But this assumption is scarcely ever correct in the case of the human

eye. On measuring with the ophthalmometer the corneal radius of curvature in the horizontal, and then in the vertical meridian, the two radii are found to differ from each other to a trifling extent even in the most normal eyes. More commonly, but not always, the radius is smallest in the vertical meridian. The two meridians presenting the greatest discrepancies are not necessarily horizontal and vertical; they may have any inclination. A difference of 0.1 mm. between the radii of two meridians at right angles to each other separates the focus of one meridian from that of the other to the extent of about 0.3 mm. Differences of 0.01 to 0.05 mm. in the radii are the most common. The cornea is hence the segment of an ellipsoid with three unequal axes. As a result, the focal length is not the same in any two meridians of unequal curvature, and hence the points of an object cannot be represented by points in the images formed in such an eye. If in Fig. 2044, *A*, we represent the ellipsoid cornea with the horizontal meridian *h h* having a greater radius of curvature than the vertical meridian *v v*, the focus in the former meridian *f h* must be farther off than *f v*, the focus of the vertical meridian. If we place a screen successively in the positions numbered 1, 2, 3, 4, and 5, the image of a distant point would appear as shown in an exaggerated manner at *B*, 1, 2,3, 4, and 5 of the same figure. The refraction by such an ellipsoid cornea can be imitated by means of an ordinary spherical lens, to which is added a cylindrical lens, the segment of a cylinder, thereby introducing a difference in the refractive strength in the two meridians, of which one is parallel with, and the other at right angles to, the axis of the cylinder. This defect of the eye is known as the regular astigmatism (from *α*, privative, and *στίγμα*, a point). There are very few, if any, eyes entirely free from it. When the inequality in the refraction of two meridians exceeds the strength of about one-half to one dioptric, it may necessitate correction by means of cylindrical glasses (see under *Astigmatism*). As the result of regular astigmatism, lines of different inclination are not seen equally distinctly. If, for instance, the eye be accurately emmetropic in the horizontal meridian, while the sharper curvature of the vertical meridian brings the focus behind the retina in the latter meridian, then only vertical lines at infinite distance will be sharply defined on the retina, while the more a line approaches the horizontal direction, the more diffuse will be its retinal image. The interference with sharp sight increases, of course, with the degree of astigmatism. A discrepancy between two meridians amounting to less than half a dioptric does not interfere with sight to any practical extent.

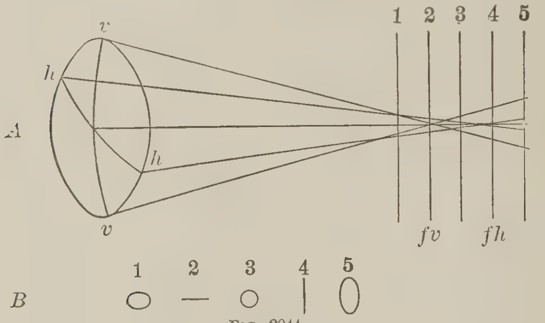

FIG. 2044.

Irregular Astigmatism gives rise to such slight imperfections of retinal images as the radiation of "rays" around stars and other small luminous points. It is due to optic inequalities in the different sectors of the lens, whereby some of the rays are deflected from the path which they would pursue in a perfect eye. This irregular astigmatism does not exist after the lens has been removed.

32. *Muscæ Volitantes.*—Few, if any, eyes do not at times see flying specks, so-called muscæ volitantes. They appear in the form of transparent rows of beads or groups of granules, or simply shadowy streaks floating about when the eye is moved. They are due to the presence of similarly shaped objects floating in the vitreous body, cells and groups of cells, and shreds of membranes, transparent, but of an index of refraction slightly different from that of the medium surrounding them. Their rims hence cast shadows similar to those of a glass ball between a light and a screen. These shadows are most marked when the rays of light are parallel in the vitreous body, when the source of light is in the anterior focus of the eye. We can observe them well by using as source of light a pinhole in an opaque screen held close to the eye and toward the sky, or on looking into a microscope. When the attention has once been called to them they may continue to annoy nervous persons, mentally rather than optically. These shadows, even if inconvenient, are not indicative of any disease.

33. *Ametropia.*—The last and most important imperfection of the eye is the not uncommon want of harmony between the focal length and the anatomical length of the eyeball, the refractive defect known as ametropia. We have seen that the radii of curvature, the distance from cornea to lens, the length of the eyeball, and perhaps even the refractive indices, may vary within certain limits in different eyes. It is only in the more fortunate instances that the ideal result, viz.: the coincidence of the posterior focal plane with the position of the retina, is obtained, while in many eyes, otherwise healthy, images of distant objects are formed, either in front of the retina, constituting myopia, or behind the retina, the condition of hypermetropia. In either of these two cases the retinal images of distant objects are blurred in proportion to the distance of the retina from the focal plane, and in proportion to the size of the pupil. The lower degrees of ametropia may be due to an unproportional curvature of the corneal and lenticular surfaces, while the length of the eyeball is normal; but when the anomalies of refraction reach any high degree, the eyeball is found, not merely relatively, but absolutely too long in myopia, too short in hypermetropia.

While emmetropia is the most fortunate refractive condition, it is not necessarily the most common. Statistics show that in the upper classes of schools, and especially high schools, in European countries, from one-third to one-half, and sometimes even two-thirds of the eyes are near-sighted, and some five to ten per cent. are far-sighted. In this country the figures are a little more favorable, as regards the frequency of emmetropia. Fuller details of these statistics will be given under the heading *Myopia*.

34. *Refraction during the Growth of the Eye.*—In the infantile eye all the dimensions are, of course, smaller than in the adult organ. The shorter axis of the eyeball is, however, proportionate to the shorter radii of curvature of cornea and lens, so that emmetropia can exist. Indeed, during childhood there are more emmetropic eyes than in adult life. The eyes of babes, however, are most frequently far-sighted, as shown by ophthalmoscopic examination. Jaeger formerly asserted the contrary, having found 78 eyes myopic out of 100, and but 5 accurately emmetropic in new-born babes. He seems to have been misled, however, by the accommodated condition of the infantile eye, for later observers, who paralyzed the accommodation by means of atropine, have arrived at different results. Thus Eli[3] found but 11 eyes myopic, 17 emmetropic, and 72 hypermetropic in 100 eyes of infants. Bjerrum[4] noted 61 hypermetropes, 23 emmetropes, and 3 myopes on examining 87 babes. Horstmann[5] found in 50 new-born infants 88 far-sighted eyes, 10 emmetropic, and but 2 short-sighted eyes. In 50 children, of the age of one or two years, 84 eyes were far-sighted, 10 normal, and 6 short-sighted; while in 50 children, four to five years old, hypermetropia had diminished, involving 74 eyes; myopia had increased to 13 eyes; 13 eyes being emmetropic. These figures show that the refraction increases ordinarily as the child advances in years. During the years of school attendance this growth leads, in many instances, to a myopic refrac-

tion. Indeed, as we pass from the lower to the higher classes in schools, we find myopia increasing steadily in frequency and in degree. The refraction remains stationary from the time of puberty, in healthy eyes. The increase of myopia so often noted from this time on until about the thirtieth year must be considered a morbid change.

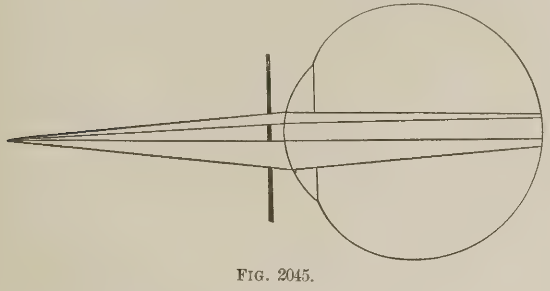

FIG. 2045.

35. Beyond the sixtieth year of age the refraction diminishes again, so that emmetropia turns into slight hypermetropia, on account of senile changes in the lens.

36. ACCOMMODATION.—According to the laws of refraction, the emmetropic eye can form sharp retinal images of those objects only which are situated at an infinite distance from the eye, or at least at a distance very large when compared with the dimensions of the refracting surfaces. Practically this amounts to any distance beyond 5 metres. But every-day experience teaches us that we can also see distinctly objects quite close to the eye; but we can never see equally distinctly, and at one and the same time, two objects, one far and the other near. On looking at a distant sign through a veil held in front of the eye, we can get alternately sharp images of the distant letters or of the threads of the adjacent veil, but we cannot see them both distinctly at one and the same time. This power of successive adjustment of the eye for distant and adjacent objects is termed the faculty of accommodation.

The exertion of the accommodation increases for the time being the refractive strength of the eye. It is evident that an eye accommodated for an object four inches distant must be equal in refractive strength to the emmetropic eye plus the strength of a convex lens of four inches focal length. For were the eye deprived of its power of accommodation it would be necessary to add to it the strength of this lens in order to get sharp retinal images of objects four inches off. The accommodative effort of an eye can therefore be represented by the strength of a convex lens of a focal length equal to the distance from the eye to the object accommodated for.

37. *Changes in the Eye during Accommodation.*—The optic changes upon which accommodation depends occur solely in the crystalline lens. Neither the corneal curvature nor the position of the retina is altered. Removal of the lens deprives the eye completely of its power of accommodation. Any eye, except one extremely myopic, becomes highly hypermetropic upon removal of the lens, requiring then a strong convex glass in order to see distinctly at a distance. On account of the impossibility to accommodate, the strength of this glass must be increased for near objects, and with a given glass accurate sight is possible only at one given distance. If the individual can read at different distances, it is done by ignoring the circles of diffusion, especially when they are small, on account of a narrow pupil. The most rigid test—whether in this or in any other case an eye is adjusted for a certain distance—is known as Scheiner's experiment.

38. *Scheiner's Experiment.*—If some luminous point—for instance, a pinhole in a screen in front of a light—be viewed through two pinholes in another screen which are closer together than the diameter of the pupil, the only effect of the latter screen held close to the eye will be to diminish the number of rays, and thereby reduce the brightness of the retinal image, if the latter be sharply defined on account of proper adjustment of the eye for the light. But if the eye is not adjusted for that distance, and circles of diffusion are formed on the retina, the screen with two perforations will cut off the rays forming the middle portion of the diffuse image, leaving instead two separate images of the luminous point, to which the eye is much more sensitive than to the circles of diffusion. Hence any want of adjustment causes the luminous point to appear double, as is evident from Fig. 2045.

39. *Changes in the Shape of the Lens.*—During accommodation the lens becomes more convex, especially its anterior surface, which also moves forward on account of the thickening of the lens. If we place a light slightly to one side of an observed eye and watch the images reflected from the various surfaces, they will appear as seen in Fig. 2046, *A*, while the observed eye looks as a distant object. When the eye observed is then adjusted for some near object, the images change, as seen in *B*, Fig. 2046. The corneal image, *a*, remains the same in both cases. The reflection from the anterior surface of the lens, *b*, diminishes in size, indicating increased curvature of the surface, and moves laterally toward the corneal image, a motion referable to the advancement of the anterior surface of the lens. The small, sharply defined, and inverted image (*c*) produced by the concave posterior surface of the lens shrinks likewise slightly in size, showing that the radius of curvature of that surface diminishes as well, though but little. No indication of any motion of the posterior surface can be observed. These changes in the curvature of the lens have been more accurately measured with the ophthalmometer, which shows that the radius of curvature can be reduced during a strong accommodative effort to about 6 mm. for the anterior surface, and about 5.5 mm. for the posterior surface of the lens, while the thickness of the lens may increase from 3.6 to 4 mm. Thereby the focal length of the lens in the diagrammatic eye would be reduced from 50.671 mm. during rest to 39 mm. during a strong accommodative effort. Calculating on this basis the refractive strength of the diagrammatic eye, we shall now find the principal posterior focus 1.644 mm. in front of the retina, while the retina itself is in the plane of focal reunion for rays coming from an object 146.6 mm. (not quite six inches) distant from the first principal point, which latter is 1.566 mm. behind the cornea in such an accommodated eye. Mathematical analysis thus confirms that the increased curvature and the advancement of the front surface of the lens suffice to account for the accommodative changes.

During accommodation the pupil diminishes in size. The utility of this contraction of the iris is evident on remembering that, according to Section 4, the spherical aberration would increase with the divergence of the rays, and hence with the proximity of the object. On account of the advancement of the front surface of the lens the iris is also moved forward, which can be seen on looking in profile view at an eye during accommodation.

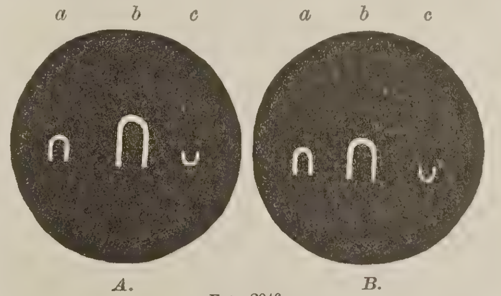

FIG. 2046.

40. *Mechanism of Accommodation.*—The accommodative changes of the lens are brought about by the action of the ciliary muscle. The lens itself is not a muscular organ, it is devoid of contractility. It is, however, an

elastic body kept stretched by its attachment to the annular ligament, as an elastic hoop would be flattened by the traction of two cords attached at two opposite points.

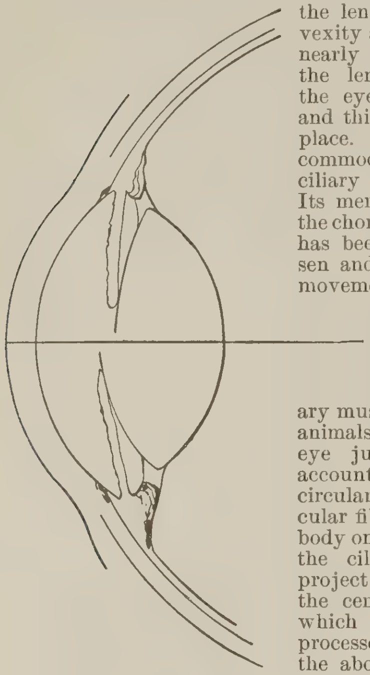

FIG. 2047.

Relieved of this traction the lens increases in convexity and becomes more nearly globular, so that the lens removed from the eye is more convex and thicker than while in place. During the accommodation effort the ciliary muscle contracts. Its meridional fibres pull the choroid forward. This has been shown by Hensen and Voelkers, by the movements of a needle put through the sclera and choroid on sending an electric current through the ciliary muscle in the eyes of animals and in a human eye just extirpated on account of disease. The circular, ring-shaped muscular fibres of the ciliary body on contracting cause the ciliary processes to project further toward the centre of the pupil, which movement of the processes is favored by the above-described traction on the choroid and consequent relaxation of its anterior insertion. In eyes in which a sufficiently extensive segment of the iris has been removed by the operation of iridectomy, and through the translucent intact iris of albinos, this advancement of the ciliary processes toward the centre of the pupil has been directly observed. Since the ligament of the lens is attached to the ciliary processes the crowding of this ring-shaped structure into a narrower space necessarily relaxes the circular band stretched across the aperture within this ciliary ring. Thus the lens is permitted to retract by yielding to the tension of its own elastic substance; for the arrangement of the fibres of the lens substance is such that they are relaxed by the approach of the lens toward the globular shape, while the flattening of the same by traction of its ligament puts them on the stretch. The changes in an eye during extreme accommodation are shown in Fig. 2047, in which the upper half represents the front half of the eye at rest, and the lower half the contraction of the ciliary muscle and its effect upon the shape of the lens.

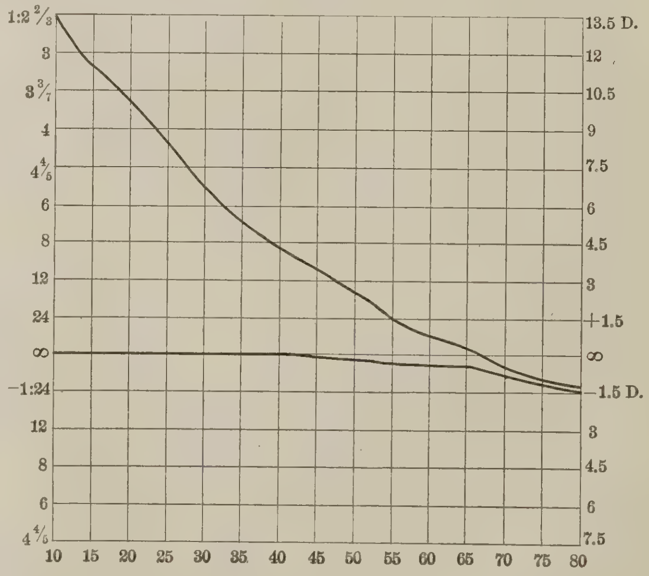

FIG. 2048.

41. *Range of Accommodation.*—The most distant point of which the eye at rest can form a sharp image on its retina has been termed by Donders the *far point* (punctum remotum = R) of the eye. In the emmetropic eye the far point is—according to our definition of emmetropia—at an infinite distance. The myopic eye, however, cannot see distinctly beyond a certain short finite distance, depending on the degree of shortsightedness, while in hypermetropia the eye cannot bring into focal reunion on the retina any but convergent rays, and the far point is therefore negative, that is to say, situated at some finite distance behind the eye. The fact that many hypermetropes can see distinctly at a distance with the unaided eye, is due to their using a part of their accommodation continuously in order to increase the actual refraction of the eye. The *near point* (punctum proximum = P) on the other hand, is the nearest point of which the accommodated eye can get a well-defined image. The range of accommodation is the total accommodative power which an individual eye possesses. We can represent it by the strength of the lens equivalent to the refractive difference between the eye at rest adjusted for the far point and the eye accommodated for the near point. Thus, an emmetropic eye, which can see distinctly an object as close as five inches, has a range of accommodation representable by a lens of five inches focal length or of the strength of about 8 D. For deprived of its accommodative power this eye would require such a lens to be held in front of it in order to get a sharp image of this near object on its retina. Practically, it will do to hold the lens very close to the cornea; for theoretical accuracy, however, the lens in question, of an infinite thinness, must be assumed situated in the first principal plane of the eye. The significance of the range of accommodation is made plainer by the use of Donders' formula,

$$\frac{1}{A} = \frac{1}{P} - \frac{1}{R},$$

in which we represent by A the range of accommodation, by P the near point, and by R the far point. This formula is applicable to ametropic eyes as well as to emmetropia, for anomalies of the refraction do not necessarily alter the range of accommodation. Thus a myope whose far point is at twelve inches' distance, and who can accommodate for objects four inches from the eye has an accommodative range $= \frac{1}{4} - \frac{1}{12} = \frac{1}{6}$. Another instance will illustrate both the condition in hypermetropia and the use of the dioptric system. Suppose a certain hypermetropic eye, the axis of which is so short that it requires a correcting glass of 4 D in order to obtain sharp retinal images of distant objects. In this eye the far point is negative, that is to say, it is situated 25 cm. behind the anterior principal point. If this eye possesses an accommodative range equal to eight dioptrics, four of them are required to see distinctly at a distance and only 4 D are left, enabling the person to get distinct images of objects 25 cm. distant by the extreme employment of his accommodation. Donders' formula reversed expresses this on using centimetres as follows:

$$\frac{1}{P} = \frac{1}{R} + \frac{1}{A},$$

which is in numerals

$$\frac{1}{P} = -\frac{1}{25} + \frac{1}{12\frac{1}{2}} = \frac{1}{25},$$

or employing dioptric notation, which is the reciprocal of the focal length,

$$P = -4\,D + 8\,D = 4\,D;$$

in other words, the distance of the near point from the eye is equal to the focal length of a glass of 4 D strength = 25 cm.

42. *Influence of Age on the Accommodation.*—From childhood on, the rigidity of the crystalline lens increases, and the extent of its elastic retraction diminishes. Hence the range of accommodation diminishes as the years advance, because the lens cannot retract as much in the later period of life as during youth, though the contracting ciliary muscle relaxes the annular ligament. The range of accommodation sinks thus from beyond ten dioptrics, during childhood, to zero toward the age of sixty years. Donders has constructed a diagram (Fig. 2048), based on numerous observations, which illustrates this decline in a graphic manner. The heavy line (the lower one) represents the refraction of the eye at rest. As before stated, the emmetropic eye becomes slightly hypermetropic in advanced age, presumably from an actual flattening of the lens or a diminution of its refractive index. The range of accommodation extends from the heavier line of passive refraction to the thin line indicating the extreme active adjustment of the eye. The figures at the bottom give the age in years; those at the side the (active or passive) adjustment in French inches (or expressed in dioptrics on the right side). Occasionally deviations are found from this standard of decline. Thus, among others, the writer has seen a gentleman, seventy years of age, who could read the finest type up to eight inches' distance. He had a slight myopia and myopic astigmatism, less than 1 D, so that this accommodative range was still a trifle over 4 D, a very unusual amount for his age. Exceptions of the opposite kind, a falling short of the accommodative range normal to the age of the patient, are always due to disease of the eye or general impairment of the health.

43. *Innervation of the Accommodative Apparatus.*—The ciliary muscle derives its nerve supply from the third cranial nerve or motor oculi, which sends the motor root to the ciliary ganglion, whence issue the ciliary nerves which penetrate the sclera. It is a common clinical observation to find paralyses of other branches of this nerve accompanied by paralysis of the mechanism of accommodation. Experiments by Trautvetter[6] have shown that the fibres of accommodation run in the trunk of the motor oculi in pigeons, while in other animals the results were negative. In dogs, Hensen and Voelkers have traced the fibres up to the floor of the third ventricle of the brain, as shown by the result on stimulating those parts.

Although the ciliary muscle consists of unstriated fibres in mammals, its movements are both as rapid and as much under the control of the will as those of any striated muscle. In birds, indeed, having evidently a very energetic accommodative mechanism, the ciliary muscle is striated. While the ciliary movements are voluntary in a certain sense, we are ordinarily not conscious of any accommodative effort. The movements of the ciliary muscle are guided by the retinal impressions which we get of the objects viewed, and may hence be classed among the complicated cerebral reflex movements. The accuracy of these movements is wonderful, inasmuch as the most rapid changes of adjustment of the eyes for different distances never give rise to any blurring of the images for which the eye accommodates. The regulating mechanism does not miscalculate the distance of the objects. The accommodating movements are always accompanied by an exactly corresponding convergence of the two eyes, so that in normal instances the object accommodated for is also the one toward which both eyes are directed, so as to place its image in the centre of the retina of each eye. The association of the movements of accommodation and convergence is so intimate that we cannot voluntarily perform either movement to any appreciable extent without the other. But by optic means, which simulate the effect of one or the other movement, we can temporarily rupture the association. Thus, with a given degree of convergence for a certain fixed object, we can either force ourselves to a greater accommodative effort by looking through concave glasses, or relax the accommodation by means of convex spectacles. Similarly, we can vary the degree of convergence associated with a certain accommodative effort by placing prisms of variable strength and inclination in front of one or both eyes. The ability to separate these two movements ordinarily associated is increased by practice. It is evident that the correlation of the two movements, as well as the disturbance of this association by optic means, subserves the same purpose, viz., distinct vision without double images.

44. *Movements and Nerves of the Iris.*—On account of the association with the accommodation, the movements of the iris can be best discussed in this connection. The iris serves the purpose of an optic diaphragm, the aperture of which can vary in size according to necessity, the physiological limits being from 1 to 6 mm. diameter. By reflex action the pupil contracts with increasing illumination, thereby diminishing both the fatiguing brightness of the retinal image and the width of any circles of diffusion due to optic imperfections. When the light is relatively feeble, a large pupil, on the other hand, permits a relatively greater brightness of the retinal images, while the enlarged circles of diffusion do not blur the sight so much, on account of their feebler intensity. The pupil contracts also with each accommodative effort, thereby diminishing the spherical aberration, which the proximity of the object and the increased convexity of the lens would produce. Independently of external light, the pupil is very narrow during sleep and during artificial narcosis. The mechanism of this latter contraction is not yet known. When the narcosis is interrupted by any sensory stimulation, or by asphyxia, the pupil indicates this change by dilatation.

The nerves of the iris are the ciliary nerves, coming from the ciliary ganglion, which, in man, has three roots—the short root from the motor oculi, the long root from the naso-ciliary branch of the fifth nerve, and the sympathetic fibres reaching the ganglion along with its arteries. The motor oculi controls the sphincter muscle of the iris. Its experimental irritation contracts the pupil; its section, or accidental paralysis, allows it to remain dilated. The reflex pupillary contraction produced by light starts with the excitation of the optic nerve. When the optic nerves are rendered inactive by disease, the normal play of the pupils ceases, and they remain in a state of moderate dilatation. Excitation of one optic nerve, however, controls the pupils of both eyes, at least in those animals which, like man, have a visual field common to both eyes. Hence, in cases of unilateral blindness, the two pupils are usually alike in size. The centre concerned in this reflex action is the anterior half of the tubercula quadrigemina (Budge). Various instances of diseases of higher parts of the brain have been observed with integrity of these parts, and hence sensitiveness of the pupils to light, although conscious sight did not exist. According to Brown-Séquard the muscular tissue of the iris itself is somewhat sensitive to light, a tonic contraction being induced in it by strong light, even after extirpation of the eyeball.

The sympathetic nerve fibres control the dilator muscle of the iris. The existence of these radiating muscular fibres, which seemed pretty well established by the researches of Henle, Iwanoff, and Merkle, after much controversy with Gruenhagen, has lately been questioned again by Eversbusch (meeting of the Heidelberg Ophthalmological Society, September, 1884). He maintains that the radiating fibres in the posterior layer of the iris, which have been interpreted as smooth muscular fibres, are really nerve fibres, as shown by various staining methods. If these statements are corroborated, it will be impossible to account satisfactorily for the action of the sympathetic nerve on the iris. The view that these nerves change the size of the pupil, through their action upon the muscular walls of the blood-vessels of the iris, is not well supported by the facts.

Their course toward the eyeball is partly along the walls of the arteries, partly along anastomoses which join the fifth cranial nerve. Section or paralysis of the sympathetic nerve of the neck is followed by contraction of the pupil, while its irritation dilates that aperture. These fibres can be traced through the rami communicantes of the last two cervical and the first two dorsal nerves into the spinal cord (Budge and Waller). The reflex centre of these fibres is partly in the corresponding region of the spinal cord, and partly in the medulla oblongata. Reflex dilatation of the pupil through this nerve channel can be readily induced by any sensory impression through almost any sensory nerve, at least when the pupil is not contracted by strong light, especially during sleep and incomplete narcosis. The pupil, indeed, is very sensitive to irritations of sensory nerves. It is not known that this reflex dilatation is of any utility.

It has recently been asserted by Tuwim[7] that the superior cervical sympathetic ganglion maintains a slight tonus of the dilator nerves of the iris, independently of, and even after, its separation from the central nervous system. Although his experiments seem conclusive, the question should be further investigated, since this would be the first instance known of tonic activity of nerves maintained by a sympathetic ganglion.

The fifth cranial nerve is the sensory nerve of the iris, endowing it with very great sensibility. Irritation of this nerve contracts the pupil very energetically in some animals, for instance the rabbit. Section of the nerve has the same effect, temporarily, the fibres being evidently kept in a state of transitory irritation by the injury, as occurs as well in certain other nerves. This influence of the fifth nerve upon the pupil does not exist in carnivorous animals. The observations in disease of that nerve in man are too conflicting to be decisive. The study of eye diseases attended with irritation renders it very likely that in man the fifth nerve is the vaso-dilator nerve of the iris, and that its reflex excitation congests the iris and contracts the pupil mechanically by the engorgement of the vessels. This is also the most plausible explanation of the intense pupillary contraction obtained on puncturing the anterior chamber, which result does not occur on operating on the dead eye.

BIBLIOGRAPHY.—The optic properties of the eye were not understood until Kepler, in 1602, evolved the theory of optical instruments in general. The importance of the various parts of the eye in refraction was further elucidated by the Jesuit Scheiner in 1619. Minor additions were successively brought out by the labor of different authors, but it was only after Gauss had published his mathematical investigation of the cardinal points ("Dioptrische Untersuchungen," Göttingen, 1841) that the complete theory of the refraction in the eye could be deduced. This was done successfully by Listing, in the article "Dioptrik des Auges" in Wagner's "Handwörterbuch der Physiologie" (1853), who, by a critical selection of the older measurements of the refractive indices of the eye by Chossat and by Brewster, of the anatomical measurements of dimensions and curvature by Kraus, Kohlrausch, and others, determined the position of the ocular cardinal points with considerable accuracy. The most marvellously accurate methods, however, for measurements of the living eye, were first introduced by Helmholtz, who, in his "Handbuch der physiologischen Optik" (1867; 2d edition, revised, 1896), has produced a masterly treatise of rare originality, which every student of the subject must consult in the original. Since the publication of his large work, the first part of which on refraction appeared in 1856, Helmholtz has pursued these studies with the aid of numerous students, most of whose articles have appeared in the running numbers of the *Archiv für Ophthalmologie.* In an article by Reich (*Arch. f. Ophth.*, 1874, vol. xx., 1), Helmholtz corrects some of his former measurements and figures, and accepts as more nearly representing the values of the cardinal points in the average eye the figures which we have reproduced in the text of this article. Extensive measurements, especially of the curvature of the cornea, have also been made by Donders ("Anomalies of Accommodation and Refraction," 1864) and by Mauthner ("Vorlesungen ueber d. optischen Fehler des Auges," 1872), and more recently by Reuss (*Arch. f Ophthalmologie*, xvii., 1, p. 27). The entire theory of the formation of images in the eye, including physiological optics in general, is most exhaustively treated in Aubert's "Grundzüge der phys. Optik," in vol. ii. of Graefe and Saemisch's "Handbuch der gesammten Augenheilkunde" (1876), while important recent additions are to be found in Nagel's "Anomalien der Refraction," in vol. vi. of the same work. Very complete is also the treatise of Fick in vol. iii. of Hermann's "Handbuch der Physiologie."* All of these works must be consulted for the complete literature of the subject. In the English language the most extensive but older treatise is the work by Donders on "Anomalies of Accommodation and Refraction" (1864), which book marked quite an era in our knowledge of the physics of the different refractive conditions of the eye. In connection with this latter subject the work of Jaeger ("Einstellungen d. dioptrischen Apparats," 1861) must also be mentioned.

The mechanism of accommodation has been extensively discussed by former authors, by whom, however, no facts were brought forth beyond those taught by every-day observation. By some the accommodative changes were referred to the variations in the size of the pupil, while others even denied the existence of any accommodation. The most complete mathematical discussion was furnished by Th. Young in the "Philosophical Transactions" of 1801, in which it was shown by experiments and by deductions that the accommodation cannot depend on any changes except those in the form of the lens. The experimental proof that such changes do occur was furnished simultaneously and independently of each other by Cramer (in various publications in the Dutch language, between 1851 and 1855) and by Helmholtz (*Monatsberichte d. Berliner Academie*, February, 1853). The mode of action of the ciliary muscle was first explained by Helmholtz theoretically, and has since been confirmed experimentally by Hensen and Voelkers, who have likewise studied the innervation of the accommodative apparatus ("Experimentaluntersuchung über den Mechanismus der Accommodation," 1868, and *Archiv f. Ophthalmologie*, 1873, vol. xix.). Important measurements of the changes in the curvature of the lens during accommodation, and a mathematical inquiry into their efficiency were published by Knapp (*Archiv f. Ophth.*, 1860, vols. vi. and vii.).† Our knowledge of the range of accommodation in health and disease is due mainly to the researches of Donders ("Anomalies of Accommodation and Refraction").

On the innervation of the iris there exists an extensive literature, scattered throughout numerous physiological and ophthalmic serials. The older literature is exhaustively compiled in Budge's "Bewegungen der Iris," 1855. The present writer presented likewise a full review of the physiology of the iris in the Chicago *Journal of Nervous and Mental Diseases* (April and July, 1874), in which the complete literature up to that date can be found. Whatever has been done since 1874 is explicitly referred to in the text.

EYE DISEASES. See under *Cataract, Choroid, Conjunctiva, Cornea, Glaucoma, Hypermetropia, Myopia,* etc.

EYE, INJURIES OF.—It will be proper, in writing on injuries of the eye, to take for granted that the reader is well acquainted with the anatomy and physiology of that organ, and such of its appendages and surroundings as, on account of structure, function, or situation, are likely, in case of injury, to require treatment differing in any way from that which would be suggested by the principles of general medicine and surgery.

It is understood, too, that the reader has acquired the art of using easily and well all the instruments and methods needed by the oculist for the diagnosis and treatment of those affections which are not traumatic. One requires, in handling cases of injury, not only to have at command an ophthalmoscope and a full case of surgical instruments, but to be well drilled in their use, and to possess also a certain adaptability to the situation and independence of thought and action, which will allow him to depart occasionally from conventionalities, and in emergency to use instruments for what they are worth, not necessarily for what they are made. For, though the results of violence may be routined off and classified as to the kind of operative interference that they may require, it is oftener in this branch than in any other that the surgeon will discover new and unprecedented situations or conditions which occur so infrequently as to have existed in literature only as forgotten curiosities.

Physical Conditions.—A word or two relative to the physical conditions which exist in the healthy eye may be of service in helping to appreciate those which are likely to exist in the injured organ, or in one in which inflammatory changes following injury have not been met by the necessary surgical interference.

The eye is a globe; it is filled with fluid, semifluid, or gelatinous matter which is practically incompressible. Its walls, though elastic and flexible, cannot be stretched very much, and as the sphere is that form which will contain the largest amount of matter within a given area of covering, the result is, there being no outlet, that if pressure is put upon this globe it will not change its shape very much without rupture. The physical conditions are very much the same as those of a leather ball filled with water—not those that exist in a rubber ball filled with air. The walls of this globe are very flexible, and when the globe itself is emptied any part of the sclerotic or cornea can be bent on itself like cloth. Neither of these tissues, either with or without its lining membrane, is subject to fracture in the true sense of the word, and when there is any complete and violent solution of continuity in these parts it is due either to laceration, to puncture, to cutting from some sharp substance, or to tension, erosion, or chemical action. The particular part at which rupture takes place will be the part at which the enveloping material is the weakest, unless, perchance, that part, at the time of the stress, is better supported by the pressure of neighboring parts, or unless some other portion is made comparatively weak by the pressure of some foreign substance which bends or indents it, and so places on it a local strain that cannot be transmitted. Rupture by contre-coup is not possible in the eye, though it is sometimes spoken of as having taken place.

Before considering each separate tissue in order, it may be well to supplement what has already been said by calling attention to the fact that the enclosing tunics of the healthy eye are more than full, and once their integrity is broken a small part of the contents is likely to be forced out by the elasticity of the tissues; that the secretion of aqueous and vitreous, and the supply of blood to the interior of the organ, keep its elastic covering always in a state of tension, and when, by rupture, cut, or puncture, or by ulceration, or decay of injured tissue, there is any solution of continuity, a part of the contents will have a tendency to escape; and while the opening remains, the constant building up of material to supply the place of what has been lost often forms a serious obstacle to the rapid healing of the wound, or the successful return of any part of its contents, such as protruding iris or vitreous, to the eye.

Without having at hand any experiments which may be quoted as giving definite knowledge of the actual strength of the materials used in the structure of the eye, it is possible to state, from records kept in cases of injury, that the part which is least capable of resisting strain put upon it by external pressure is the sclerotic, 3 or 4 mm. from the sclero-corneal margin. This is by far the most frequent seat of rupture, which nearly always takes place in a direction parallel to the sclero-corneal margin. The fact that it is usually found to have broken through the meridional fibres in the upper and inner quadrant is probably explained by the position of the surrounding parts, which are such as to protect it from external pressure, and yet to give little or no support when the eye is pressed upon from some other direction. The cornea rarely ruptures, and when it does, it is from some ragged extension of an irregular sclerotic tear, and is not to be looked upon as primarily a corneal lesion. The thickness of the sclerotic and cornea in the accompanying cut is not to show the actual size, but to indicate diagrammatically the relative liability of different parts to give way whenever, from any cause, sufficient pressure is put upon the eye itself to make a rupture of its tunics inevitable. In the same figure the choroid is drawn as if it were attached to the inner side of the sclera only at the nerve, at the venæ vorticosæ, and at the ciliary processes (Nos. 1, 2, 3). This is not really the fact, but it is so much more loosely attached at the intermediate points that, whenever the choroid itself ruptures—as it sometimes does if pressure so distorts the eye as to pull this membrane away from the overlying sclera—the break does not ordinarily occur at any of the three points named above, but at some intermediate place. Such ruptures are most frequently seen, of course, in the posterior part of the eye, often nearer the nerve than the equator. They also do occur anteriorly to the venæ vorticosæ, and sometimes so far forward as to be unrecognizable during

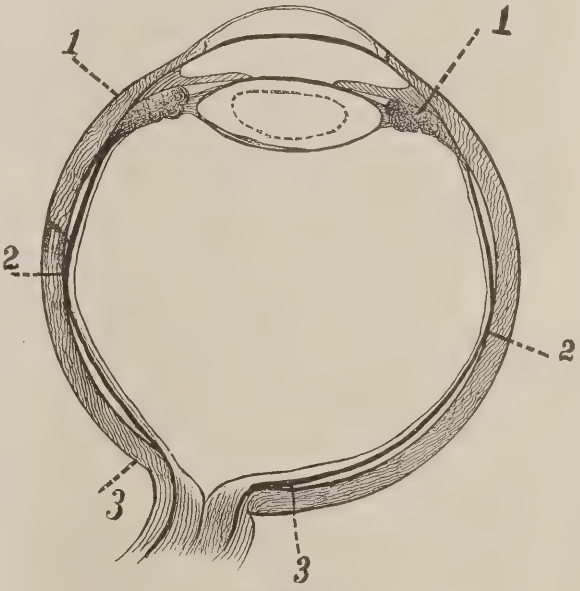

Fig. 2049.

life. The writer has seen one case in which history, symptoms, and ophthalmoscopic appearances warranted the diagnosis of rupture of choroid, with only this element of doubt in the case. The linear cicatrix which was in other respects so characteristic passed downward and inward about forty degrees from the vertical, directly across the head of the optic nerve, being visible up to the edge of the nerve above and reappearing at the edge of the choroid on the other side below.

The lens, in its capsule, and the suspensory ligament form rather an unsubstantial partition between the anterior and posterior chambers, and, while the outer tunics are intact, this structure is not very likely to be ruptured by any pressure which is uniformly distributed over the outside surface of that organ; but a distortion of the globe which tends to lengthen any diameter of the ciliary ring will do serious injury to this delicate structure, and a rupture of its walls in the immediate proximity of the lens or zonula so disturbs the equilibrium between the two chambers that dislocation is almost sure to follow. Quite often lens, iris, and zonula are all carried away by the pressure and expelled through the wound which has taken place in the stronger membranes.

The suspensory ligament is so delicate that it is said to have been ruptured by blows upon the head, which, not touching the eye at all, have caused the comparatively heavy lens to tear away its support by the rapid and violent vibrations thus imparted to it; though dislocations first discovered after such blows may be congenital.

It would be wrong to leave this subject without saying a word concerning the iris. The iris is one of the weakest muscles in the body, and the contractile tissue, which changes its size and shape so readily, is not able to do so against any appreciable resistance. In health it floats in the aqueous, attached only at the periphery in about the same manner that a delicate film of sea-weed exhibits its natural conformation in water, but collapses and loses its form when removed from that element. When the support of the lens is removed from behind it, it trembles with every movement. If there is a leak in the cornea in front of it, it is drawn into the opening, however slight, and unless extra precautions are taken it is sure to get in the way and interfere with the execution of any operation which is planned in the cavity that contains it.

It is well, of course, to know the strength as well as the weakness of different parts. The cornea is as deceptive in its strength as is the iris in its weakness. The reason that the amateur of the workshop so often fails to remove small foreign bodies which have stuck fast in the cornea is because he has been afraid to more than touch it for fear of penetration. This accident is much more likely to happen to the professional than to the amateur; but in view of the serious result of such accidents, it is well perhaps that the popular impressions be allowed to obtain. Still, though the cornea looks as fragile as a bubble, it will withstand considerable rough treatment from the hand of an expert. It is hard and almost ligamentous in its texture, and though extremely sensitive on the outside, is somewhere near 1 mm. in thickness.

EXAMINATION.—In examining an injured eye one must look at it as if he had never seen an eye before, and were going to find out just how it is made and what had been going on around it. Knowledge of what ought to be will call attention to what is. But injuries do not come tagged and labelled, and with hemorrhage, inflammatory swellings, lymph deposits, discoloration, and destruction of tissue, there is often as much difficulty in the diagnosis of injury as of disease. The lids should be pulled wide open and examined thoroughly for cuts, scars, perforations, and foreign bodies; neighboring cavities should be probed and foreign substances removed. One should look the cornea over at the window as he would examine any other lens for chips or scratches; he should also, by the aid of focal illumination at the gaslight, hunt for perforations, and should explore all depths of aqueous, lens, and vitreous by the lenses in the ophthalmoscope which will put them in and out of focus, being careful not to be so absorbed and interested in one injury that some other is overlooked and neglected.

Some readers of this HANDBOOK, who do not make or do not wish to make a special study of ophthalmology, will doubtless be called on for advice, and will feel obliged to assume the care of diseased and injured organs of sight until such cases can be transferred to other hands. The first lesson to be learned by those who are thus feeling their way is what not to do.

Cases may be divided into those which need astringents and those which need anodynes. There is one astringent that must never be used—it is acetate of lead. Useful as it might be in some cases, it is so dangerous to many corneal affections that it should never be given except by an oculist so proficient as to be able to ignore rules and indulge in ophthalmological jugglery; but by him it is seldom needed. There is one anodyne that excels all others—it is atropine. The cases which are injured by atropine when they need astringents are so few as to be counted on the fingers of one hand. The cases which are injured by astringents when they need atropine are very many; so, when in doubt, if you use atropine you will benefit half the cases and injure none, whereas the astringents blindly used will benefit half the cases and injure many. The fact that atropine is poisonous to swallow, while most astringents are much less so; that atropine blurs the sight, while astringents do not; that atropine is nearly always used in serious cases, astringents in those comparatively simple, leads the novice to hope for the best and use astringents where he would much better, if he feels himself at all off his ground, believe in the worst and use atropine. The cases in which atropine must not be used are easy to diagnose, with the exception of glaucomatous trouble, with which this paper has nothing to do. Atropine may be used with caution where there is perforation or rupture of the globe near the sclero-corneal margin. Its use is said to predispose to prolapse in such cases. In the writer's belief neither the physical conditions nor the results of experience tend to corroborate this view. Atropine, generally speaking, should not be used when a foreign body is lodged on the iris or is loose in the anterior chamber, and likely from slight disturbance to fall down behind the iris or behind that part of the sclera which forms the opaque peripheral front wall of the chamber. In most other injuries atropine is the one remedy which the surgeon cannot well dispense with, while astringents, though sometimes useful, are seldom indispensable in the treatment of recent injuries.

Arlt found it convenient to divide injuries into:

1. Those produced by sudden compression or concussion.

2. Those produced by foreign bodies not acting chemically: (*a*) Those in which the foreign substance does not remain in the eye; (*b*) those in which the foreign body does remain in the eye.

3. Those produced by scalds, burns, and corroding substances.

This is a classification which must naturally run through any attempt to consider this subject, whether from a medical or a mechanical standpoint.

HEMORRHAGE.—A word or two may be said in a general way concerning hemorrhages, which are not connected with any lesion more definite than the breaking of a blood-vessel, the location of which is often unknown. Conjunctival extravasations of blood, such as come from slight blows, or from straining, coughing, stooping, or any violent disturbance of the circulation or increase of the heart's action, are of no particular importance, and require no treatment; apart from their gorgeous coloring they would scarcely attract the attention even of the patient. The parts should be examined carefully, to make sure that there is no solution of continuity. Then, if there has been no impairment of vision, either peripheral or central, the patient may be assured of certain recovery.

Hemorrhage into the anterior chamber is almost always due to violence; it is rarely dependent upon scurvy or upon the presence of a neoplasm, and very rarely it has been reported due to other causes, such as menstrual or diathetic influence. The blood generally comes from the iris, and, unless the hemorrhage is caused by some dislocation or rupture other than that of the vessel's wall, is rapidly absorbed, sometimes disappearing within three days, sometimes remaining for as long a time as three weeks. When enough blood has been effused to conceal the inner structures of the eye, the diagnosis should be guarded, as they may have suffered serious injury.

Hemorrhage also takes place occasionally into the posterior chamber, leaving no trace of injury by which to account for the presence of blood. The ruptured vessels are supposed to be in the anterior extremity of the choroid. The depreciation of vision is often just as great as would attend choroidal rupture or other serious injury, so that it is impossible to tell at the time whether or not such injury has occurred. The treatment, of course, should be the same as that of the serious injuries which it sometimes accompanies and conceals, and it may not be possible, for six weeks or more, to say decidedly that no separation of retina or rupture of choroid has taken place near the posterior pole of the eye.

Commotio Retinæ.—After a blow on the eye, producing no other visible injury, vision may be reduced, the pupil becoming small and responding slowly to atropine while the retina is white and anæmic over the whole or a large part of its area. This condition reaches its height in about twenty-four hours and by the end of a week should be well on the way to recovery. The name, though given before the nature of the trouble was well understood, seems particularly well chosen, as the vitreous is violently forced into the region of the nerve fibres and other retinal layers are more or less affected. Such cases recover without treatment, but before allowing them to do so it is necessary to satisfy one's self that there is no rupture of the choroid or partial dislocation of the lens; that the amblyopia is not due to fracture of the skull at the optic foramen, to stretching of the zonula, or to paralysis of the accommodation.

Paralysis of Sphincter of Pupil and Ciliary Muscle.—Another injury which seems rather intangible, as far as its etiology is concerned, but which has actual existence, is the paralysis of accommodation, with partial or complete mydriasis, which sometimes follows a severe blow upon the eye. In mild cases recovery may be expected in a few days, but where the pupil is widely dilated and there is total loss of accommodative power, the patient does not recover. The indications, if any, are for the instillation of eserine.

Lids.—Passing now to those injuries in which actual damage has been done to the tissues themselves, I may simply remark, concerning the lids, that whatever may happen to them it is proper to treat the condition in accordance with the usual methods of general surgery, always remembering that they are much needed coverings for the eye itself, and when destroyed should be replaced at the expense of the surrounding tissue; care should also be taken to adjust the parts so that the contraction of the scars will not result in turning the lashes in upon the cornea or conjunctiva. Finally, it must not be forgotten that cuts across the edge of the lid margins are liable to gape and consequently they should be adjusted and supported during the healing process.

Conjunctiva.—Wounds—such as cuts, punctures, or tears—of the conjunctiva, unless they are inflicted by some instrument that causes contagion, and provided they do not involve other tissues, are not of a serious nature. They are amenable to the same treatment as is found effective in mild forms of conjunctivitis.

The extent of danger varies with the situation of the wound, the nature of the offending instrument, and the fitness of the system to undertake repair. In the first place, it is important to remember that even a slight cut in the conjunctiva of the lid may be the avenue through which some sharp instrument or foreign body has entered the orbit and has done serious injury to the optic nerve or the brain itself, a specially dangerous fracture of the orbital walls being produced by thrusts from sharp instruments which penetrate the upper part of the inner wall. Hence wounds near the peripheral part of the ocular conjunctiva should be closely examined, and evidence of foreign substances remaining in the wound or of serious injury to the orbit carefully weighed.

Small cuts or punctures limited to the conjunctiva are of little moment. The edges should be cleansed, sterilized, and freed from any particles of foreign matter that may still remain. Rest and cleanliness are the necessary conditions of recovery, and, though these wounds are not likely to be of an especially dangerous character, they demand some attention. The surgeon will often find it a difficult matter to decide just how far it is advisable to place restrictions upon the patient's usual manner of life. If wounds are comparatively large and the inflammation seems likely to affect the corneal tissues, or if there is any danger of serious results from the contraction of cicatricial tissue which may produce symblepharon, or ankyloblepharon, or entropion, or lachrymal obstruction, conjunctival wounds may be considered serious, and the patient should be made to consider recovery his first duty.

It may be necessary in some cases to put a stitch or two in the conjunctiva, to keep it in place until the healing process is established. Fine silk may be employed for this purpose, and usually it can be put in so lightly as to come out of its own accord when it is no longer needed. In putting in sutures about the eye it is very useful to have acquired sufficient dexterity to make the forceps take the place of one hand in tying the knot.

Should granulations spring up in or near the wound, they may be touched with nitrate of silver every other day. This and a one-per-cent. solution of alum for instillation will cause them to disappear.

If one of the recti muscles has been completely divided by a wound through the conjunctiva, the fact will be made manifest by an inability to move the eye toward the affected muscle, or by the occurrence of double vision, in which the image is displaced toward the injured side. The end of the muscle should be sought with a pair of fixation forceps and fixed in its proper place, as in the operation of bringing forward for strabismus.

The most serious wounds of the conjunctiva are, however, those which are made by burns from hot metals, acids, unslacked lime, and other irritating and corroding substances. The cornea is more than likely to be included, and upon the depth and extent of the corneal injury the final result is in great measure dependent. The principal danger, so far as the conjunctiva is concerned, is not so much the destruction of tissue as that, in healing, two surfaces which usually move freely over each other may become firmly united, causing symblepharon or ankyloblepharon, thus closing in part a cavity which should remain open. There is also the further danger that adhesions may take place between different parts of the conjunctival mucous surface of the lids, or between the lid and the cornea or some other part of the globe, and thus seriously lessen the mobility of the eye, or disfigure and inconvenience the patient by unsightly deformity or by the constant irritation of an organ so attached.

The first thing to be done in such cases is to remove the irritating substance, if it has not already been removed. Melted metal, which has cooled into place, must often be removed by the use of considerable force and with some mechanical injury to the parts. Lime and sand may be scraped carefully from the *cul-de-sac* with a Daviel's curette or spoon. It has been recommended that at the time of the accident alkalies should be washed from the eye with weak acids like vinegar, acids with weak alkalies like soda or salaratus; these remedies are usually at hand, and are chemically appropriate. But there is nothing so swift and appropriate as plenty of water, with which the eye may be flushed immediately. The fact that strong sulphuric acid and lime evolve heat and are more injurious when small measures of water are added does not count for much when water can be supplied in large quantities and without any delay.

These injuries, when the cornea is not implicated, call for quiet antiphlogistic treatment, with the instillation of sterilized olive oil, linseed oil, or vaseline, and of atropine to allay any irritation or tendency of the cornea or iris to become inflamed.

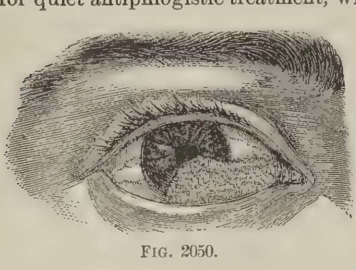

FIG. 2050.

If the injury is attended with much pain, cocaine should be used as often as necessary to secure the comfort of the patient. When the destruction of tissue extends so deeply in the *cul-de-sac* that there is no bridge, or only a narrow bridge of sound conjunctiva between the two injured parts, little or nothing can be done to prevent their growing together during the healing process. The opposed surfaces must be separated frequently, and in spite of this the contraction of cicatricial tissue will almost always bring them together as they heal, and will do this with persistency. Plates of wax, glass, silver, or gutta-percha may be worn for a while at some risk of irritating the eye, but in the course of time they will be crowded out, and are more likely to do harm than good. Attempts to improve the local conditions by resorting to surgical interference after the wound has entirely healed, are not likely to produce materially better results. Cutting the bridles and attachments affords only temporary relief, and it is only by the performance of a suitable plastic operation or by skin-grafting that we can hope occasionally to secure some measure of success.

If there is a free passage for a probe beneath the substance of the symblepharon, considerable improvement, or perhaps permanent relief, may be expected; but frequently the surgeon will exercise his ingenuity in vain. It may be put down as entirely improbable that any extensive symblepharon or ankyloblepharon which has grown up from the bottom of the *cul-de-sac*, will be greatly decreased in size by any of the measures mentioned.

The accompanying cuts are from Lawson, and represent very well the conditions indicated by the text. Fig. 2050 "represents the appearance produced by an injury to the eye from some fresh mortar, which was thrown into the eye the day before the boy was brought into the hospital." The coloring, of course, is not present, but the appearance of a burn caused by mortar is very characteristic. Fig. 2051 "is a good illustration of a case of partial ankyloblepharon, and shows very well the position of the fistula which is frequently met with when the inner portions of the lids are united." The particular case here pictured happens to have been the result of mechanical violence, but it may well have happened from either mechanical or chemical injury.

CORNEA.—Although the cornea is never ruptured by a blow or by pressure causing momentary increase of tension, and although it seldom suffers from any force transmitted to it through the closed lid (unless the lid itself is perforated), it often suffers severely from the impact of small bodies which have appreciable weight, and which so bruise without breaking its substance as to cause local death of the part struck. This results in the formation of what is known as corneal abscess. The abscess thus formed is, on account of the thinness of the membrane, not likely to exist as a sac filled with fluid of a purulent nature, but consists of tissue infiltrated with purulent matter which discharges itself either forward on the conjunctiva or backward into the anterior chamber, or more likely in both directions. This abscess may be of any extent, small or large; it may be superficial or it may involve the inner and deeper layers of the membrane. Its extent cannot be told at the time of the accident. The first sign of serious injury, apart from accompanying pain, is the conjunctival reddening and well-marked ciliary injection, which may extend entirely around the organ or may be confined to the immediate proximity of the part struck. Pain, photophobia, and lachrymation are naturally attendant on this condition, which may continue for two or three days before the grayish discoloration and opacity that follow the injury have marked out the seat and the limits of the destructive process. After this the disease follows the course of corneal abscess from any cause. Pus soon forms in the layers of the cornea and also in the anterior chamber, settling down to the lower part between the cornea and iris. By this time the inflammation will have advanced so far as to threaten the iris and ciliary region, and the pain is likely to be very severe. There is therefore danger that if the process is not checked by operative interference it may end in panophthalmitis. Pus at the bottom of the anterior chamber may be distinguished from that in the layers of the cornea by placing the patient on the side for a moment or two and witnessing the change of place caused by gravitation.

The treatment for corneal abscess of traumatic nature, either actual or threatened, is atropine, rest, and protection from the light. During the early stages, before the formation of pus has begun, cooling applications externally and iced compresses are likely to be of benefit. After suppuration is established, lukewarm or even hot water will be more gratefully borne and will probably hasten the progress of the disease toward recovery. Antiseptic precautions, of course, are necessary. They consist in frequent bathing with water of suitable temperature, to which four per cent. of boric acid has been added, or one-thirtieth of one per cent. of corrosive sublimate.

With pus in the anterior chamber and threatened or existing iritis or irido-cyclitis, it will often be necessary to administer morphine to relieve pain and to give the patient sufficient rest and comfort to insure the best recovery. Whatever the attitude of the patient is toward the use of this narcotic, it will be well to remember that pain is often worse than poison, and the surgeon should demand the right to choose.

If the pus at the bottom of the anterior chamber is more than 2 mm. in depth, or if the abscess takes on at its edge the halo of light gray, which indicates that the process at first due to traumatism is extending beyond the margin of the original injury, it may be necessary to evacuate the anterior chamber, and, perhaps, to open the abscess according to Saemisch's method, by passing a Graefe knife, which is held with its back to the pupil and iris, into the anterior chamber on one side of the abscess and out on the other, thus cutting entirely through the abscess from within outward. After this, the wound must be kept freely open until recovery is well established. This operation is not always necessary, paracentesis of the lower part of the cornea, in such a position as to favor the evacuation of pus from the anterior chamber, being often attended with the best results. This opening should be renewed at least every second day, until no pus remains.

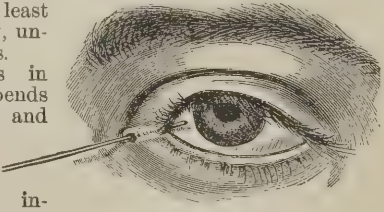

FIG. 2051.

The prognosis in these cases depends upon the extent and location of the abscess and the depth to which the tissues are involved. Wherever the abscess is, there will remain a white scar. This, of course, is of little importance if the scar is small and situated at the periphery; but if, on the other hand, it is situated in front of the pupil and is of such an extent as to obviate the possibility of making an artificial pupil, its presence will render the eye practically blind. If the abscess breaks externally, the lens or the iris is likely to rest against the wound and ultimately to become adherent to it, thus giving rise to unpleasant symptoms of irritation and inflammation, which may be well borne for many years, but which in some cases finally result in panophthalmitis and phthisis bulbi, or sometimes cause large and unsightly staphylomata. The usefulness of atropine and eserine in placing the iris in given positions should not be forgotten during the progress of the disease.

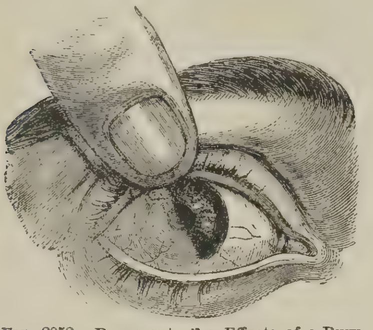

FIG. 2052.—Represents the Effects of a Burn from Molten Lead, that Splashed into the Eye from a Pot which the Patient was Carrying. (Lawson.)

Wounds of the cornea entailing solution of continuity may be mere superficial scratches, in which hardly more than epithelium has been removed, or they may penetrate the anterior chamber, injuring iris or lens, or extending to the deeper tissues of the eye. As the cornea is the principal lens in this physiological camera, the danger is twofold—that of its destruction as part of the firm enveloping membrane which holds the structures together, or that of distortion, deformity, or opacity, which destroys its usefulness as an optical instrument. If the wound is a mere superficial abrasion, complete recovery may be expected, though such injuries are often attended with great pain, neuralgic in its nature, with photophobia, lachrymation, and ciliary injection. The use of cold compresses, or of a bandage which keeps the eye closed and prevents the lid from rubbing up and down over the abraded surface, will allow it to heal in a few days, and the instillation of atropine, thrice daily, will banish the pain and hasten recovery. Occasionally, a slight abrasion made by some rough instrument, perhaps by the nail of an infant, on the cornea of its mother or nurse, will apparently heal within a few days, giving rise to no trouble at the time; but two or three weeks afterward, when the incident may have been entirely forgotten, severe and persistent neuralgic pains will call the surgeon's attention to a slight irregularity on the surface of the cornea, and with the instillation of atropine and a light bandage worn for a few days, the patient will entirely recover.

The prognosis for these wounds is favorable for the most part. Unless the loss of substance extends as deeply as the membrane of Descemet, there will be no visible scar, the transparency of the tissue remaining; but if the wound is at or near the centre of the organ, and not of a rather superficial nature, so much irregularity of surface will remain as materially to affect the eye as an organ of sight. Very slight injuries, such as those just considered, are often fraught with considerable danger to old people who are poorly nourished, or to those suffering from debilitating disease, such injuries taking the form of persistent and progressive ulceration, which is checked with difficulty. After the character of such trouble is established, it is no longer traumatic in its nature, and should be treated like any other similar ulceration.

When the cornea is penetrated by a clean, sharp instrument, which does not at the same time injure iris or lens, the wound, if not of large dimensions, may be expected to heal up quietly without any very great disturbance. The aqueous humor will, of course, be evacuated, except in very minute punctures; then, afterward, if the lips of the wound are adjusted by gentle pressure (preferably through the lid with a Daviel's curette), they will often unite by first intention, and allow the chamber to be re-established by the secretion of aqueous, which takes place very rapidly. Quite often, furthermore, the iris will not become attached to the wound against which at first it was pressing. Punctured wounds made by rough or blunt instruments often give rise to much more trouble. There is a larger vent for the escape of aqueous. The iris or the lens is likely to be pressed against the wound, or perhaps pushed through it. The healing process does not take place without some destruction of tissue and the formation of a white scar, to which either iris or lens or both may be permanently attached.

If the wound is seen at the outset, effort should be made to get the eye into something approaching its normal condition. Ragged edges of the wound or of the protruding iris, which cannot live, should be snipped off with the scissors. Gentle manipulations with Daviel's curette scoop or with the rubber spatula may cause the iris to return into the chamber. If it does not return, it should be excised, unless it has become adherent or seems to occupy a useful position in preventing the further escape of the contents of the anterior chamber. Should it be necessary to allow the iris to heal into the wound, or if later it becomes irritable, an iridectomy can be done to set the matter right.

Any wound which so opens the walls of the globe as to allow the escape of any appreciable part of its contents is a serious affair, and demands perfect quiet on the part of the patient—usually, indeed, the recumbent posture, especially during the early part of recovery. Next to rest, the most important thing, in corneal injuries, is to give frequent irrigations with normal salt solution or with some mild antiseptic solution (boric acid, for example). Avoid all depleting measures; allay pain with atropine or cocaine instillations, or with morphine subcutaneously if necessary to give the patient needed rest. If, after the healing process is well under way, there remains a fistula through which aqueous continually escapes, touch it with nitrate of silver, or burn it very slightly with the electro-cautery. It may be, and often is necessary, after recovery, to perform an iridectomy, for the purpose of affording relief from the irritating effects of iris attachments, or for that of making an artificial pupil.

Burns, scalds, and injuries of the cornea from irritating and corroding substances are of a more serious nature than similar accidents which affect only the conjunctiva; any deep destruction of tissue brought about in this way is followed by serious reactionary inflammation and resulting opacity. The danger of symblepharon is great in some cases, and should be guarded against as in conjunctival injuries. If the wound is seen immediately after the injury, it will in most cases give very little evidence of the amount of damage which has resulted or will result, but after the lapse of two or three days one can judge more accurately of the extent of this damage. Another word of warning should be given here against all collyria containing preparations of lead. Many cases, in which the eyes have been burned by acid or other corroding substance, have been made hopelessly blind by the use of acetate of lead collyria prescribed by some well-meaning apothecary who must needs do something in the emergency. The harmfulness of the lead preparations lies in the fact that they render all scars in the corneal tissue thoroughly opaque, and so interfere with the transmission of light to the retina.

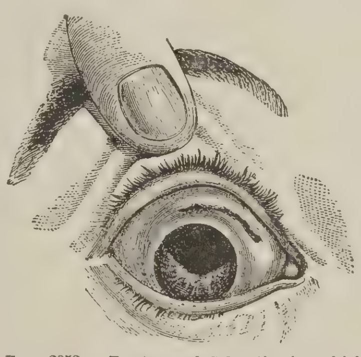

FIG. 2053.—Rupture of Sclerotic, in which Lens and Upper Half of Iris were Lost at the Time of the injury. (Lawson.)

Rupture of the sclerotic usually takes place upward and inward; the rent is from 6 to 12 mm. in length, and nearly always parallel to the sclero-corneal margin. It may also occur—though less frequently—in an outward or downward direction, and it may be irregular in shape, extending through the sclero-corneal margin. In rare cases rupture may occur in the posterior part of the globe. In that position it does not admit of positive diagnosis, but may be suspected in cases in which hæmophthalmus posterior is attended with very considerable decrease of tension.

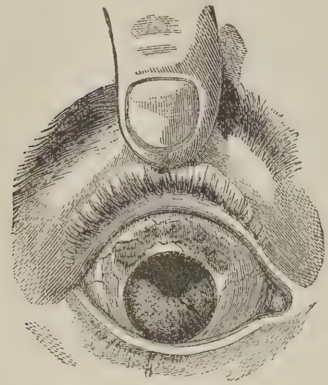

FIG. 2054.—Staphylomatous Appearance. Result of blow on the eye, which caused at the time rupture of sclera and dislocation of lens beneath the unbroken conjunctiva.

The complications which may exist are in great measure dependent on the force of the blow, and the extent to which iris, lens, or vitreous have been forced out at the time of the accident. Sometimes the lens is forcibly expelled, and may be found under the lid, or may be lost. Sometimes it may be seen at the seat of the rupture in a sac formed by the unbroken conjunctiva, where it (usually with a part of the iris) should be allowed to remain until the wound is healed and normal tension re-established. When this has taken place the iris may be removed through a suitable incision in the conjunctiva. Rupture of the sclera is usually attended by hemorrhage into the anterior chamber, often by prolapse of iris and escape of the lens.

Perfect rest is, of course, the first thing called for in the treatment of a rupture of the sclera. The patient should be confined to the room, and, if not kept in a recumbent posture, should avoid sudden movements or stooping, coughing, straining, which may lead to complications from hemorrhage into the choroid or to retinal separation. Iris or vitreous which protrudes from the wound may be removed with the scissors, if such interference can be borne without the administration of ether. If the lens is so situated as to prevent the lips of the wound from closing, or if it seems to press on the iris or the ciliary body, an attempt should be made to extract it. Atropine is usually indicated.

The prognosis in cases of rupture of the sclera is not so bad as one would be inclined to fear. Sometimes panophthalmitis, with its attendant train of destructive changes, supervenes; but often the usefulness of the eye is not entirely destroyed.

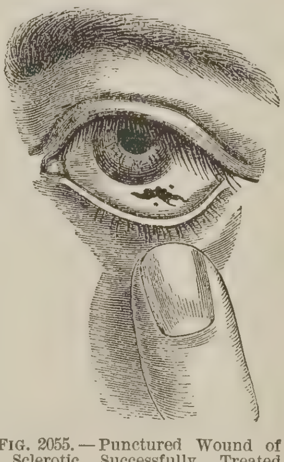

FIG. 2055.—Punctured Wound of Sclerotic Successfully Treated with a Fine Suture. (Lawson.)

Cuts and punctures in the ciliary region are almost sure to end disastrously so far as sight is concerned. The best result that can be expected is a quiet subsidence of the immediate inflammatory action, to be followed very likely by gradual cessation of function and partial atrophy of the tissues of the globe. Suppurative irido-choroiditis is very likely to follow any punctured wound of the sclera, even though it be situated so far back as to have escaped the ciliary region. It is not absolutely impossible that a clean cut through the sclera at the ciliary region, if made with a smooth, sharp instrument, may heal and leave a useful visual organ, but such a result is not to be expected.

The treatment for cut or punctured wounds is the same as for open ruptures. Tissues presenting themselves in the wound should be trimmed away as much as possible, without so disturbing the condition of affairs that more of the contents of the eye will be forced out to take the place of those removed. Gentle manipulation with the spatula or the scoop should be used in the attempt to leave the edges of the wound as nearly in their normal places as possible. If there is much gaping of the wound a very fine suture should be put in, if possible, through the outer edge of the sclera only; then both eyes should be kept closed and under gentle pressure. Even after the wound has healed and everything gives promise of a fair recovery, the contraction of cicatricial tissue may be the cause of retinal separations, followed or attended by gradual destruction of the wounded eye or by sympathetic trouble in the other.

IRIS.—Non-penetrating wounds of the globe are sometimes the cause of a rupture or a tear of the iris. Radiating rents and fissures are quite rare, and are not accompanied by any hemorrhage. The most frequent injury is a dialysis or separation of the peripheral portion from its attachment. This separation may be of almost any extent. It has been known to include so much of the membrane that it might be said to be entire, not enough of its ordinary support being left to retain any part of it in its normal position. The effect of a dialysis is usually to allow that part of the iris which is separated from its attachment to hang somewhat smoothly in the position of a chord to the arc which originally marked its place, so that both peripheral and pupillary margins are altered, as is seen in the accompanying cut, which is taken from Lawson. The kidney-shaped pupil is quite characteristic. This injury is often attended with considerable hemorrhage into the anterior chamber, which is of no particular moment and rapidly undergoes absorption. Beyond keeping the patient quiet, little or no treatment is necessary. Active inflammation very seldom follows the injury, and the harm that results, apart from cosmetic effect, is principally optical, due to the presence of two pupils instead of one. The patient either suffers from monocular diplopia or from an indistinctness of sight, due to the entrance of light into the eye without passing through that part of the lens which is capable of forming a distinct image.

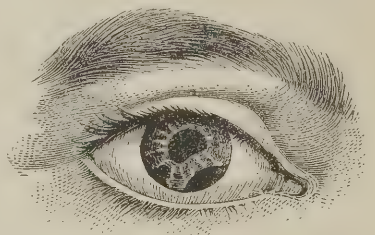

FIG. 2056.

It has seldom been thought worth while to attempt any operative correction other than an iridectomy to remove any portion of the membrane which interferes with visual ability by hanging directly across the optical axis. An iridectomy should be performed only when time enough has elapsed after the accident to prevent any unusual tendency to inflammation.

Cuts and punctured wounds of the iris occur concomitantly with the injuries of the cornea or sclera, and require no special treatment other than what has already been mentioned in connection with those injuries.

LENS AND ZONULA.—The position occupied by the lens and zonula may be represented by a circle formed by the intersection of the walls of the globe with a plane which cuts the visual axis at right angles, a few millimetres behind the iris.

A blow or pressure which causes the globe to depart momentarily from its approximately spherical shape, is likely to lengthen any one of the diameters of this circle and stretch or tear the zonula or the capsule containing the lens. And further, any pressure on the anterior part of the globe which increases the tension of the walls of the anterior chamber is likely to throw the lens backward, because the larger area of the walls of the posterior chamber allows of a greater increase of capacity before the same tension is reached. A bulging backward of lens and zonula is therefore likely to follow, so that each and every diameter of the circle in which they lie is increased in length.

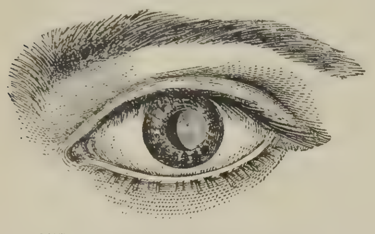

FIG. 2057.—Partial Dislocation of Lens which is Becoming Cloudy. (Lawson.)

One of these two conditions has probably existed in most of those injuries in which the only organic disturbance is a partial or total dislocation of the lens, either with or without rupture of the capsule.

It is said also that a severe blow on the head will cause such shaking or oscillating of the comparatively heavy lens as to tear the delicate membrane which suspends it between the fluid and semi-fluid humors. It seems almost necessary to allow this if we wish to account for certain dislocations that are reported—those, for instance, in which the eye itself has not been touched by the body inflicting the blow.

The disturbance that takes place in all these cases varies greatly, from the slight displacement forward which indicates a mere stretching of the ligament, to an entire breaking away from its support on all sides, so that the lens is thrown back into the vitreous, and sinks eventually to the bottom of the eye, or so that it is forced forward entirely through the pupil and lies entirely in front of the iris. Occasionally the lens is pushed a part of the way through the pupil, or it is pushed so that it comes to lie a little to one side behind the iris, in which position its edge may be seen across the centre. Under these circumstances the fundus is visible clearly with a minus glass if the observer looks through that part of the lens which is in sight, or with a strong convex glass if he looks at it through that part of the pupil from which the lens has been removed. Whenever the edge of the lens is in sight, if brilliantly illuminated, it may be recognized by a thin meniscus of vividly contrasted light and dark, caused by refraction and total reflection at the edge where the front and back surfaces curve round to meet each other.

Where the suspensory ligament is torn, the lens, of course, is left free to assume the convexity natural to extreme accommodation. Hence one of the symptoms of subluxation is (in the emmetropic eye) apparent myopia with entire loss of accommodation, and amblyopia, which latter may be due in part to astigmatism. If the lens has been moved backward and to one side, so that it only partially covers the pupil, monocular diplopia may be present; and if it is entirely removed from its place, as when it has fallen back toward the bottom of the vitreous humor, an apparent hypermetropia of somewhere near eleven diopters will be found; and on looking at a reflection of the candle flame in the eye, only that image which is due to reflection from the corneal surface will be seen. The two fainter pictures which are reflected from the anterior and the posterior lens surfaces will, of course, be wanting. A tremulous iris calls attention to the fact that its pupillary border has been deprived of the support usually given it by the anterior surface of the lens; still this symptom is not pathognomonic.

Partial dislocations of the lens backward are likely to become complete in time, that body finally sinking down to the bottom of the posterior chamber, and remaining there, after undergoing partial atrophy, for years—perhaps the least dangerous foreign body that can exist in that place. The eye is subject to the same inconveniences and accidents as were entailed by the old operation of couching.

In all posterior dislocations, unless there is some cogent reason for extracting, such as ciliary irritation or threatened sympathetic, it will be best to leave the lens as it is and make no attempt at removal. But if it presses forward on the iris, or has partly or wholly passed through the pupil and remains immediately behind the cornea, it should be removed as soon as the chemosis that immediately follows the accident has disappeared. The danger of attempting to remove a dislocated lens from the posterior chamber is very considerable. The cut is made of course as if for the operation for cataract, but the lens will rarely present itself on pressure, and recourse must be had to the spoon or the hook, and then, even when the utmost care is exercised, the lens will sometimes sink into the vitreous, where it cannot be recovered, or its extraction will be accomplished only with the loss of vitreous and perhaps subsequent accidents of hemorrhage and retinal separation.

If a dislocated lens is allowed to remain in the anterior chamber it gradually diminishes in size and sinks to the bottom of that cavity, where it remains in a shrunken opaque condition, and usually causes deterioration and opacity in the part of the cornea on which it rests.

When the lens is injured by a penetrating wound the cornea, or possibly the sclera, must of necessity have been punctured, and injury of the iris and ciliary body may also have taken place at the same time. Apart from the danger of these accompanying wounds, which of themselves may or may not be of a serious nature, there is every reason to expect serious trouble with the crystalline body. Any cut or puncture of the anterior capsule which brings the substance of the lens proper in contact with the aqueous humor is followed by an opacity and a swelling in that body, conditions which seriously interfere with nutritive and functional processes. Such an accident is much less serious in a child than in an adult, the softness and solubility of lens substance being such in the child as to admit of its somewhat rapid disintegration and absorption. These changes may take place so quickly and completely as to produce no serious injury other than the loss of the lens itself; or there may remain a capsular opacity which can be removed by any of the methods usually employed after the operation for cataract.

If much of the lens surface has been exposed by the opening of the capsule the swelling will be greater, there will be an increase of tension in the globe, and the pressure of the lens on the iris will cause a greater degree of irritation. If the patient has reached, or is nearing, adult life, the reaction caused by this disturbance will be quite severe, usually dangerous, and the result, so far as disappearance of the lens is concerned, will in no way be complete.

The closure of the capsular wound in such injuries is an impossibility. The indications are for temporizing and antiphlogistic treatment. Atropine should at once be given to prevent anterior synechiæ. Iritis and cyclitis should be combated with anodynes, and if the pain is severe, ice-cold applications should be added to the latter. Extraction should not be attempted unless the lens or a greater part of it has found its way into the anterior chamber. If the iris is pushed forward by the swollen lens and the symptoms are dangerously severe, the anterior chamber may be tapped repeatedly to allow the escape of aqueous and of any softened lens matter which has found its way into it; and in this way the process may be allowed to go on until sufficient absorption has taken place to permit the organ to return to its natural quiet.

After all inflammatory symptoms have subsided, if nothing but opaque capsule is left it may be operated on as before suggested; but if the rent in the capsule has been closed by a false membrane and there are considerable nucleous and cortical remains, these may be removed as in cataract operation, discission being the method which promises the best results, especially in children. It is very important to delay such operations until all danger of inflammatory reaction has passed away. The processes above described will seldom be completed in less than two or three months, and during this time the patient should be kept constantly under the care of the surgeon, and during convalescence he should wear shaded glasses. In spite of every precaution many cases of injury to the lens are not likely to end happily either for the patient or for the surgeon. Capsular inflammation is likely to block up the pupil with a dense membrane to which the iris becomes strongly fastened; pus also may show itself in the anterior chamber; and, finally, there may be panophthalmitis with complete destruction of the affected eye.

The Choroid.—The choroid is often ruptured as the result of sudden compression. The rent may occur at a point so far forward as not to admit of diagnosis during life, and from such accidents no doubt come many of the cases of hæmophthalmus posterior which make a fair recovery without any special mark to indicate the source of the hemorrhage. These anterior ruptures also are supposed to account for some of the hypothetical cases of commotio retinæ. Though ruptures are sometimes seen at a point anterior to the venæ vorticosæ, most of those which fall under surgical observation are near the posterior pole of the eye. They do not come at a point directly opposite the blow or pressure which causes them, but are situated on the same side of a vertical plane which passes through the centre of the globe from front to back. This seems to be in accordance with *a priori* reasoning concerning ruptures. The choroid has been known to rupture in two places at once, both ruptures being situated in the same meridian and on the same side of the eye as the compression which caused them.

Very often the perception of light becomes quantitative as soon as the accident happens, but sometimes the diminution of vision is not very great until after several days have elapsed. However this may be, the power of accommodation is at once suspended, and after recovery vision rarely reaches its normal acuteness. The wound, when first examined, will be found—if there has been no very great hemorrhage—to be filled with blood which conceals its edges. The uninjured retinal vessels may sometimes be traced over the wound; at other times the retina is broken through and separated at its edges from the choroid. The indications for treatment are the same as in other ruptures of the external tunics, except that constant recumbency is not so imperative and the patient may be allowed a little more freedom after the first few days. The inflammatory disturbance that follows rupture of the choroid, though sometimes destructive, is not usually very severe, and the amount of useful vision that is recovered is dependent very much on the seat of the lesion. Of course, if the tear has extended through the macula there will be a permanent central scotoma. The size of the final scotoma is not always commensurate with that of the original injury, it being sometimes much less than would have been thought probable.

Foreign Bodies.—Concerning foreign bodies in general, that have entered the eye and remained in it, a word or two is necessary. The eye is never safe so long as they remain imprisoned in its tissues. Still there is hardly any place inside its walls where, according to reported cases, foreign bodies have not remained for months and years. But in all, or nearly all, the cases so reported serious trouble eventually developed and brought the patient to the oculist. Yet it is fair to suppose that patients have sometimes carried foreign bodies in their eyes to the grave without serious trouble, but this is so exceedingly rare that in general, when a foreign body has penetrated the globe, it is good surgery to remove it as soon as the diagnosis is made; and if it is not possible to remove it from the eye, then it should be removed with the eye.

This rule admits of one or two exceptional cases, to be mentioned hereafter—cases in which foreign bodies, on account of the slight inconvenience which they cause at the time, invite delay for the purpose of escaping for a time the reaction which is sure to follow operative interference. Temporizing may be allowed only when the success of operative interference is not compromised by delay.

An investigation of the cases in which the globe of the eye has been penetrated by a foreign body and no attempt has been made to remove it, shows that in not a few instances the patient has experienced months of suffering and danger, and then finally has lost the sight of one eye, if not of both. Under these circumstances the surgeon should advise against a protracted postponement of operative interference. In a few cases only is it permissible to advocate delay. Thus, for example, if a patient presents himself having in the lens, or on the iris or retina, a small bit of copper or steel, an eyelash, or other substance which has been forced through to its position without exciting any lasting reaction, and if the eye has retained its usefulness in great measure, it is not necessary to attempt to remove it if it is so fastened in its position that any ordinary accident or change in the surrounding tissue is unlikely to make it at some future time more difficult of access. If it is so situated that to remove it is an easy and safe procedure, it would of course be the part of wisdom to do so without further delay. But if, as is often the case, it is where it can be reached only by operative interference attended with great risk of injury or failure, it is better to counsel delay, while giving the patient emphatic warning that when any change for the worse does occur operative interference will then become imperative. Ciliary injection, pain, tenderness, photophobia, or lachrymation, or any of the symptoms of beginning iridochoroiditis, should warn both surgeon and patient that further delay is dangerous.

The Use of Magnets in Removing Foreign Bodies.—Quite a large per cent. of the foreign bodies that penetrate the globe and would remain there but for surgical interference are made of iron or steel and may be removed more easily by the magnet than in any other way. Even if the magnet itself is not all-sufficient for this purpose, it may be of great assistance by adding magnetic attraction to the force applied by the surgeon to any steel instrument that he may employ.

For purposes of diagnosis the electro-magnet is especially useful. Definite sensations of pain in the eye as the circuit is made or broken furnish undoubted evidence of the presence of a magnetic metal. It must be added that the lack of such sensations does not with like certainty determine its absence.

There are three classes of magnets in use. The permanent magnet of Gruening is independent of batteries or electrical connections, and has proved to be a useful instrument. More powerful than this is the electro-magnet introduced by Hirschberg. Various forms of this are in use, most of them from five to eight inches in length and capable of developing an attractive force of considerable strength, even across the whole diameter of the eye. A giant form of this very valuable instrument has been constructed by Haab. This new instrument so enlarges its sphere of usefulness that it has become a well recognized part of the equipment of the hospital operating room. The fact that in its most desirable form it takes up a square metre of floor space, weighs nearly 200 kgm., and costs relatively a large sum, has somewhat interfered with its general adoption as an office accessory.

The methods of using the magnet are such as are naturally suggested by the situation. Various forms of tips are easily attached to the iron core; some being intended for insertion into the eye, others for placing on or near its surface. The greater the mass of the magnetic metal and the nearer the foreign body, the better. It should be remembered that although the attractive force is practically instantaneous in its action, the movement of the attracted body is not.

Viscosity and other structural conditions of the tissue are such that repeated attempts to extract a hypothetical foreign body on several successive days may give no evidence of its existence, and yet, on a subsequent repetition of the attempt, the body in question will appear.

The presence of a foreign body in the eye is so serious a matter, and the immediate results of extraction by means of the magnet are so brilliant, that one may easily overestimate the average benefit to be expected. It is to be remembered that many of the cases in which a foreign body has been removed from the eye without infection or undue violence, turn out badly, ending in atrophy or other serious trouble. Notwithstanding all this the magnet is a very valuable addition to the surgical outfit.

Foreign bodies that find their way between the lids, and stick fast in the conjunctiva without deeply penetrating it, seldom give rise to any trouble after they are discovered. If they are not easily seen by everting the lids under good illumination, it may be on account of their minute size, or because they have been carried up to the fold of transition beneath the upper lid. Particles of glass are particularly apt to escape observation. Focal illumination and a careful exploration with a Daviel spoon is all that is needed for their recovery, and this is easily managed unless there is considerable spasm of the orbicularis, when it may be necessary to anæsthetize the eye with cocaine, or possibly, in children, to resort to general anæsthesia. The seat of injury should be carefully examined to see that nothing has penetrated beyond the limit of the conjunctiva and has become lodged in the orbit or sclera.

Foreign bodies most frequently encountered in practice are those which have lodged in the substance of the cornea. They are sometimes very small and difficult to see, on account of their color being such as to harmonize with that of the pupil or iris. They can be detected readily in the direct light of the window, or by focal illumination, and can be removed nearly always without the aid of a magnifying glass. The point of a discission needle, cataract knife, or any other sharp instrument will be found useful for the purpose. The patient should sit or stand before the window and fix the eye on some object which will insure its being held in the right position, while the surgeon stands wherever the substance can be most distinctly seen. Some patients will fix better by looking with both eyes, others with only the injured one.

It is not always possible to pick up a small particle of steel or emery on the point of a needle until after repeated efforts. In order to diminish the pain caused by such efforts it is a good plan to scrape off the epithelium from the very small surface (less than a millimetre in diameter) immediately surrounding the foreign body. When these small substances have penetrated deeply into the cornea, great care should be taken not to push them through into the anterior chamber. Such an accident is of a most serious nature; it is quite likely to necessitate an iridectomy for the removal of the foreign body. When the foreign body is so deeply situated that this accident seems imminent, it is best to enter the anterior chamber with a Graefe knife, which should be introduced at a point 2 or 3 mm. to one side of the foreign body and made to emerge at some distance beyond it. The flat of the knife will thus serve as a support for the foreign body, which may then be removed with safety by the usual manipulations. Care should be taken not to turn the knife so as to allow the escape of aqueous and not to encroach any more than is necessary on the pupillary area. Sometimes a splinter penetrates the layers of the cornea and seems to be placed lengthwise in its substance in such a manner that it can neither be removed by forceps nor grasped by a needle. In such a case, the upper layers of the cornea may be opened by a Graefe or a Beers knife, held with its back to the anterior chamber. In rare cases a small bit of foreign substance may be driven through the cornea in such a manner that one end of it hangs loose in the anterior chamber, while the other remains fast in the deeper layers of the cornea. When this state of affairs exists, the foreign substance may be removed by making a cut in another part and removing the offending substance from within with a pair of delicate forceps.

Foreign bodies in the anterior chamber, unattached to the iris or lens, often sink to the lower part of the sclerotic border. Very small bodies may be concealed there or behind the iris or the opaque sclera. They sometimes become partly encapsulated or surrounded with lymph before exciting destructive inflammation. In some cases they may be removed by an iridectomy. Occasionally such a foreign body has ulcerated through and has been discharged before the eye was entirely ruined. If such a process is going on when the patient first presents himself, it may be well to temporize, but never to delay operating with the hope that the substance may be gotten rid of through the establishment of such a process.

In cases in which it is otherwise impossible to diagnose or localize a foreign body it may often be seen by the aid of an "*x*-ray" apparatus and a fluorescent screen. Two pictorial reproductions from different positions are usually necessary and sufficient to determine, with some degree of exactness, the position of the foreign body. This is done by comparing its position in the picture with that of other substances, which though outside of the eye have been placed in the field in a manner suitable for comparison.

Lens and iris seem particularly tolerant of foreign bodies. If a small foreign body is attached to the iris in such a manner that it does not seem likely to fall to the bottom of the anterior chamber, it may be left *in situ* as long as it causes no disturbance, provided the chance of successful removal is not growing less. A foreign body in the lens, if the opening in the capsule is small, may be left in place until it can be successfully removed by a cataract operation. If the capsule is widely opened, the case should be treated as a traumatic cataract, and the foreign body should be removed if possible with the swollen cortical.

A foreign body in the vitreous, immediately behind the lens, will sometimes present itself at the wound and be expelled by gentle pressure, or it may be removed by a scoop or hook, after the lens has been removed by a cataract operation. Such a result, though gratifying, is hardly to be depended on. In fact, the removal of a foreign body from anywhere in the vitreous is something of a forlorn hope. An incision either equatorial or meridional, may be made back of the ciliary region, and in such a manner as not to divide entirely any of the muscles. Through this opening the foreign body may come, or may be made to come. A few cases have been recorded, but no one has had so many, or has been so successful, as to warrant us in establishing any rule or definite course of action.

When a foreign substance has been in the eye so long as to cause considerable inflammation, which has rendered the vitreous opaque and full of connective-tissue opacities, removal is out of the question as a means of preserving sight, and a constant watch should be kept over the patient, so that the globe itself may be enucleated before the establishment of severe or dangerous inflammation. Small substances (less than 2 mm. in their longest diameter) that rest on the retina, or are suspended in the vitreous, do not demand surgical interference if, when they are first seen, the symptoms of irritation have passed away, and if delay in removing them does not seem likely to render the operation more difficult.

Foreign bodies, both large and small, may pass through the conjunctiva and remain in the orbit. If their presence is not recognized at the time, the external wound is quite likely to heal. In rare cases the body then becomes encysted, but more commonly it gives rise to orbital abscess, and is discharged or removed with the contents of the abscess. Orbital abscesses are not unattended with serious danger, on account of possible pressure on the globe or extension to the cerebral cavity.

William S. Dennett.

EYE, TUMORS OF.—I. TUMORS OF THE EYELIDS.

A. *Benign Tumors.*—The benign tumors of the lids are partly congenital, partly acquired later on in life Their growth is but seldom accompanied by any inflammatory symptoms. These tumors, of course, during their growth, are influenced by the nature of the tissue from which they spring and into which they grow, and the variety of tissues which constitute what we term the eyelids necessarily brings about a number of distinct forms of tumors, and an endless variety in their shape.

1. *Warts* and *epithelial horns* (not to be confounded with epithelial growths) are sometimes found on the outer dermoid surface of the lids, more frequently on the upper lid. They may be congenital, and they may keep on growing gradually until it becomes necessary to remove them on account of their unsightliness, or because their weight is felt disagreeably and has become a hindrance to the free movements of the lids; or, finally, because they actually obstruct sight by obscuring a part of the visual field in certain positions of the eyeball.

Such warts usually spring from the lid, with a broad basis. They are not easily confounded with epithelial growths, because they lack a zone of inflammation and infiltration, which, in the case of the latter, is never wanting. Furthermore, epithelial growths usually show points of ulceration. Moreover, epithelial growths of the eyelids, although observed in young subjects, are more frequently found in the declining years of life, and lie most frequently near one of the canthi or at the lid margin. Warts and horns, however, are found in all ages, and seem to be more frequent near the middle portion of the eyelids than at any other locality.

According to their superficial arrangement, such epithelial warts of the eyelids have been described as papillomata when resembling cauliflower, and as condylomata when resembling the broad or pointed condylomata observed in other regions of the body.

The histological structure of these warts has nothing that would distinguish them from other warts of the skin. They consist of hypertrophic papillary structures, covered by very thick and horny layers of epithelial cells.

Although such warts are in themselves benign tumors, we must state here that in later years epithelial growths often begin from such warts, and their removal is therefore to be recommended.

2. *Granuloma* or *chalazion* of the eyelid is, in contradistinction to the other benign tumors of the eyelids, an inflammatory tumor. In its origin it is a hordeolum, that is, an inflammatory process caused, in the more superficial or the deeper layers of the eyelid, by the stoppage of one or more secretory canals of the Meibomian glands, be this merely mechanical (by foreign substances) or due to an infection or an inflammatory process, which only secondarily involves the secretory ducts of these glands. Such a Meibomian hordeolum is originally the distended Meibomian gland, filled with its own secretion and pus, and later on with an atheromatous detritus. This sac, so to speak, lies, as is clear from its mode of development, embedded within the tarsal tissue, and pushes out the skin of the lid in the form of a roundish elevation, the periphery of which falls off into the surrounding tissue at a more or less acute angle. These tumors vary considerably in size, and, aside from the deformity which their presence causes, they may have to be removed because they interfere with sight.

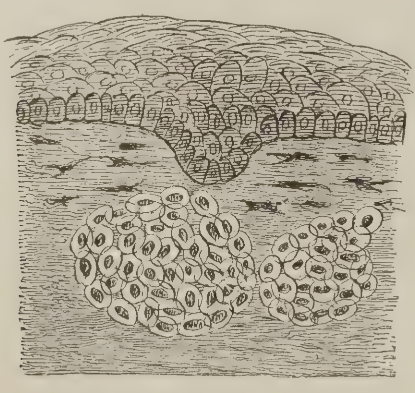

FIG. 2058.—Xanthelasma of the Eyelid.

We find, then, usually, that these tumors (tarsal tumors, as they are often styled) consist, at a later period, to a great extent, or even totally, of granulation tissue, which, having sprung from the walls of the sac, has forced the semifluid contents of the original cyst to one side where they have undergone partial absorption. Later yet, we may find solid granulomata, and no vestige of the atheromatous or purulent contents of the sac. As curiosities we may mention that one author claims that chalazion is due to the tubercle bacillus, while another author has even found an enormous bacillus chalazicus.

This is undoubtedly the form of tumor most frequently met with on the eyelids.

3. *Xanthelasma* or *xanthoma* of the eyelids is not a rare affection. It seems, however, to be more frequent among females than among males. It is a roundish or lobulated elevation of the skin, of a peculiar yellowish appearance, which has given it its name. Its development has often been brought into relationship with diseases of the liver.

Very frequently these elevations occupy symmetrical positions on both eyes, especially on the upper eyelids. They are not found in early youth, and undoubtedly belong to the later years of life. In females they often develop in the catamenial years. Aside from the deformity which they cause, there is hardly any reason for their removal.

So far as their histological formation is concerned there can be no doubt that different forms of tumors which have nothing in common except their yellow aspect, may be taken for xanthelasmata. This yellow coloring is due to the presence, in the subcutaneous tissue, of a large number of stellate connective-tissue cells which contain yellow pigment granules. Aside from these, the tumor may consist of connective tissue which has undergone fatty infiltration and degeneration, or it may show plainly a hypertrophic condition of the sebaceous glands, with stoppage and perfect occlusion of their excretory canals. We find then, in these tumors, large, round sacs of connective tissue filled with the enormously swollen epithelial cells of these glands, which are undergoing retrogressive metamorphoses (see Fig. 2058). In other cases we find simply a dense connective tissue, void of even a trace of the glandular structure, but containing the pigmented, stellate cells which these tumors all have in common, and from which they derive their name. The same enlarged and degenerated epithelial cells are found in molluscum contagiosum and have been claimed to be the characteristic molluscum bodies. They are, however, also found in epithelial horns and other pathological conditions of the lids.

According to their form, these tumors have been described as xanthelasma planum or tuberosum.

4. *Angiomata* of the eyelids are almost always congenital tumors, although, from their slow development, they may become noticeable only several years after birth. They belong either to the cavernous or the arterial variety.

The cavernous angiomata cause a swelling of the lid in which they are embedded, and usually impart to it a dark-blue color. If the upper lid be the one affected, it cannot be raised freely, or else it shows the condition known as ptosis. Any impediment to the continuous flow of the venous blood (stooping down, coughing, pressure, etc.) causes the tumor to swell. These growths frequently extend backward into the tissues of the orbit, or into the tissues surrounding this cavity. From their site, color, and conformation, such cavernous angiomata may be, in rare cases, confounded with orbital cysts, which sometimes cause a very similar aspect of these regions.

The histological structure of these cavernous growths shows, of course, nothing peculiar.

The teleangiectatic tumors are usually smaller than the cavernous ones, and since they generally reach to the cutaneous surface, they are recognized at a much earlier period. There is very often but little or no swelling, but the bright-red, enlarged blood-vessels can be seen through, or even in, the skin. This kind of angioma is but seldom confined to the eyelid alone. Yet there are also teleangiectatic tumors of the eyelids so well defined that they can almost be enucleated like a granuloma.

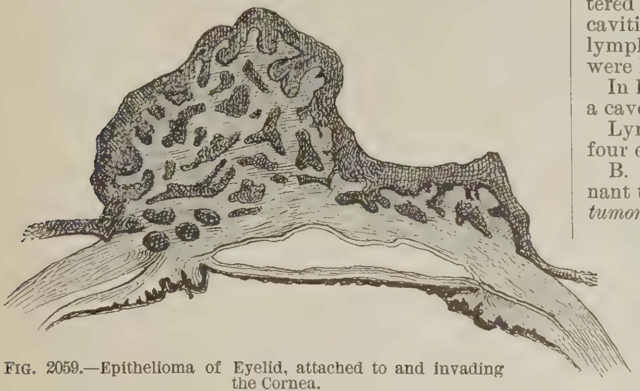

FIG. 2059.—Epithelioma of Eyelid, attached to and invading the Cornea.

While cavernous angiomata are apt to grow with advancing years, the teleangiectatic angiomata do not seem to have this tendency to a very marked degree.

5. *Fibromata.—a. Hard fibromata* of the eyelids are of very rare occurrence, and may possibly take their origin from a granuloma formed in the cystic distention of a Meibomian gland (hordeolum). The writer has seen and examined only two such cases. In both, the round tumor was implanted in the tarsal tissue, and raised the skin of the lid just as a chalazion does. In both, the tumor was situated in the upper lid and was harder to the touch than a chalazion usually is. The size of the tumors was about that of a cherry pit, and they consisted altogether of a dense connective tissue with short spindle cells.

β. The *soft fibroma* (fibroma molluscum) of the eyelids is also of very rare occurrence, and is usually found at the same time on other parts of the body.

These tumors, which appear always in large numbers, vary in size from that of a pea to that of a large pear, and even much larger ones have been observed. As they grow they usually become pedunculated, and hang pouch-like by this pedicle.

Their histological structure has not as yet been satisfactorily studied. Some authors have found only soft connective tissue, while others report the presence of peculiar cells undergoing retrogressive metamorphoses—probably epithelial cells of the sebaceous glands, resembling closely those found in xanthelasma.

γ. A third form of *fibroma* of the eyelid has been described as *plexiform neuro-fibroma.* This rare kind of growth is said to be congenital, and to consist of a series of swellings and cords which lie in the subcutaneous tissue, and which in parts are extremely painful to the touch.

The histological examination has not cleared up the nature of these fibromata very materially. They are said to consist of dense connective tissue, rich in nuclei, and surrounding simply atrophic nerve bands, or nerve fibres undergoing fatty degeneration.

6. *Lipomata* of the eyelids are of rare occurrence. They may be congenital, or they may appear in very obese people in advanced life. In the latter case they are apt to grow, and may have to be removed because they interfere with the sight, and this is especially apt to be the case when they develop in the upper lids and hang over the lid margin.

No further importance is attached to this kind of growth.

7. *Lymphangiomata* and *lymphomata* have also been found in the eyelids.

The case reported as lymphangioma seems to be unique. It is said to have been situated at the lid margin, the size being that of a split pea. It consisted of fibrous connective tissue, throughout which were scattered a large number of cavities of different sizes. These cavities contained a fine, granular substance in which lymph cells were suspended. The walls of the cavities were lined with an endothelium.

In harmony with this description the tumor was styled a cavernous lymphangioma.

Lymphomata of a very large size were found in all the four eyelids of a man suffering from leukæmia.

B. *Malignant Tumors of the Eyelids.*—1. Of the malignant tumors of the eyelids the most frequent are *epithelial tumors,* and among them especially the flat epithelioma.

The epithelioma of the eyelid begins almost always at the lid margin, especially on the lower lid, and it seems to grow with preference near the inner or outer canthus.

In the beginning we usually find a small, roundish, reddish nodule, which is quite hard. Sometimes this hardness and some redness around the original nodule are the only symptoms by which we may distinguish it from a common wart. After a while, either spontaneously or because the patient keeps irritating it with his fingers, the surface of this nodule becomes slightly ulcerated, and a crust is formed. Now this one nodule may keep on growing and spreading, and become excoriated at its surface, or new nodules may spring up around it and share the same fate. Thus there is finally developed a flat ulcer, with a hard base, and hard, ragged edges, which frequently bleed profusely when but slightly injured. As the ulcer creeps along some parts may heal, and the tough white bands of scar tissue give the affection then an aspect very similar to that of scirrhous cancer in other parts of the body. The infiltration of the tissues, the breaking down of the lid margin, and the development of bands of cicatricial tissue—all these alterations, singly or combined, may cause very annoying and unsightly deformities of the eyelids. The lower lid, as a rule, becomes everted, and to all other afflictions is added a continuous flow of tears. The growth of this kind of epithelioma is but slow and, *quoad vitam,* very much less to be dreaded than another form of this growth which eats rapidly into the tissues and breaks them down in a very short period. In the latter variety the rapid progress of the primary disease is soon followed by infiltration of the lymphatic glands and of the parotid, or the disease may spread over the conjunctiva bulbi into the cornea, and, eating its way through it, may enter the eyeball, or grow around it and invade the tissue of the orbit. This form is, luckily, observed rarely, and the prevalent form is the one which we first described.

Epithelioma of the lid is a disease which is found in individuals of advanced age only.

When this form of tumor involves the eyelid the histological elements found are precisely the same as those observed in the growth when it involves some other part of the body. The pre-existing epithelial cells of the cutis, as well as those of the sebaceous glands, become hypertrophic, and grow in the typical way into the under lying and surrounding tissues, in the shape of cylinders. Frequently the rapid increase in number of the epithelial cells causes the formation of pearl nodules. The periphery of the growth shows the usual zone of infiltration and inflammation.

2. *Adenoma* and *adeno-carcinoma,* especially of the Meibomian glands, but also of other glands in the tissues of the lids, have been found in a number of instances. When seen at the proper time it has been found that what originally was an adenoma had developed, later on, a carcinomatous character.

3. *Sarcomata* of the eyelids, at least those of primary nature, have been observed in small numbers (about fifty in literature). The eyelids are more frequently invaded by sarcomatous growths from the orbit and the surrounding tissues.

In the cases of primary sarcoma of the lid which have been observed, the patients were nearly all children. The tumors grew rapidly and soon infiltrated the whole tissue of the lid. The neoplasms were mostly of the round-cell type; in some instances, however, the growth belonged to the melanotic variety, and in still others it was composed of spindle cells, of cells of a myxomatous type, or of cells arranged in alveoli.

Of course, the danger to life due to sarcomatous growths makes their removal as urgent when they originate in the eyelid as when they develop in any other region of the body.

II. TUMORS OF THE CONJUNCTIVA.—A. *Benign Tumors of the Conjunctiva.*—1. *Lymphangiectasia* of the conjunctiva appears usually as a conglomeration of small, roundish elevations, filled with a watery fluid, and often strung together like beads. These little tumors give rise only very rarely to an inflammatory condition of the surrounding conjunctiva, and, as a rule, cause the patient no annoyance to speak of. When punctured they collapse, but are generally soon refilled. Their usual seat is the bulbar conjunctiva.

From the appearances presented under the microscope these tumors consist, undoubtedly, of distended lymph vessels. The little tumor is composed of a system of canals and cavities, which are in no way connected with the blood vessels. The latter show the more plainly, as they are usually hyperæmic. The cavities and canals just spoken of are separated from each other by trabeculæ of dense connective tissue, but they intercommunicate. The surrounding conjunctival tissue appears condensed and pressed aside. This system of canals contains a perfectly translucent serous fluid in which are suspended a number of lymphatic cells. The walls show, now and then, some traces of an endothelial coat (see Fig. 2060). The writer has had occasion to report a case of acute formation of hemorrhagic lymphangiectasia in an idiotic girl.

2. *Serous cysts* of the conjunctiva may undoutedly result from what was originally simply a lymphangiectasia; the septa existing between the canals and cavities of such a tumor having gradually yielded to the pressure, and all the cavities having thus become united into one. But serous cysts have also been found in the conjunctiva at birth, and they may develop without being preceded by a typical lymphangiectasia, especially after injuries, or they may be due to the cystic degeneration of small glandular lobules situated in the fornix.

They appear as round or oblong or oval swellings in the conjunctiva, and, owing to the nature of their contents, they usually present a somewhat yellow tinge. They are not, as a rule, movable under the conjunctiva, but they may become large enough to annoy the patient, and must then be removed.

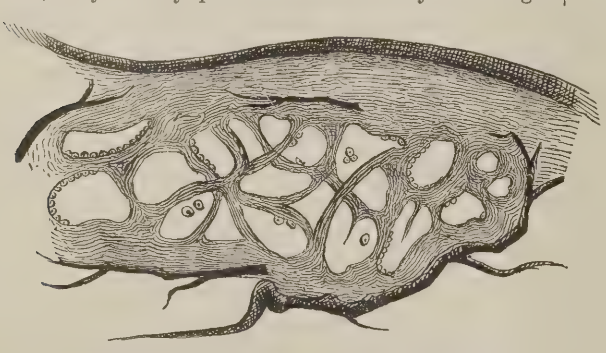

FIG. 2060.—Lymphangiectasia of the Bulbar Conjunctiva.

They have a well-defined cyst wall, consisting of connective tissue, and are usually lined with one or two layers of endothelial cells.

3. *Teleangiectatic* tumors are also occasionally found in the conjunctiva of the lids and eyeball, and usually there is then, at the same time, a teleangiectatic tumor in the lid. The seat of these tumors seems to be mostly in the region of the lachrymal caruncle.

Their histological structure is the same as that of other teleangiectatic tumors.

4. *Granulomata*, commonly called polyps, of the conjunctiva are comparatively frequent. They are red, softish nodules which project into the conjunctival sac; their mode of attachment to the conjunctiva being either by a broad base or by a slender peduncle. They are found chiefly near the inner canthus. They are due either to injuries or to chronic inflammatory affections of the conjunctiva, and may attain a considerable size, especially on phthisical eyeballs. Now and then they make their appearance at the site of a tenotomy for strabismus.

Their structure is that of all granulomata. They consist mainly of newly formed round cells and small spindle cells, here and there intersected by connective-tissue trabeculæ. This tissue is often full of blood-vessels, and usually contains a number of cavities filled with serous fluid. In rare cases the tissue is found to be of a higher organization, the granuloma being changed into a fibroma.

5. What has been described as *lipoma* of the conjunctiva is a subconjunctival growth of fat tissue. In the few cases which have been described this kind of tumor was congenital, in some it increased in size in later life. The subconjunctival lipoma appears as a yellow, roundish, and soft swelling, usually consisting of several lobules. They seem to be generally situated between the external and the superior rectus muscles.

According to the descriptions given of their histological structure these tumors are very closely allied to the dermoid tumors; it even seems as if they were dermoid growths with an excess of subcutaneous fat tissue. In one or two cases bone and fibrous tissue have been found in connection with such a fatty growth.

6. *Papilloma* of the conjunctiva has been found in a number of instances. The tumor, when seen, usually encroached upon the cornea, thus simulating a pterygium. Its histological examination alone revealed the true character. In one case reported by the writer, almost symmetrical papillomata developed in both eyes and, growing over the cornea, rendered the patient blind.

7. *Dermoid* tumors of the conjunctiva are always congenital tumors. Their seat is at the corneo-scleral juncture, and very frequently they lie partly in the corneal and partly in the conjunctival tissue.

The tumor appears as a grayish or yellowish round elevation, about the size of a pea—sometimes, however, much larger. Where it ends in the corneal tissue it is usually surrounded by a zone of gray corneal tissue, not unlike an arcus senilis. Conjunctival blood-vessels may enter it. Its surface is usually smooth and shining, and it may be partially or totally covered with fine hair. Sometimes one or more of these hairs grow very long and protrude through the palpebral fissure. Such a tumor may remain stationary a whole lifetime and cause no greater annoyance than what may be due to the growth of the hair. In other cases some irritation causes the tumor and its surroundings to become inflamed, and then the tumor may begin to grow and invade the thus far healthy tissue of the cornea. In such a case, or from cosmetic reasons, the removal of a dermoid tumor may become necessary, and is, as will be seen from the histological conditions, easily accomplished.

The dermoid tumor, as its name indicates, consists essentially of the elements of the skin. It is covered by epithelium, the outer flattened cells of which are, however, not always horny, but often undergoing a retrogressive metamorphosis. This is probably due to the moisture in which the surface of the tumor is continuously bathed. There are also usually a number of mucous cells to be found in this layer. This epithelial coat is uneven, like the surface of the skin, and numerous offsets are sent into the depth surrounding the papillæ of the tumor. From almost all of these indentations one or two fine hairs spring forth, and here lie also the orifices of the acinous glands, which are usually found in these growths. The connective tissue under the epithelium is very dense and fibrous. It contains elastic fibrillæ, and, as a rule, but few cellular elements, unless the tumor be in an inflammatory condition. The basis of the tumor, which is only very loosely connected with the episcleral tissue, is made up of fat tissue. Where the tumor lies on the corneal tissue, the union is usually a very firm one. These tumors contain a moderate number of blood-vessels, but it seems that they are but scantily supplied with nerves.

8. *True osteomata* of the conjunctiva have been observed in a small number of cases. The formation of bony tissue seems not to have been congenital. There appeared, in one case, a small tumor on the eyeball near the outer canthus, and it was removed on account of the annoyance which it caused. In another case the tumor had attained the size of a bean. The histological examination revealed true bone tissue.

9. The writer, on one occasion, removed from the eye of an infant a tumor which must be styled a *chondro-adenoma* of the conjunctiva. This tumor sat on the bulbar conjunctiva with a broad base, was whitish in color, and presented a perfectly smooth surface. The parents had observed it at the time of the child's birth, and thought that it had been gradually growing since that time. Its size was about that of a split pea when the writer saw it. The histological examination revealed the fact that it consisted of a large cluster of glandular tubules, resembling somewhat in their arrangement those of the lachrymal gland, and a large, roundish piece of embryonic cartilage. These two kinds of tissue were separated from each other, and together they were surrounded by a dense connective tissue.

B. *Malignant Tumors of the Conjunctiva.*—1. *Sarcomata* of the conjunctiva are of rare occurrence. They are either unpigmented, or, what is more frequently the case, pigmented. These tumors take their origin almost invariably from the region where the conjunctiva bulbi joins the cornea, that is, from the episcleral tissue at the corneo-scleral juncture, in rare cases from the loose tissue of the fornix. Their development has, in a number of cases, been ascribed to an injury.

The sarcomatous tumors of this region usually form roundish, sometimes lobulated swellings, which soon encroach upon the corneal tissue. They are very vascular, and bleed easily. They are usually of a rusty brown color, or they may even be almost black, at least in parts. Their surface appears smooth and shining, which is due to the fact that the growth for a long period remains covered by the conjunctival and corneal epithelium. Sometimes new nodules appear at some other point of the corneo-scleral margin, occasionally at a point diametrically opposite the original tumor. In their further development these tumors may spread into the interior of the eye, and, from the dissemination of their elements, death may ultimately result.

Histologically, the sarcomata of the conjunctiva are usually of the small round-celled variety. The original nodule, when growing on to the cornea, spreads for a time between the corneal epithelium and Bowman's layer, in the way pannus tissue is known to spread. Later on, Bowman's layer is destroyed at the periphery, and the sarcomatous elements invade the corneal tissue proper (see Fig. 2061). Yet the resistance of Bowman's layer is so great that the tumor will now spread underneath this layer into the cornea. In rarer cases the elements of the sarcoma are spindle cells. The pigmentation of the cells varies considerably in one and the same tumor. The more superficial parts are, however, usually the least pigmented ones. There is but very little intercellular substance. The large quantity of blood-vessels which these tumors usually contain has already been mentioned. There are always signs of former hemorrhages, and usually evidences of recent ones are to be found. In the propagation of these tumors the blood-vessels seem to play an important rôle, as they are sometimes found to be filled with pigmented molecules and pigmented cells. The periphery of these tumors is formed by a well-pronounced zone of inflammation.

2. *Epitheliomata* of the conjunctiva are more often observed than any other kind of conjunctival tumors. Although they are seen more frequently in persons of an advanced age, they make their appearance also in young individuals. They are generally situated on the bulbar conjunctiva, and, like the sarcomatous tumors, they most frequently start from a point near the corneo-scleral juncture.

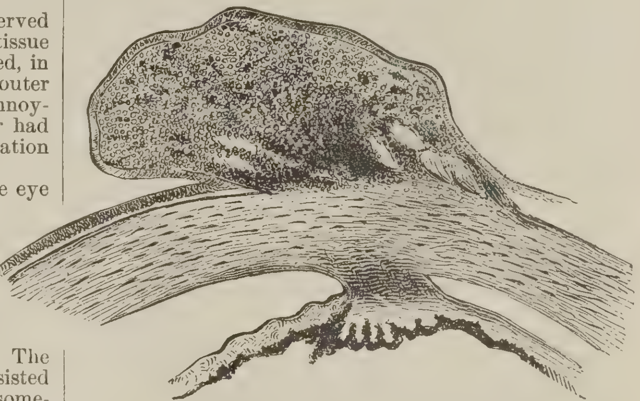

FIG. 2061.—Sarcoma of the Conjunctiva.

Their formation may begin with the development of a small phlyctenula-like nodule covered with hyperæmic blood-vessels; usually a number of larger and distended blood-vessels going to this nodule may be seen in the scleral conjunctiva. The growth may for a long period remain stationary, or it may keep on increasing gradually in size, or upon some special irritation it may start to develop rapidly, and be accompanied by inflammatory symptoms, and sometimes by considerable pain. The tumor usually spreads upon the cornea, which it may gradually penetrate, and thus find an entrance into the interior of the eyeball. The pain and suffering usually force the patient to submit to the removal of the eyeball before any further spreading of the elements of the tumor has taken place. In its early stages the new formation may be removed from the eyeball without much difficulty, as this has been stated of the sarcomatous new formations. Such epithelial growths of the conjunctiva have sometimes been found to be pigmented, and have then been described as *melanocancroids.*

The epitheliomata of the conjunctiva, like those found in other parts of the body, originate in a hyperplasia of the pre-existing epithelium. Thus we find in the beginning the epithelial layer considerably thickened, the serrated cells very numerous and well pronounced. In some cases we find a layer of horny cells of considerable thickness. This original tumor is usually surrounded by a tissue which is hyperæmic and infiltrated with round cells. When the tumor grows, epithelial-cell cylinders begin to dip into the underlying tissue and send off new branches. Gradually the new formation invades the cornea, this invasion being always preceded by the new formation of blood-vessels and by round-cell infiltration. Bowman's layer gives way, and the epithelial-cell cylinders spread into the corneal tissue proper. In the same way the epithelioma spreads into the sclerotic. Sometimes the surface of the tumor is ulcerated.

The epithelioma may spread into the interior of the eyeball. Thus it has been seen to invade the ciliary body and the choroid along an anterior ciliary artery, or the iris, after perforation of the cornea and anterior synechia had taken place. In some cases the conditions seemed to warrant the assumption that the external tumor had spread to the interior of the eyeball by metastasis.

The earlier the operation is resorted to, the easier is the removal of such tumors. This may be done successfully by means of either the knife or the galvano-cautery.

III. TUMORS OF THE CORNEA.—The cornea proper does not seem to be the seat of primary tumors. What has been described as such is to be found in section II. (Tumors of the Conjunctiva).

IV. TUMORS OF THE SCLEROTIC.—The sclerotic, like the cornea, does not seem to be a field for primary new formations. Those which have been described as such probably belong to the conjunctival (episcleral) tumors, and have, therefore, been treated under II.

V. TUMORS OF THE IRIS.—A. *Benign Tumors of the Iris.*—1. *Simple granulomata* of the iris have sometimes been observed, and have a number of times been mentioned in the older ophthalmic literature. They were described as small, round, yellowish, or grayish swellings, which made their appearance usually in the lower half of the iris. Gradually such a tumor would grow until it reached Descemet's membrane, and finally it would lead to perforation of the cornea. This generally was followed by shrinkage of the eyeball and the formation of scar tissue.

Histologically, these tumors are found to consist of round cells, and to contain numerous giant cells ("myeloplaxes"). Such a structure is so similar to that of tubercles that some recent authors have described the simple granuloma of the iris as tuberculosis of the iris. It is certainly strange that, since we have learned what tumors may grow in the tissue of the iris in consequence of syphilis and tuberculosis, no further case of simple granuloma of the iris seems to have been observed.

2. A special kind of tumor has been observed, in a few instances, to spring from the iris; it is generally mentioned among the cases of granuloma. This is a very vascular swelling, from which on slight provocation the anterior chamber would be filled with arterial blood. I should suppose that in such a case we would have to deal with a *teleangiectatic* tumor, rather than with a granuloma. The writer has had occasion to report the histological results of the examination of two cases of iris tumor which had been diagnosed as sarcomata, but which proved to be vascular tumors. The one had the character of a capillary, the other of a venous angioma. The cases reported as granulomata of the iris, accompanied by more or less periodical hemorrhages, have probably been of a similar character. A case described as a "papilloma of the subepithelial tissue of the iris" undoubtedly also belonged to this class of nævi.

3. *Traumatic granuloma* of the iris is occasionally met with,—in some cases after the corneal wound is perfectly healed, but in most cases after the iris has undergone a prolapse and is exposed to the air. In the former cases the granulation tissue was found to perforate the cornea, and cause perfect loss of sight in the same way as do malignant intra-ocular tumors. In the latter cases the tissue of the granuloma gradually becomes organized and forms scar tissue, and may thus bring about a spontaneous cure.

Such granulomata also consist of round cells and small spindle cells, and contain but little connective tissue and new-formed blood-vessels. Later on, the round cells gradually are changed into spindle cells, and finally we find a dense connective tissue containing but few cellular elements. The granulomata which start from a prolapsed portion of the iris are usually covered with epithelium.

4. *Melanoma* of the iris has occasionally been observed. It appears as a darker raised spot in the tissue of the iris, and it is, to say the least, as yet questionable whether what has been called melanoma was not in reality a melano-sarcoma. The authors usually state that a benign melanoma may at any time assume a malignant sarcomatous character.

Such a melanoma is said to consist of a circumscribed accumulation of "stroma cells of the iris, the larger part of which are pigmented, have many offsets, and anastomose with each other. They pass without a sharp boundary into the neighboring tissue, and the remainder of the iris is normal."

5. *Cysts* of the iris have been observed in a large number of cases. They are either serous cysts or cysts filled with epithelial material—epidermoid (atheromatous) cysts.

Cystic formations in the iris, as a rule, develop only after an injury. They begin as small, round, yellowish, or grayish tumors. The yellowish color is more characteristic of the epidermoid character, while the grayish or grayish-white color seems to be that of the serous cysts. Such cysts gradually grow until they reach Descemet's membrane, and then may become firmly adherent to it. Oblique illumination will usually show at once whether the cyst contains serum or some other material, for in the former case the tumor will be plainly translucent. In some cases the presence and the growth of such a cyst seem to cause but little discomfort; in others, however, severe inflammatory symptoms make their appearance, and sight may be destroyed.

The manner in which the formation of such cysts takes place is as yet not absolutely settled. But from recent experiments it seems that these cysts usually develop in small portions of epithelial tissue which have been forced into the iris by some previous injury; these parts enclosing organs which are apt to retain their contents and secretion. There can be no doubt, however, that in some cases serous cysts are formed, provided a fold of the iris becomes adherent to Descemet's membrane or to a wound canal in the cornea. The closure and subsequent expansion of iris crypts has also been mentioned as a possible cause for cystic formations.

The cyst walls have usually been found to consist of atrophied and attenuated iris tissue, lined with a layer of endothelial cells, and usually firmly adherent to the cornea. There is scarcely any pigment found in the cyst walls. The contents of the serous cyst are a perfectly transparent fluid, while the contents of the epidermoid cysts correspond with those of other atheromatous cysts and sometimes contain hair.

B. *Malignant Tumors of the Iris.*—*Sarcomata* of the iris have been met with in comparatively few cases. They have been mostly pigmented, but in a few cases they were unpigmented, or at least only slightly pigmented.

These tumors of the iris seem to have originated mostly in the parenchyma of this membrane, and near its sphincter edge. When allowed to grow, the tumor slowly spreads over the iris, and at the same time presses against the cornea, which it finally perforates. During its development it causes increase of intra-ocular pressure and inflammatory attacks, with subsequent destruction of sight. Later on, it leads to metastases. The rule is, undoubtedly, that these tumors grow on the anterior surface of the iris. The writer has in one instance seen a darkly pigmented sarcoma spring from the posterior surface of the iris near the pupillary margin, and, pressing the lens backward, spread into the interior of the eyeball. In its early stages sarcoma of the iris has been successfully removed by iridectomy; later on, the eyeball has to be sacrificed.

In the few cases which have been histologically examined the tumors were either pigmented round-cell sarcomata or sarcomata of the pigmented and unpigmented spindle-cell variety. They seem to take their origin from the parenchyma of the iris.

VI. TUMORS OF THE CILIARY BODY.—A. *Benign Tumors of the Ciliary Body.*—1. Up to the present time the writer has examined nine instances of *adenoma* of the ciliary body. These small tumors, which sprang from the pars ciliaris retinæ, were usually confined to one ciliary process, and seemed to cause no symptoms during life. Histologically, they consist of the cells of the pars ciliaris retinæ, arranged in double rows like glandular ducts, and these tubules form numerous convolutions. Between these tubules lies a coagulated amorphous substance. The tumors are surrounded by pigment epithelium. It is as yet not clear whether these adenomata are congenital or develop later in life.

2. *Myoma* of the ciliary body has only once been observed and described. In this case a brownish-red tumor was found to press part of the iris against the posterior

surface of the cornea and to protrude for some distance into the pupillary space. The tumor showed smooth elevations. There was increase of intraocular tension, and attacks of severe pain were complained of. The tumor grew slowly but continuously, and was considered to be a sarcoma. Finally, the patient consented to the enucleation of the eyeball. The tumor was found to have the size of a filbert, and to be firmly attached to the ciliary muscle. When divided it presented a cut surface of a roseate color, and it was only slightly pigmented in the peripheral parts. On microscopical examination it was found to consist almost exclusively of non-striated muscular fibres.

3. A *cyst* of the ciliary body has also been observed and described in a few instances, but these cases have not yet come to be examined microscopically. The cystoid formation followed an injury to the lid and eyeball. The cysts are described as oval bodies lying just behind the lens, springing from the ciliary region, and reaching with the larger end half-way across the eye into the vitreous. By oblique illumination the edge of such a cyst looks white, and can be clearly defined. Its surface is dotted, here and there, with pigment deposits. By direct examination with the ophthalmoscope the cyst walls are found to be transparent, and the details of the background of the eye may be dimly recognized through them unless they contain blood. These cysts have been observed to grow slowly, and to cause attacks of increased intra-ocular tension.

B. *Malignant Tumors of the Ciliary Body.*—Primary leuco-sarcoma and melano-sarcoma undoubtedly occur in the ciliary body, but are comparatively rarely seen, and yet more rarely examined microscopically. Moreover, these forms of tumors have nothing which would distinguish them from the sarcomatous growths of the choroid, and they are, therefore, best considered under that head (VII., B). Of late, in a number of instances, carcinomata of the ciliary body have been reported. They are described as having sprung from the pigment layer, more especially from the so-called glands of the ciliary body (Collins). This matter, however, needs further investigation.

VII. TUMORS OF THE CHOROID.—A. *Benign Tumors of the Choroid.*—1. *Granuloma* of the choroid is sometimes found in the course of histological examinations. Whether it has ever been clinically diagnosticated the writer does not know. In literature no mention is made of such a diagnosis.

In eyes in which the choroid has been injured (through the sclerotic), or in which round-cell accumulations have, after the manner of abscesses, perforated the lamina vitrea of the choroid, we find occasionally a small tumor consisting of granulation tissue, *i.e.*, of free nuclei, round cells and small spindle cells, and newly formed blood-vessels. These tumors may either lift the retina from the choroid and thus cause a circumscribed detachment of the former membrane, or they may pierce the retina also and protrude into the vitreous body. Later on, these granulation tumors are changed into connective tissue, and ultimately, after contraction has taken place, they form a simple scar.

There is one observation on record of the presence of small granulomata of the choroid in the eye of an individual who had long been suffering from "granular lids."

2. So far as I can learn, *cystoid* formations in the choroid have been seen only once, viz., by the writer, and then only in the course of the microscopical examination of an eye. They were found situated in the peripheral portions of this membrane, and formed a small number of round and oval cavities embedded in the parenchyma of the choroid. They had a membrana propria and were lined with endothelium. As regards their structure they were probably composed of dilated lymph vessels. The tissue of the choroid, which was displaced by these cystoid formations, was infiltrated with round cells and hyperæmic.

B. *Malignant Tumors of the Choroid.*—The only form of primary malignant tumor found in the choroid (and ciliary body) is that of the sarcoma in some one of its numerous varieties.

Since sarcoma of the choroid (and ciliary body) is undoubtedly the kind of intra-ocular tumor most frequently met with, we will give it a more extensive consideration, the more so as its clinical development is typical for that of all malignant intra-ocular tumors. It happens but comparatively seldom that we have occasion to see and diagnosticate a choroidal sarcoma, and afterward to verify our diagnosis by a microscopical examination at the period which is usually described as the first one in its development. At this stage the patient usually complains only of a diminution of sight. If the tumor springs from the ciliary region it can usually be recognized by the protrusion of the iris, and be seen under oblique light. The diagnosis is more difficult when the tumor is situated more centrally, or, as is frequently the case, near the optic-nerve entrance. The difficulty may be considerably increased if the retina at the site of the choroidal tumor has become detached. This seems, however, to be less frequently the case than was formerly stated by the authors. At this stage the ophthalmoscope may reveal one larger-sized, roundish elevation in some part of the background of the eye, or a flat elevation with a smooth or undulating surface covered by the retina, whose blood-vessels appear accordingly distorted in their course. The pigment of the sarcoma may perhaps be seen through the retina; even in cases in which the retina at the site of the tumor is detached it may be possible to recognize the latter through the retina with the aid of strong illumination and a high magnifying power. In most cases, however, it will be necessary to make repeated examinations of the fundus throughout a considerable period of time, in order to be able to determine whether there is any change in the picture and whether the supposed tumor increases in size. If an apparent detachment of the retina lying in the upper half of the eyeball, or to one side, remains confined to its original seat, and if the lower half of the retina does not become involved, the condition should be considered very suspicious of the presence of a choroidal sarcoma.

The growth of a choroidal sarcoma may vary considerably as to rapidity. While some reach the second period in, say, one year, others may take a number of years to reach the same stage.

The second period in the development of a choroidal sarcoma is characterized usually by an increase of the intra-ocular tension to a varying degree (glaucomatous stage), combined with inflammatory attacks and often severe pain. In some cases glaucomatous symptoms are wanting. In this period the tumor fills the vitreous chamber more and more, and pushes the retina, the condensed vitreous body, the usually cataractous crystalline lens, and the iris toward the cornea. Or it spreads through the whole uveal tract, forming, so to speak, a sarcomatous shell which encloses the retina, the condensed vitreous body, and the cataractous crystalline lens. In this period the eye usually shows, externally, the signs of a chronic inflammation.

The third period in the development of a choroidal sarcoma is usually called that of perforation and the spreading of the tumor outside of the eyeball. Thus the elements of the tumor usually grow through the sclerotic, along, or even by way of, a blood-vessel (venæ vorticosæ, anterior ciliary arteries, etc.), or through the channel of a ciliary nerve, or, what is quite often the case, when the tumor originates near the optic nerve, by way of this nerve or its sheaths, or by way of the intravaginal space. In other cases, the tumor will cause a staphyloma-like distention of the anterior parts of the sclerotic or of the cornea, and cause a rupture there. In this case the lens is usually expelled from the eye, and the tumor, no longer restrained in its growth by a resistant capsule, grows rapidly outward until the lids can no longer be closed over it.

At the same time dissemination of the elements of the tumor has usually taken place. Such elements taken up into blood-vessels are carried away by the current of the blood, and, wherever they are deposited, new (metastatic) tumors are formed, which ultimately cause the death of the patient. The organs which are usually attacked by such metastatic tumors are chiefly the liver, the lungs, pleura, intestines, kidneys, spleen, brain, etc.

In very rare cases sarcoma has been found to attack both eyes of the patient.

The development of sarcoma of the choroid is usually observed at an advanced age, yet it has also been found in very young individuals. It seems to be somewhat more frequent in males than in females. In a considerable number of cases its development may rightly be attributed to an injury.

Histologically, we find the choroidal sarcoma to be more frequently pigmented than unpigmented. The pigmentation varies considerably, however, even in one and the same tumor. The elements of the tumor are either round cells or spindle cells. The spindle cells seem to be prevalent in the unpigmented sarcomata. The round cells of the pigmented sarcomata (melano-sarcomata) are usually very large. The round-cell sarcomata are mostly very vascular. The spindle-cell sarcomata have generally but few blood-vessels, and in certain respects they present rather the characteristics of a fibroma. They also seem to grow more slowly than the round-cell sarcomata.

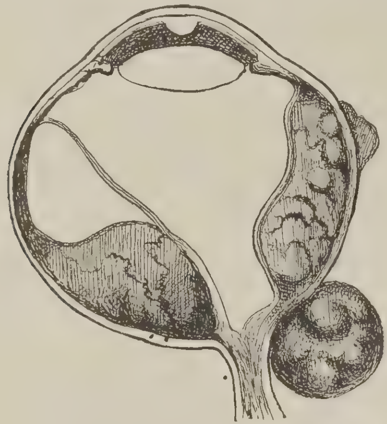

FIG. 2062.—Sarcoma of the Choroid.

The sarcomata of the choroid may take their origin from the different layers of the choroidal parenchyma. The statement has been made, and its correctness has been denied, that the unpigmented spindle-cell sarcomata spring usually from the outer layers of the choroid. The writer is satisfied that this is the correct view, and that the pigmented sarcomata, especially the darkly pigmented ones, spring as a rule from the inner layers of the choroid. They get their dark pigment from the broken-up cells of the pigment epithelium, and from hemorrhages. Sarcomata starting from the outer layers of the choroid may remain perfectly unpigmented, and grow to quite a size, until by the final perforation of the lamina vitrea of the choroid, and the subsequent breaking up of the pigment epithelium, a large quantity of pigment molecules is set free, and then only does the tumor become to some extent pigmented. Before this happens the pigment epithelium is usually found in a state of proliferation.

Occasionally there may be more than one primary sarcoma nodule in the choroid of one eye. From the primary nodule the sarcoma spreads in the choroid in the following manner:

When the elements of the original tumor have perforated the lamina vitrea of the choroid, detachment of the retina may take place, or the retina may remain in contact with the inner surface of the tumor and become firmly adherent to it. The choroid surrounding the tumor, which at first may appear normal, or hyperæmic and slightly infiltrated, is gradually invaded by the elements of the tumor. This invasion takes place at first in the outer (venous) layers. In these cases the growth of the tumor is a more diffuse one. In other cases metastatic nodules are formed in other regions of the choroid, at some distance from the primary nodule. Gradually the elements of the tumor reach the lamina suprachoroidea, and the tumor soon adheres to the sclerotic. This union is sooner or later followed by the perforation of the sclerotic and the growth of secondary nodules on the outer surface of the eyeball. As stated before, this perforation of the sclerotic takes place along a pre-existing canal (nerve or blood-vessel) in the sclerotic. In rarer cases the cornea is perforated by ulceration, and thus the tumor spreads outside the eyeball. On the other hand, the tumor may spread backward by way of the optic nerve. This happens in one of the following ways: the elements of the tumor may invade the substance of the nerve itself, or they may enter into the porus opticus along the central blood-vessels, or they may invade the intravaginal spaces of the optic-nerve sheath. The glaucomatous symptoms, which are observed in most cases of choroidal sarcoma, are due to the pressure exerted by the growth.

The sarcoma of the choroid is sometimes found to contain deposits of amorphous lime.

In rare cases osseous tissue is found to have been developed within the sarcoma (osteo-sarcoma).

Chondromatous tissue is found somewhat more frequently (chondro-sarcoma). It usually appears in the shape of round or oval islets, which are generally surrounded by a tough connective-tissue capsule, and lie near or around a larger blood-vessel.

In a few of the cases observed the sarcoma was a cystic sarcoma, and in another small number it was an alveolar sarcoma.

The spindle-cell sarcomata are, as a rule, hard and tough, while the round-cell sarcomata are softer, sometimes even semifluid.

In a few cases metastatic carcinoma has been seen in the choroid of women, the primary growth having its seat usually in the mamma. In a man the seat of the primary tumor was in the lungs and pleura. In one case a metastatic sarcoma was found in the choroid.

From the foregoing it is evident that, as soon as the diagnosis of choroidal sarcoma is made, the eye should be removed, as it is impossible to state when the tumor will spread outside the capsule of the eyeball, although this usually takes place only at a late period.

VIII. TUMORS OF THE RETINA.—A. *Benign Tumors of the Retina.*—*Teleangiectatic tumors* and small *fibromatous tumors* have been occasionally found in eyes examined anatomically, but they do not seem to have ever been observed during life, nor are they of any importance.

B. *Malignant Tumors of the Retina.*—The only malignant tumor observed to take its origin from the retinal tissue is the *glioma* of the retina.

Glioma of the retina (fungus hæmatodes) is essentially a disease of childhood; the oldest patient in whom it was undoubtedly observed was but twelve years old. It is probably, in most cases, a congenital affection.

As with the sarcoma of the choroid, we may divide the clinical history of the development of a glioma into three periods.

In the first period the growth causes but slight outward symptoms, and its existence at this period is but seldom discovered. The first symptoms, on account of which the parents bring the child for examination, are usually diminution or total loss of sight and the observation of a light yellowish or yellowish-red reflex from the pupil (amaurotic cat's eye). In this stage the pupil is also generally found to be dilated, probably from paralysis of the nerves of the iris.

The reflex from the background of the eye may at first be visible only in certain parts, and then the ophthalmoscope may reveal only a partially swollen retina, and the optic papilla may as yet be visible. Gradually the background of the eyeball is shifted more and more forward in the vitreous chamber, and it may now be possible to see different round nodules by the aid of oblique illumination. On the anterior surface of this yellow nodular mass a number of blood-vessels may be visible. Usually some whitish spots are seen, which correspond to parts which have undergone fatty degeneration, or to deposits of lime. Finally, the whole of the vitreous chamber is filled, and the tumor reaches the crystalline lens and presses it forward. This is usually soon followed by the formation of cataract.

Before this stage is reached, as a rule, the second period has begun, which is characterized by an increased intra-ocular tension, pain, and inflammatory symptoms. The eyeball is now frequently ectatic in the equatorial region; there is iritis, and soon the cornea ulcerates and is perforated. The blood-vessels of the conjunctiva and episcleral tissue are hyperæmic and tortuous. These symptoms are often combined with cerebral ones; there may also be fever and vomiting. The ulceration and perforation of the cornea, in rare cases, may be followed by the formation of scar tissue and shrinkage of the eyeball. Such cases have been described as cases of spontaneous healing of glioma; but even after a considerable period of latency the tumor makes its appearance again, and thus valuable time may have been lost.

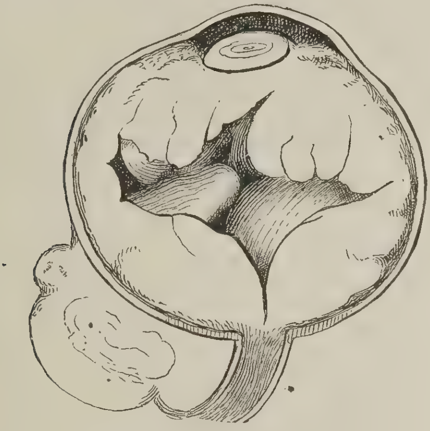

FIG. 2063.—Glioma of the Retina.

The third period is that of perforation. The glioma grows outward usually after the perforation of the cornea,—more rarely after perforation of the sclerotic. If it grows out through the cornea it increases very rapidly in size. The soft, easily bleeding, often partially necrosed tumor soon protrudes between the eyelids, and may in a short time attain an enormous size.

When the tumor has spread through the sclerotic, before the cornea has been perforated, the episcleral tumor or tumors may cause a considerable degree of exophthalmus. The tumor may furthermore invade the optic nerve and thus grow backward toward the chiasma.

Usually during this period secondary tumors are formed in the lymphatic glands of the face, in the parotid or submaxillary glands, in the bones of the skull, in the brain, in the liver, and in other organs.

Death follows from exhaustion.

In a large proportion of the cases (eighteen per cent.) glioma of the retina attacks both eyes. The affection of the second eye seems, however, not to be due to an infection from the one first attacked. Frequently several children of one family suffer from this new formation. It seems that it is more frequently found in males than in females.

The writer has reported one case in which glioma of one eye gave rise to sympathetic disease in the fellow eye.

In a few cases purulent choroiditis, with purulent hyalitis (pseudo-glioma), has been confounded with true glioma. In such cases, however, the intra-ocular tension is, as a rule, reduced, and pain seems to be wanting. Moreover, the eyeball appears rather shrunken than distended, as it does in a case of true glioma.

The opinion formerly held by the writer, in common with numerous authors, that histologically considered the glioma (or glio-sarcoma) of the retina must be counted among the small round-cell (medullary) sarcomata seems no longer tenable, since the characteristic "spider cells" of the glia have by Golgi's and Ramon y Cajal's process been demonstrated in glioma tissue. Besides these characteristic glia cells the elements of the tumor are round cells, smaller or larger than white blood cells, or identical with them. Sometimes these cells have small offsets. Between them we find free nuclei and some spindle cells. There is a very small quantity of intracellular substance. The tumors are usually very vascular, and their blood-vessels are very wide. The cells seem to be very prone to degenerate. Rosettes, formed by the rods and cones, have been given of late an undue importance in the histology of glioma. In the opinion of the writer they are purely accidental formations. Tumors in which they were found have of late been called neuro-epitheliomata, these cells belonging to the so-called neuro-epithelium of the retina.

The tumor usually takes its origin from the outer retinal layers, especially the granular layers; in rarer cases its primary seat is in the inner layers, especially the nerve-fibre layer. In some cases it appears as if the whole thickness of the retina had been primarily affected, and, in fact, the tumor may take its origin from the connective tissue of all the layers of the retina.

As already stated, the glioma cells are apt to undergo fatty degeneration, and deposits of lime are often found in these tumors.

When the tumor starts from the outer layers (*glioma exophytum*), the retina in its neighborhood soon becomes detached and is pressed toward the axis of the eyeball. In these cases the inner layers of the retina may remain intact for a long time. On the other hand, when the tumor has started from the inner layers (*glioma endophytum*), the rods and cones may be preserved for a long period. The tumor gradually spreads all over the retina, and enters the choroid either simply by continuous growth or by infection (metastasis). During the growth of the tumor, parenchymatous hemorrhages frequently take place within it. Later on, the tumor may spread into the ciliary body and the iris, and we may thus find an eyeball filled perfectly by glioma, and but few traces of its former structures left.

At a comparatively early period, usually, the elements of the tumor invade the substance of the optic nerve.

The perforation of the sclerotic, and the formation of secondary tumors outside of it, generally take place along a preformed channel (nerve or blood-vessels), as we have seen it take place in the development of the sarcoma of the choroid.

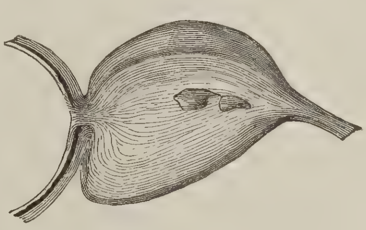

FIG. 2064.—Myxo-sarcoma of the Optic Nerve.

Glioma is known to be pre-eminently a malignant growth; therefore the removal of the eyeball, or even of the whole orbital contents, is necessary at the earliest possible period. In this way the life of the patient has been saved in a number of cases.

IX. TUMORS OF THE OPTIC NERVE (ORBITAL PORTION).—The tumors of the orbital portion of the optic nerve have a number of symptoms in common, whatever the nature of the growth may be, the chief ones of which are loss of sight and exophthalmus. The latter is often the first symptom to be observed. This exophthalmus is, as a rule, in a straight forward direction, yet there may also be a deviation in another direction, if the tumor should develop more rapidly to one side. The eyeball can usually be moved, but its movements are restricted in all directions; later on, they may be totally abolished. If the tumor is large enough to be palpated, it is found to move with the movements of the eyeball, and to be nowhere attached to the orbital walls. When it is small it cannot be felt. In a number of cases the development of the tumor is attended with severe pain; in most cases, however, this symptom is wanting. In all cases sight gradually fails. In the early stages the ophthalmoscope reveals optic neuritis; later on, we find white atrophy of the optic nerve. The rapidity with which sight is abolished varies considerably in the different cases, and this is, of course, due to the manner in which, in the given case, the nerve itself is constricted or invaded by the elements of the neoplasm. Thus, when the tumor originates in the outer sheath, sight will be preserved longer than when the new formation has its origin in the perineurium or the substance of the nerve itself. As the tumor grows and pushes the eyeball out of the orbital cavity, the cornea becomes less and less protected by the lids, and finally this membrane ulcerates and is perforated.

It seems that in all the known cases, except one, the tumor with the eyeball, or the tumor alone, has been removed and a perfect cure has been obtained. From this it would appear that tumors of the optic nerve, *quoad vitam*, are not to be considered malignant.

As regards the nature of the tumors of the orbital portion of the optic nerve they seem to be chiefly myxomatous (myxo-sarcomatous) or gliomatous; in some cases the tumors had to be interpreted as endotheliomatous (psammoma), and a few cases, described as cancers of the optic nerve, most probably belong to this latter class. In one case the tumor was found to be a true neuroma. In a few cases the tumor has been described as being formed by a hypertrophy of the pia mater trabeculæ which hold the nerve-fibre strands in position.

Being enclosed within the space which is limited by the muscles of the eyeball, and the posterior aspect of the sclerotic, all of these tumors are more or less spindle-shaped (see Fig. 2064).

1. *Myxoma* or *myxo-sarcoma* of the optic nerve consists of spindle-shaped and stellated cells, with long offsets. These cells are usually packed more densely in the central parts of the tumor than in the peripheral ones. They are separated from each other by a hyaline intercellular substance. The cells often appear concentrically arranged, and thus form nests which resemble the pearl nodules of epitheliomatous neoplasms. These tumors are, furthermore, well provided with blood-vessels. The mucoid substance is often found to be accumulated in cysts of varying dimensions. Closely adherent to the new formation are the sheaths of the optic nerve, which form a capsule around it. Sometimes some traces of the optic nerve may yet be found in the centre of the tumor.

2. *Glioma* (glio-sarcoma) of the optic nerve shows the same elements as we find in cases of glioma of the retina, viz., round cells varying in size, cells with offsets, and spindle cells.

3. *Endothelioma* (psammoma) of the optic nerve consists of connective tissue, in the alveoli of which cells lie embedded in more or less concentric layers. These cells are large, flat, membrane-like bodies, somewhat thicker at the spot where the nucleus is situated. Their contours are not sharply defined, and some of them have long offsets. Giant cells are not wanting. These cells, the nature of which is that of endothelial cells, are often grouped concentrically around a round or oval shining body (arenoid body), from which these tumors have also received the name of psammoma.

4. In the only case of true *neuroma* of the optic nerve thus far described in literature, the whole egg-shaped tumor consisted of double-contoured as well as of non-medullated nerve fibres.

X. Tumors of the Orbit.—The chief symptom of orbital tumors, and the one which they all have in common, is exophthalmus—protrusion of the eyeball. This protrusion may, of course, take place in any direction, and we can only state, as a general rule, that it is in a direction opposite to the site of the tumor or to its greatest development. Usually the movements of the eye in the direction toward the tumor are impaired or abolished. While some orbital tumors cause a great deal of pain, others do not seem to cause any. According to the seat and size of the tumor, sight will be more or less impaired or totally destroyed, and we find accordingly, with the ophthalmoscope, simple anæmia or optic neuritis or atrophy of the optic nerve either partial or total.

Orbital tumors do not seem to be apt to invade the optic nerve, or the eyeball, but they generally grow around it. On the other hand, tumors from the cavities adjacent to the orbit may and do invade this cavity. Such tumors have been found to come from the ethmoid cells, the naso-pharynx, the frontal sinus, Highmore's antrum, and the sphenoid cavity, as well as from the cranial cavity. These growths are sarcomatous, endotheliomatous, or osseous in character.

As a rule, one may locate the tumor by palpation, and it is possible to distinguish one of orbital origin from a tumor of the optic nerve by its situation outside of the cone formed by the external muscles of the eyeball, and by its being in many cases adherent to the walls of the orbit. As the tumor (and consequently the exophthalmus) grows, the upper lid is dragged along, and it often continues to protect perfectly the cornea even when the eyeball protrudes to an enormous degree. The lid is then in the condition which we call paralytic ptosis.

When the lid can no longer protect the cornea, ulcerations take place, and perforation of the cornea may be the result. According to the nature of the tumor it may, of course, invade the brain, and cause metastatic tumors to be formed in other organs, and thus bring about the death of the individual. When the orbital tumor cannot be easily removed without detriment to the eyeball, Kroenlein's osteoplastic method should be employed.

A. *Benign Tumors of the Orbit.*—1. *Cysts* of the orbit have been designated, according to their contents, as hygroma, meliceris, oil and fat cysts, and atheromatous, hæmatomatous, or steatomatous cysts. They all are probably congenital and *dermoid* in character, and owe their existence to faulty development during fœtal life. This is the more probable, since some of the cysts have been found to contain a tooth, or hair, or other epithelial formations. In many of the cases the cysts were distinctly known to have been congenital, and in another number they were observed in small children. There is usually but one cyst, although in some cases several have been found. Their size varies considerably. They lie mostly outside of the cone formed by the external muscles of the eyeball, and seem to be situated more frequently in the temporal parts of the orbit than in any other region. They may extend far back into the orbital cavity.

These tumors increase but slowly in size, unless stimulated to a more rapid development by an injury, and they do not give the patient much discomfort until they are large enough to cause exophthalmus and displacement of the eyeball, which is, of course, in the direction opposite to the growth. They now may generally be seen as bluish swellings in the lid (generally the upper one), and may even be directly demonstrated by eversion of the lids. It may be possible to detect fluctuation in the tumors, yet this can hardly be done with any degree of satisfaction, and it is therefore better to make sure of a correct diagnosis by the use of an aspirator.

Cysts of the orbit seem to be equally frequent in both sexes, and have mostly been observed in young people.

2. *Angiomata* of the orbit are either cavernous or teleangiectatic (erectile tumors).

a. The cavernous angioma of the orbit, which can attain a very considerable size, is either congenital or develops in later years. It is usually situated in or starts from the fat tissue within the cone formed by the external muscles of the eyeball. The tumor is often surrounded by a tough capsule of connective tissue. It may, as a rule, be seen as a bluish swelling under the skin of the lid, and from this similarity with orbital cysts mistakes in diagnosis have occasionally occurred. A characteristic symptom of the angioma is, however, that everything tending to hinder the reflux of the venous blood will cause a swelling and protrusion of the angioma; furthermore, the tumor may be compressed and emptied. The growth of the tumor is slow, and it is not apt to cause any pain. In rare cases a spontaneous cure has been observed. The removal of the tumor is practicable, and the more readily so the earlier it is undertaken.

β. The teleangiectatic tumors of the orbit are usually found to be accompanied by similar tumors in the lids and neighboring tissues, and they also form soft, compressible swellings. This kind of angioma seems to grow more quickly than the cavernous angioma. It is desirable that the growth should be removed at an early period.

3. *Lipoma* of the orbit has been described a few times. Yet it seems that in these cases the lipoma originally involved the eyelid.

4. *Enchondromatous tumors* of the orbit occur but rarely, if at all. The descriptions of such tumors thus far laid down in literature are, to say the least, doubtful.

5. *Osteoma* of the orbit has been often observed. It takes its origin from the diploë of the walls of the orbit. It is generally an ivory exostosis, sometimes partially spongy or cartilaginous. Its seat of predilection seems to be the upper inner wall of the orbit. In some cases osteoma has been found to develop symmetrically in both orbits of the same individual. These osteomata are usually round tumors, hard, and with a smooth or nodulated surface, and are mostly attached to the underlying bone by a broad basis. Their growth into the orbits may take place simultaneously with the growth of similar tumors into the neighboring cavities, or they may originally have started in one of the neighboring cavities and from there have grown into the orbital cavity. Their growth is most likely due to some faulty development during fœtal life.

Such tumors grow very slowly; in some cases their development is accompanied by pain. They may cause exophthalmus with all its sequelæ. When superficial, they are easily recognized by their seat, and by their consistency and immobility. It has, however, happened that retention cysts pointing into the orbit from a neighboring cavity, have been mistaken for osteomata. The tumors under consideration may have to be removed on account of their danger to the eyeball and its functions. Their removal is sometimes comparatively easy, yet it may be attended with danger from subsequent meningitis.

Histologically these tumors are found to consist of bone tissue. In most cases this tissue was found to be extremely compact and to be almost bare of Haversian canals (ivory exostoses). In other cases they contained varying quantities of marrow.

6. *Lymphoma* and *lymphadenoma* of the orbit have been described, but they took their origin probably not from the orbital tissue proper. Lymphangioma has also been found in the orbit.

7. Benign tumors consisting of striated muscular fibres and nerve fibres have in a few instances been removed from the orbit. The writer has seen a *rhabdo-myoma* and a *myo-neuroma* of the orbit.

B. *Malignant Tumors of the Orbit.*—1. *Cancer* of the orbit has been described as epithelioma, cancroid, adenoma, and adeno-carcinoma. It seems, however, that such new formations do not take their origin from the orbital tissue, but, having originated in the tissue of the eyelids, the episcleral tissue, or the lachrymal gland, have gradually invaded the tissues of the orbit. It is, therefore, not probable that a primary cancer of the orbital tissue has ever been observed.

2. *Sarcoma* of the orbit has frequently been observed and described. Its clinical diagnosis is extremely difficult, since we have but scanty means on hand wherewith to distinguish the nature of a tumor which has its seat in the deeper parts of the orbit. When the nature of the tumor is recognized, its removal with or without the simultaneous removal of the eyeball is, of course, imperative. Sarcomata have their origin usually in the orbital tissue. In a few cases the tumor had started in the brain and secondarily invaded the orbit. There are cases in which such an invasion takes place more or less symmetrically in both orbits.

A variety of forms of sarcoma have been described.

a. *Cylindroma*, a form of sarcoma characterized by a system of wide, anastomosing canals with larger cyst-like cavities filled with fluid, or gelatinous or fibrinous contents, has but very rarely been found in the orbital tissue.

β. *Myxo-sarcoma* of the orbit has been observed in about a dozen cases. These tumors were seen more frequently in children and young individuals than in older ones. In some their growth was a very rapid one, and in some it was accompanied by severe pain. The tumors consisted of long spindle and stellate cells, with a mucoid intercellular substance.

γ. *Round-cell* and *spindle-cell* sarcomata are the most frequent ones among the orbital sarcomata. In some cases they are melanotic.

δ. *Osteo-sarcoma* of the orbit always springs from the bony walls of this cavity. It seems to spring most often from the inner upper part of the orbital wall. It is usually a small round-cell or spindle-cell sarcoma, with spicula of bone tissue embedded in it. These spicula of bone tissue may be very numerous, and make the tumor appear very hard to the touch.

ε. The writer has recently examined and reported the case of an orbital tumor, which was situated over the nasal wall of the orbit and which proved to be a *myo-fibro-sarcoma*. The elements of which it consisted were very numerous unstriped muscular fibres and bands of denser fibrous tissue; in some parts giant cells and spicula of bone were situated.

3. Another form of malignant growth found in the orbit is that known as *chloroma*. It consists of small round cells undergoing a peculiar fatty degeneration accompanied by a greenish-brown color. It springs from the periosteum. Probably it is also a sarcoma.

XI. TUMORS OF THE LACHRYMAL GLAND.—The tumors of the lachrymal gland may be diagnosticated by their situation in the outer upper part of the orbit, and by the consequent exophthalmus inward and downward (at least at the beginning of the development). These tumors generally grow but slowly. Gradually they cause a bulging of the upper eyelid, most marked near the outer canthus, and it is, as a rule, now possible to palpate the tumor, or even to see it protruding into the conjunctival sac, pushing the upper fornix downward. By palpation a tough, lobulated swelling is felt, which may be slightly movable; in most cases, however, it is immovable. When the tumor grows it often fills the posterior parts of the orbit, and thus it may cause the exophthalmus to change its direction, and when the tumor has filled the apex of the orbit altogether, and has grown around the optic nerve (which tumors of the lachrymal gland never seem to invade), the eye may stand straight forward, as if there were a tumor of the optic nerve. For this reason the movements of the eyeball, which at first are restricted only in an upward and outward direction, may become, later on, restricted in other directions too, and even finally be totally abolished. If the tumor grows still further, ulcerations of the cornea, etc., may take place. During the development of such a growth, the optic nerve is, of course, considerably pressed upon and stretched, and accordingly we find it anæmic, or swollen and inflamed (optic neuritis), or atrophied. From the state of nutrition in which the nerve is when the tumor is removed, it will depend how far sight may be recovered. This removal may frequently be accomplished without sacrificing the eyeball.

Tumors of the lachrymal gland are usually observed in individuals of an advanced age, and their origin is sometimes attributed to an injury. Sometimes the lachrymal glands of both orbits in one individual have been found to be similarly affected. The tumor may, by entering the cavity of the brain and the brain substance, cause the death of the patient.

Various forms of tumors of the lachrymal gland have been observed, but opinions differ very considerably with regard to what may be considered a tumor of the lachrymal gland and what not.

The writer has seen and examined the following forms of tumors, which unquestionably took their origin from the lachrymal gland.

1. *Adenoma* of the lachrymal gland shows the typical picture of an epithelial neoplasm. Epithelial-cell cylinders, which compose the bulk of the tumor, lie embedded in a small quantity of connective tissue. The cells of every one of these cell cylinders are arranged around a central canal, which in some cases is very considerably enlarged by a transparent fluid. The cell cylinders are made up of one layer of polyhedral, almost cuboid epithelial cells, and have a distinct membrana propria.

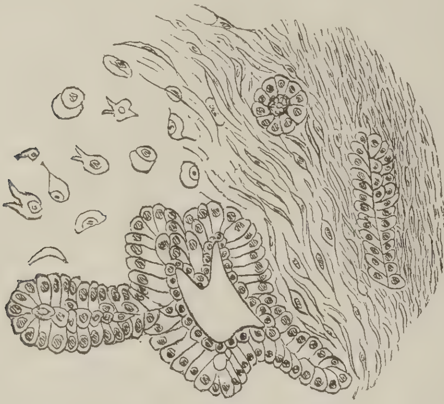

FIG. 2065.—Enchondroma Myxomatodes Carcinomatodes of the Lachrymal Gland.

The lachrymal gland has also, in a number of instances, been the seat of *adeno-carcinoma*, of *lymphoma*, and of *lymphadenoma*.

2. *Myxoma* and *myxo-sarcoma* of the lachrymal gland are characterized by the development of spindle cells with long offsets, and stellate cells embedded in a mucoid intercellular substance, and by the gradual disappearance of the glandular structure. This kind of tumor of the lachrymal gland is, however, but seldom observed alone. It is more frequently the case that the glandular tissue does not disappear, but, instead, an atypical growth of tissue takes place, at least in some parts of the tumor, and thus gives to it the character of an adeno-carcinoma. In some cases we find, moreover, besides these two kinds of new formations, a number of islets of hyaline cartilage tissue. Thus, instead of a simple myxoma or myxosarcoma of the lachrymal gland, we have then a myxoma carcinomatodes, or a myxoma carcinomatodes chondromatodes. In other cases the hyaline cartilage may be the prevailing tissue; in which case we would have to call the tumor an enchondroma myxomatodes carcinomatodes.

3. *Spindle-cell sarcoma* of the lachrymal gland has been described by a number of writers. In one of my own cases the tumor developed quite rapidly, and consisted of densely packed spindle cells in its older portions. The younger portions of the tumor showed round cells and small spindle cells. Not a trace of glandular tissue was found.

4. *In lympho-sarcoma* of the lachrymal gland the bulk of the tumor consists of densely packed lymphatic cells, with hardly any intercellular substance.

5. *Epithelioma* of the lachrymal gland is formed when an atypical growth of the epithelial elements of the glandular tissue takes place. We find, then, instead of the glandular apparatus, solid epithelial-cell cylinders and nests of epithelial cells. This form of growth seems, however, generally to be combined with the development of myxomatous tissue in the lachrymal gland. The cases described as epithelioma of the lachrymal gland should probably with more correctness be regarded as cases of adeno-carcinoma.

6. In the older ophthalmological literature, a number of cases of *cystic degeneration* of the lachrymal gland, or its ducts, have been described as *dakryops*. These cysts grew very slowly, and had to be removed on account of their impairing the motility of the eyeball. It is not known whether the whole of the lachrymal gland is likely to undergo such a change.

XII. TUMORS OF THE LACHRYMAL CARUNCLE.—The lachrymal caruncle is sometimes the seat of a new formation. Thus, congenital dermoid tumors have been observed in this region. Papillomata are not rare.

In advanced life the caruncle may become the seat of epitheliomatous new formations as well as of sarcoma. The latter kind of tumors are usually pigmented. The development of these tumors is almost always attributed to an injury.

XIII. TUMORS OF THE LACHRYMAL DRAINAGE APPARATUS.—In rare cases small *granulomata* (polyps) have been found in the lachrymal sac, and even in the lachrymal canaliculus. It is obvious that such little tumors may gain some clinical importance by the stoppage of the canals through which the tears ought to be carried off. Their formation is due to chronic inflammatory conditions of the mucous membrane of these channels.

Adolf Alt.

EYELIDS, AFFECTIONS OF THE.—The eyelids present two surfaces, both of which are subject to disease. The posterior, or under surface, *i.e.*, the surface which is in contact with the eye, is covered with conjunctiva, and affections of this surface are described under this head. (Cf. *Conjunctiva, Diseases of.*) In describing the affections of the eyelids we have to consider the anterior or upper surface, and the structure between the two surfaces.

The upper surface of the eyelid is covered with integument which is continuous with the integument of the forehead and face. It differs from the integument of the forehead and face in being thinner. Under the skin of the eyelids we find the subcutaneous areolar tissue, which frequently becomes infiltrated with effusions, and distended with air in injuries to the nose and air sinuses. The next tissue is the orbicularis muscle, the function of which is to close the eyelids. This is the muscle which is affected in paralysis of the facial nerve, producing inability to close the eyelids, or, as it is sometimes called, lagophthalmus. Beneath this muscle are the tarsal cartilages, upper and lower, the functions of which are to add to the protection of the eye, to preserve the contour of the lids, and, in the upper lid, to give attachment to the muscle which raises the lid—the levator palpebræ superioris.

The tarsal cartilages contain in their substance the Meibomian glands, whose sebaceous secretion lubricates the edges of the lids. The tarsal cartilages are thicker at the free margins of the lids, and gradually taper back to a thinner edge; they are about one inch in length. The upper cartilage is about one-third of an inch in breadth at its centre, and narrowing toward its outer and inner extremities has a somewhat semilunar shape. The cartilage of the lower lid is much smaller in width, having a more or less elliptical shape. The free margins of the upper and lower lids—*i.e.*, the edges where the anterior or cutaneous surface and the posterior or conjunctival surface meet—lie in contact with each other when the eye is closed, and contain the cilia, or eyelashes, together with the openings of the ducts of the Meibomian glands. The extremities of the margins of the upper and lower eyelids are joined together, and are called the outer canthus and the inner canthus.

These canthi, with the extremities of the cartilages, are attached to the frontal processes of the superior maxillas at the inner sides, and to the malar bones on the outer sides, by the canthal ligament. It is important to bear this in mind in operations on the outer canthi especially.

The inner canthi are shaped somewhat like horseshoes, and at the free extremities of the shoes are the openings of the lachrymal canals, the puncta lachrymalia. Under the tarsal cartilages is the palpebral portion of the conjunctiva.

The eyelids are subject to diseases affecting the integument generally, as well as to affections peculiar to themselves, because of the structures involved.

The departures from the normal which may affect the cutaneous surfaces of the eyelids, either separately or in common with the skin of the forehead and face, are, erysipelas, exanthemata, ecchymoses, herpes, œdema, emphysema, venereal sores, eczema, and acne.

Erysipelas and exanthematous diseases seldom, if ever, attack the eyelids except as they affect the cutaneous surface generally. Erysipelas is never confined to the integument of the eyelids alone, except that the attack may originate in this situation and spread to other parts. Its restriction to the eyelids, under these circumstances, would be only temporary, lasting, at most, not more than forty-eight hours. The writer has seen a patient attacked with what appeared at the onset to be a purulent conjunctivitis, with eyelids red, swollen, and œdematous, together with a moderately profuse purulent discharge from the conjunctiva, develop in less than thirty-six hours into a case of facial erysipelas, the eye symptoms subsiding as the disease spread over the face. There are none of the exanthemata in which the eruption manifests itself first about the eyelids, and when the eyelids are involved it is only as a part of the general cutaneous involvement. Eczema may manifest itself on the eyelids as the result of a general facial condition, or may be secondary to the inflammatory condition of the edges of the lids known as blepharitis; of this we will speak later.

Acne may also affect the eyelids as the result of a general cutaneous affection.

The treatment of these general inflammatory affections of the integument of the eyelids does not differ from the treatment of the same disease when located elsewhere in or on the cutaneous surface. It may be necessary to be cautious in the employment of lotions, embrocations, and ointments, containing irritating substances, because of the danger of injuring the delicate structure of the eye itself, but other than this the treatment of affections of the lids, such as we have mentioned, will not differ from the usual treatment employed when these affections are situated in other parts of the body.

Venereal sores which may affect the integument of the eyelids are chancres, chancroids, and venereal ulcers. One would be naturally suspicious of the nature of an ulcer or sore on the eyelid in a patient known to be suffering from syphilis, or in one who had chancroids or sores known to be of venereal origin, located elsewhere. Even when symptoms of venereal disease do not exist elsewhere, venereal sores may exist on the eyelids. When patients present ulcerations of the integument of the eyelids which do not yield promptly to treatment, and which the microscope does not demonstrate to be malignant, our suspicions should be aroused at once as to their possible venereal origin.

Chancres of the integument of the eyelids are not so common as chancres of the conjunctiva, and we do not wish to be understood as intimating that they are commonly met with in the latter situation. They are, however, occasionally encountered in the integument of the eyelids, and are not always easily distinguished, macroscopically, from malignant diseases, especially epitheliomata. The diagnosis may have to be made with the microscope.

The treatment of venereal sores and ulcers will depend on whether their origin is syphilitic; but whether syphilitic or not, their treatment will differ radically from the treatment of malignant growths or neoplasms.

Syphilitic and venereal sores and ulcers of the eyelids will require the local and constitutional treatment commonly given this class of affections without regard to their situation. Malignant growths, on the other hand, will generally require operative treatment.

Herpes affecting the eyelids, oftener the upper, is not uncommon. We commonly meet with a mild form of herpes—fever sores as they are called—but we also meet with a severe form, the two differing so as almost to warrant describing them as different affections. We have herpes in the mild form, occurring as the result of febrile disturbances in children, occasionally also in adults. It may follow exposure to high winds, sunburn, and irritations of the skin generally. The herpetic eruptions from these causes affect all parts of the integument of the face indiscriminately, often both sides at the same time, including the eyelids. There appears a slightly elevated red spot, more or less rounded in outline, varying in size from 3 to 20 mm. in diameter, or even larger. This red spot tingles and burns, and in twenty-four hours begins to be vesicular in character, composed of a number of small vesicles. The fluid in these vesicles, which in the beginning is watery, soon becomes flocculent, changing into pus. The vesicles coalesce and break down, forming a scab. If this scab is removed we find the surface beneath ulcerated. Whether removed or not, the sore heals in a week or ten days, leaving a reddened surface, which may persist for a week or two weeks longer. Attacks of herpetic eruption such as this are of frequent occurrence in neurotic people, the result of some slight nervous irritation, or of direct irritation of the terminal endings of the sensory nerves. The course is mild, the treatment palliative, and the prognosis good.

We have another form of herpes, as we have said, known as herpes zoster, which affects the supra-orbital branch of the fifth nerve, generally unilateral, and often very serious in its consequences. Herpes zoster is ushered in with violent pain over the distribution of the nerve, producing intense supra-orbital neuralgia, which may last a day, or even two days, before the eruption takes place, and at times persisting during and after the eruptive period. The skin of the upper eyelid becomes reddened and swollen, and the lid itself œdematous. There is more or less marked febrile action. The eruption appears to be the same as that described in the simpler form of herpes, except that the underlying ulcers are deeper and frequently leave scars. The condition takes its name from the parts affected, as herpes zoster frontalis, herpes zoster palpebralis, and herpes zoster ophthalmicus. When it affects the eye itself (herpes zoster ophthalmicus) very serious results, even destruction of the eyeball, may follow.

The writer has seen several cases of herpes zoster affecting the eyelids and forehead which have been diagnosed by attending physicians who were not familiar with the disease as erysipelas, all coming from malarial districts.

The treatment consists of cathartics, hot applications to the affected parts to relieve the pain, and even opiates may be necessary. During the beginning of the eruptive stage, the intense irritation may be allayed by applications of weak solutions of acetate of lead, lead and opium wash, or carbolic acid. After the vesicular stage has passed, an ointment of carbolic acid and vaseline will soften the scabs and prevent, possibly, the formation of deep scars. In the writer's experience the best results have followed the internal administration of quinine.

Œdema of the eyelids is a symptom of importance in affections of the eye itself, as denoting the intensity of the exciting cause, which is generally of an inflammatory nature. Œdema may occur in the eyelids also because of disease of organs remote from the eye, as in cardiac and renal disease, and in anæmia.

When due to local causes situated in the eye or adjacent structures, the amount of the œdema will generally be in proportion to the intensity of the disease which produces it, as well as to the location of the affection. For example, we frequently find in iritis, both primary and when due to cataract extractions, an œdema of the lids at the inner canthus. The same will be true of keratitis, scleritis, tenonitis, and inflammations of the eye and its appendages generally. Œdema of the eyelids from affections of the eye itself is never so extensive or marked as we sometimes find it as the result of purulent inflammations of the conjunctiva, dacryocystitis, panophthalmitis, frontal-sinus disease, and retrobulbar abscesses or tumors, in which affections it may become so marked as to threaten the destruction of the eye from pressure. Œdema of the eyelids may also be present as the result of stings of insects. There is ordinarily very little to be done for œdema of the eyelids. When due to renal disease it is more pronounced after rest in a recumbent position; when due to cardiac disease it is more or less constant, although more pronounced after physical exertion. There is no local treatment which will remove œdema when due to these two causes. If we find associated with the œdema—as we sometimes do—an irritation of the eye and the under surface of the eyelids, we can obtain a certain amount of relief from the use of biborate of soda and tannic acid, each ten grains to the ounce, or a solution of boric acid in camphor water.

When due to inflammatory conditions of the eye and surrounding parts there is nothing to be done for the œdema itself—beyond the application of a light bandage —except when the swelling of the lids is so great as to threaten the eye, when the pressure can be relieved by the operation known as external canthotomy, or division of the external canthus. Such extreme treatment is, of course, seldom necessary.

It this connection we may mention an affection of the eyelids which may be mistaken for œdema. This is emphysema, due to injury of the nose or of the sinuses which surround the eye. The onset is sudden, following a traumatism, and characterized by swelling of the eyelids, one or both, depending on the situation and extent of the injury. There may be redness of the integument of the lids,—which, in fact, is true in any swelling of the lids, even when not of an inflammatory nature; and palpation gives to the fingers a crackling sensation. This distention is apt to be more marked in the lids than in the surrounding parts, for the reason that the integument of the lids is so loosely connected with the underlying parts, and its areolar tissue has so little adipose tissue in its meshes that it becomes easily inflated when the walls of the sinuses, or other air cells which abound in this situation, are broken. No treatment is necessary for the emphysema itself, except in extreme cases, when a bandage may be applied. When the cause of the emphysema is removed the air disappears.

The pathological conditions grouped and described under the heading of skin diseases may affect the integument of the eyelids, acne and comedo being perhaps the least common, while milium, molluscum, and xanthelasma occur frequently; acne merits, at our hands, no description, differing in no way from the acne seen in other parts of the body. Comedones, or black-heads, can be removed, here as elsewhere, excepting that while in other parts they may be removed with the time-honored watch key, or the expressly designed comedo pressers, in the eyelids they are best removed by pressure between the thumb nails. The minute white elevations with sebaceous concretions known as milia, or the larger masses with depressed centres known as mollusca, require a slight incision made in their apices before they can be expressed without the infliction of considerable traumatism, or bruising of the skin.

Xanthelasma, the buff or yellowish-colored patches which are found at the inner part of the lids, and which affect middle-aged people, especially women, can be removed only with the knife or scissors. If they are not too large, the writer's method is to grasp them with a broad-pointed forceps and snip them off with scissors. The skin, which is very loose on the eyelids, can be slightly undermined with the same scissors, and one or two sutures will obliterate all trace of the affection, which is never anything more serious than a blemish. If the xanthelasma is large it may be impossible to excise it without sacrificing more skin than it is wise to remove. In such a case it would be better to advise the patient to tolerate the blemish, with the assurance that it will never assume a serious or malignant character.

We meet occasionally, in or under the skin of the eyelids, with horny and warty growths, lipomata, and cysts. These are easily removed, under either cocaine or general anæsthesia, leaving only small scars, which time effaces.

The skin of the eyelids is not infrequently the seat of malignant growths, the most common form being epitheliomata.

Epitheliomata seldom appear in the eyelids before middle age; indeed, most of the cases seen by the writer have occurred long after middle age. The history is alike for all cases; there has appeared a small, roundish, elevated patch or pimple, which may exist for months or even years, without causing very much annoyance. Then without apparent cause, or sometimes as the result of the patient's picking it, this patch or pimple becomes ulcerated, and refuses to heal under ordinary treatment. When these patients present themselves to the specialist the growths have passed, as a rule, into the ulcerative stage, and the patients are prepared to hear that they have malignant disease or cancer.

Even when ulceration has begun, a long time may elapse before the affection takes on a rapidly growing malignant character. There is always, in cancerous affections of the eyelids, a long period during which removal can be effected without serious deformity to the lid, and during which time removal means permanent cure. It is only after the disease has existed long enough to involve the entire structure of the eyelid, the skin, the conjunctiva, and the tissues between, when not only is there a deeply ulcerated spot, but the surrounding tissues are infiltrated, that the question of extensive operation, possibly the removal of an entire upper or lower lid, has to be considered.

It is not just to our patient to conclude hastily that a suspicious-looking ulcer of the eyelid is a malignant growth, any more than it is to defer action in the hope that it may not be malignant. We of course consider the history of the case, the age of the patient, and other points which may occur to us at the time, but the knowledge which should influence us, and which we should obtain as soon after seeing the patient as possible, is that furnished by the microscope. When we have this information, and are satisfied that a patient has malignant disease, the indications for treatment are very clear. There is but one thing to do in cancerous disease of the eyelid as elsewhere, and that is to remove the offending neoplasm; and, should we elect to remove it with the knife, we should not hesitate to remove sufficient tissue to include not only the growth itself but all infiltrated structures as well.

In removing cancerous disease of the eyelids, ophthalmic surgeons, almost without exception, prefer to resort to the knife. Some of the authorities mention the use of caustics, but the writer has been unable to find, among the various text-books on diseases of the eye, even one which recommends any other method than the knife.

It is safe, as a rule, to be guided by the advice of those who have had large experience and who are considered authorities; the exclusive use of the knife in removing cancerous growths of the eyelids is, no doubt, advocated as the result of experience. One author on diseases of the eye (Noyes) mentions the use of caustics, and his objection to their use is that they leave scars which have to be removed by operation later, while with the knife in the beginning both the cancerous growth can be removed, and the resulting deformity remedied at the same time, which is of course true. Still, a deformity of the eyelid, while it may be disfiguring, is not fatal to life, and many persons have so great a fear of the knife that, to them, death may be preferable. Then too the element of time may be a consideration. A surgeon would hesitate to perform a plastic operation for the removal of a cancerous growth and the repair of the eyelid except under general anæsthesia, and with the knowledge that his patient would remain quiet for at least two weeks following the operation, in order to secure proper healing. With the caustic treatment it would perhaps be possible for a patient to attend to his ordinary business occupation while undergoing treatment. We have in mind a case of this kind. An elderly gentleman, earning a precarious living as an insurance agent, with a large and helpless family depending on him, presented himself for treatment for an epithelioma of the upper eyelid. The disease had entered upon the ulcerative stage, and involved a spot in the centre of the lid, about 3 mm. in diameter. He was willing to submit to an operation providing it did not interfere with his work; he was unable to stop his work for even one week. In such a case it seems as if one would be justified in employing a caustic application. The resulting scar could be remedied at any time, while the epithelioma, if allowed to go on unchecked, would destroy tissue, and involve structures which could be remedied only by great sacrifice, if at all. Dr. A. R. Robinson, in "Observations in the Treatment of Cancer," concludes "that the majority of cases of cutaneous cancer can be removed with the greatest certainty and with least deformity by caustics, provided the patients are seen before the lymphatic glands are invaded." This, of course, applies to cutaneous surfaces generally, but with less force, perhaps, when the disease is in the integument of the eyelid, because of the danger to the eye itself from the caustic application. It is impossible to lay down rules which shall be invariable guides, or to give advice which is to apply to all cases indiscriminately, but the writer believes that while the use of the knife is the best method of treatment in most cases of cancer of the eyelids, there are times when caustics may be employed with advantage.

Of the affections which are situated at the margins of the eyelids, one which is not uncommon is phthiriasis, or pediculi ciliares. This affection, which is not by any means confined to unclean people, is discovered by the specialist or the family physician, and its discovery horrifies the patient and fills him with wonder. The symptoms are, itching and redness of the margins of the eyelids, and, if the condition is neglected, falling of the eyelashes. Inspection reveals the presence of the pediculi on the edges of the lids and the ova pediculi on the lashes. The treatment will consist in the removal of the offending parasites, crushing them between the thumb nails, and the application of some parasiticide. Bichloride of mercury wash must be used with caution, because of the irritating effect of this drug on the cornea. As a rule removing the parasite with the nails, as mentioned above, and the application of the yellow oxide of mercury ointment, will effect a cure in a few days.

Hordeolum is an inflammation of one of the glands of the skin of the eyelids, situated at or near the margins of the lids, and often attended with considerable swelling and tenderness, and even constitutional disturbance. There are generally a succession of the hordeola, a new one appearing as another gets well, until a dozen or more have appeared. Such a condition has often underlying it some general constitutional debility, and will require for its treatment nourishing diet, fresh air, and tonics. It is doubtful, however, if this condition of furunculosis, if it may be given this name, ever attacks and is confined to the eyelids, even when there is marked constitutional debility, unless there is added to the general derangement a local exciting cause as conjunctivitis, or some weakness or abuse of the eye itself. It is advisable, as a preliminary to the general treatment, to give attention to the local cause. If there is found to be an uncorrected refractive error in the eye, it should be corrected, and a coexisting conjunctivitis should be treated. For the hordeolum itself, nothing relieves the pain and hastens the termination of the inflammation so much as the application of hot water. Warm poultices, to hasten suppuration, which would be advisable elsewhere, should not be used for inflammations here, because of their effect on the conjunctiva. Some of the most aggravated cases of conjunctivitis the writer has ever seen have been caused by the application of flaxseed and tea-leaves poultices. Suppuration is the final outcome of a hordeolum, but it has seldom been necessary in the writer's experience to employ the knife for the evacuation of the pus, this being, as a rule, rapidly brought about by the hot applications. Spirits of camphor has been recommended to abort the inflammatory process, and while it does not invariably accomplish this, the writer has seen beneficial results follow its use.

A chalazion is a distention of a Meibomian gland with its normal secretion. This is caused by an occlusion of the duct of the gland, which may be either permanent or temporary. The distended gland sometimes becomes inflamed, when it simulates a hordeolum. Ordinarily a chalazion presents itself as a circumscribed swelling, hard to the touch, and of variable size. It may be in either the upper or lower eyelid, and not infrequently there are more than one in the same lid, and they often exist in all four eyelids at the same time. They also are caused by conjunctivitis, which may or may not be due to uncorrected errors of refraction.

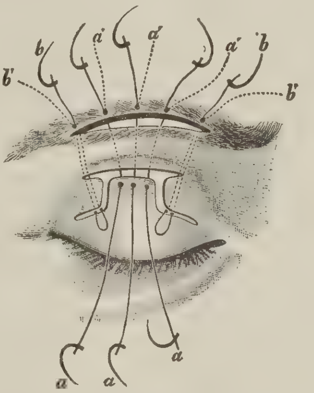

FIG. 2066.—Panas' Operation for Ptosis. (After de Schweinitz.) *a*, *a*, Sutures uniting flap to integument of brow; *b*, *b*, sutures advised by Panas to prevent possibility of ectropion resulting.

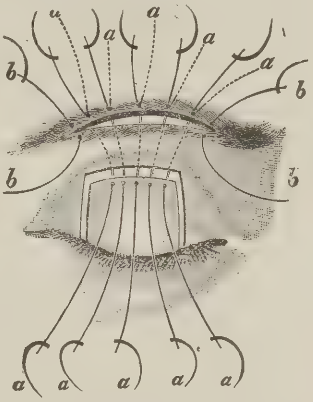

FIG. 2067.—Van Fleet's Modification of Panas' Operation for Ptosis. *a*, *a*, Sutures uniting flap to integument of brow; *b*, *b*, sutures closing extremities of incision in brow.

A chalazion may sometimes be cured by massage of the eyelids, the accumulation within the gland being pressed out through the duct. When this cannot be accomplished the cyst can be incised and the sac curetted. It has been recommended that the incision be made into the sac through the margin of the lid, or, if the incision is made through the conjunctiva, that it be perpendicular to the margin of the lid, so as to avoid cutting other Meibomian glands than the one involved. While the incisions can be made equally well in either situation, *i.e.*, through the margin of the lid or through the conjunctival surface, in some cases, in others the method to be employed will depend on the size of the tumor and its location. There is no danger of the incision destroying other glands in either case, and no evil results ever follow incisions made in either situation.

Blepharitis marginalis can be properly classed as an affection due to the same causes as hordeola and chalazia. It is possible to have blepharitis as the result of phthiriasis, but the affection commonly known as blepharitis is due either to conjunctivitis or to uncorrected errors of refraction, and more often to the latter.

Blepharitis is characterized by a redness of the margins of the eyelids, with which is associated a scaly condition, and finally by an interference with the nutrition and growth of the eyelashes.

This may be the cause of trichiasis and districhiasis, but oftener it results in the death of the eyelashes, the lids finally becoming entirely devoid of these hairs.

The treatment of this condition is local, and consists in applications to the eyelids themselves, and the correction of errors of refraction with suitable glasses. It is not unusual to see stubborn cases of blepharitis, which resist treatment, or after frequent relapses, finally become cured and remain so, when properly fitted glasses have been adjusted and worn.

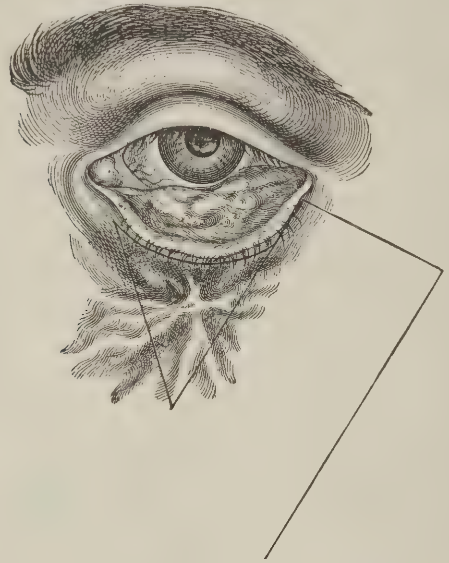

FIG. 2068.

Pagenstecher's ointment (Unguentum hydrargyrum oxidum flavum) is the local remedy generally employed in this affection. It is often made too strong, when it is very irritating; the greatest care should also be exercised in selecting a proper base, and having it thoroughly mixed. The ointment should never be made stronger than one grain to the drachm (except as a parasiticide) and the best base to employ is vaseline. Fatty bases, as cold cream, simple cerate and others—which contain lard—decompose; the fatty acids alter the chemical nature of the yellow oxide, making, as before mentioned, an irritating ointment. This is an important consideration which should not be forgotten.

Trichiasis and districhiasis, together with entropion, are the results of inflammatory affections of the conjunctiva, such as chronic conjunctivitis and chronic trachoma. As a result of cicatrization of the conjunctiva, the tarsal cartilage becomes curved, and the eyelashes, instead of curving outward, curve inward and sweep over the eyeball. The eyelashes can be pulled out, and for this purpose specially devised forceps have been made, called epilation forceps. The relief afforded by this treatment is only temporary and incomplete. The eyelashes grow again, and even if pulled again the inner edge of the margin of the lid rubbing over the eye keeps up the irritation. The radical cure of this condition is by operation, and the writer prefers the operation in which a wedge-shaped piece of the tarsal cartilage is removed. The results obtained from this operation are good and lasting. It is performed as follows: The patient is anæsthetized (which, by the way, is best in all plastic operations about the eyelids). Cocaine gives satisfactory results only in operations on the eye itself. An incision is made through the skin, parallel with and about 2 mm. from the tarsal margin, extending down to the tarsal cartilage. Pushing the muscle and connective tissue aside, the operator should expose the whole surface of the cartilage and should carry the incision straight down, in such a manner as to involve almost the entire thickness of the cartilage. Sometimes the knife will go through the cartilage, but this does no harm. A second incision is then made in the cartilage, about 2.5 mm. from the first, tapering to and meeting the first incision at the ends. This second incision, instead of going straight down through the cartilage, is made obliquely, and meets the first incision not only at its ends, but at the bottom as well. The wedge-shaped piece of cartilage thus formed is removed. A central suture is then passed through the lower edge of the incision in the skin, and through the lower edge of the incision in the cartilage. It is then carried through the upper part of the cartilage, passing over the groove made in the cartilage by the removal of the wedge, and finally brought down through the upper edge of the cutaneous incision. Two more sutures like the first are inserted, one on either side of the central suture, and as many more as the operator thinks necessary. When these sutures are tied the margin of the lid and the lashes will be permanently everted. This operation can be employed only in the upper lid. Operations for the relief of entropion of the lower lid are not nearly so satisfactory. The cartilage in the lower lid being so small, the best we can do is to remove an elliptical piece of skin, which will give relief, often lasting a long time.

Ectropion is the result, as a rule, of cicatricial contractions of the skin of the eyelids, and requires for its relief a plastic operation. We will consider these operations under wounds and burns. There are two forms of ectropion of the lower lid, however, one due to chronic conjunctivitis, in which the hypertrophy of the conjunctiva and the underlying connective tissue everts the lid, and the other the result of senile change, which can be relieved by applications of alum or sulphate of copper to the conjunctiva.

Blepharophimosis, a narrowing of the palpebral orifice, which may be congenital or the result of chronic trachoma, can be remedied by the operation known as cantholysis, or canthotomy. A wire speculum is inserted between the eyelids, and the external canthus put on the stretch. With straight and strong scissors the external canthus is then divided, both mucous membrane and integument, back to the margin of the orbit. The mucous membrane is then lifted with forceps and the external cantha lligament divided. The mucous membrane at the bottom of the wound thus made is united to the integument and at the sides as well. A vaseline dressing is applied, and the stitches are removed in three or four days.

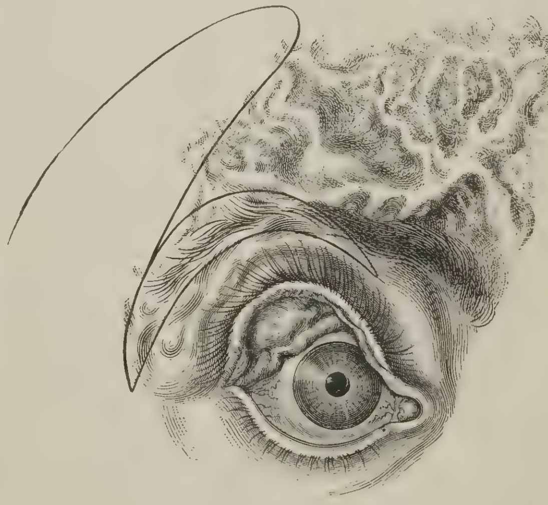

FIG. 2069.

Canities is a name given to white eyelashes, of which there may be one or more in an eyelid whose other lashes are of darker color, even black. This condition may be congenital, or the result of some interference with the nutrition of the cilia. Nothing can be done for this except epilation, which may be resorted to if the white lashes are not too numerous.

Interference with the motility of the eyelids, due to paralysis or other causes, is of frequent occurrence and demands attention. The most annoying and dangerous to the patient's sight, and which will often baffle the physician, is the inability to close the eyelids in paralysis of the seventh nerve. In this condition the eyelids are open when awake and when asleep, and the eye frequently becomes irritated and even ulcerated and destroyed, from this constant exposure to wind, smoke, and irritating substances generally. If the paralysis is transitory, it may only be necessary to protect the eye with a bandage or with a shield; when the paralysis becomes permanent, however, as sometimes happens, it may be necessary to resort to operative procedure, and to close the eyelids by suturing the upper and lower lids together, first denuding the edges.

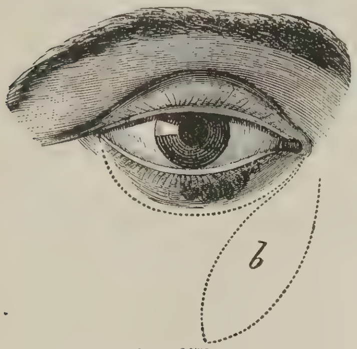

FIG. 2070.

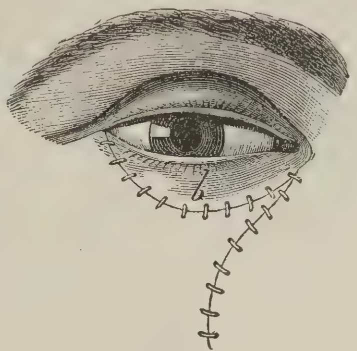

FIG. 2071.

The opposite condition to paralysis of the seventh nerve is the inability to open the eyelids when the third nerve is paralyzed. This condition is known as ptosis, and when due to paralysis of this nerve is generally acquired, and amenable to treatment by drugs. Paralysis of the third nerve—the motor oculi communis—may be due to intracranial growths, when it becomes a very serious condition; in the majority of cases, however, this paralysis is due to acquired syphilis, and responds quickly to antisyphilitic treatment. We do occasionally meet patients in whom ptosis due to this cause persists, even after prolonged treatment, and when we have every reason to believe the syphilis has been cured, and then it is necessary to resort to operative treatment if we desire to remedy the defect. We may not consider it advisable to remedy this deformity always, as we shall consider later.

Ptosis may be due to other causes; it may be congenital or it may be the result of chronic conjunctivitis or trachoma.

In congenital ptosis there may be associated with the paralysis, or imperfect development of the levator palpebræ superioris, paralysis or imperfect development of some of the other muscles of the eye, notably the superior rectus. Any or all the recti muscles may be involved, generally one of those supplied by the third nerve. The writer has seen a patient in whom not only were the muscles supplied by the third nerve affected, but the external rectus, which receives its motor power from the sixth nerve, was also involved. When the superior rectus is involved the eye will be rotated downward, and when the internal alone is affected the eye will be drawn outward. The recti muscles are generally affected in syphilitic ptosis, and frequently are not affected in congenital ptosis. They are not involved when the ptosis is due to inflammatory conditions of the conjunctiva. To overcome the ptosis by operation when any of the recti muscles are involved may, by exposing a deviating eye, produce an annoying diplopia, and this will have to be considered before advising such an operation.

In trachoma, after the disease is cured, a drooping of the upper eyelid will sometimes persist, which may necessitate an operation, and it is in cases due to this cause that our best results are often obtained. Various operations have been devised to overcome this deformity, and the results have been until recently rather unsatisfactory. The levator palpebræ superioris muscle, which raises the upper eyelid, arises in the orbit, from the lesser wing of the sphenoid bone, directly in front of the optic foramen. Its insertion is in the upper eyelid, to the convex margin of the tarsal cartilage. Its action is to draw the lid upward and backward. In the absence or imperfect development of this muscle, and when it is inoperative because of some affection of the nerve supplying it with motor power, operators have endeavored to make the occipito-frontalis muscles—the anterior portion of which is intimately adherent to the skin of the forehead—take the place of the levator. The results obtained by Pagenstecher, De Wecker, and others, have been only partially satisfactory, the effects not being permanent.

The operation devised by Panas has given satisfactory results, which have been permanent. The operation is, however, somewhat complicated and difficult to perform. The writer has modified this operation, making it extremely simple, and the results in his hands, and in the hands of other operators as well, have been generally successful. It is performed as follows: The patient being anæsthetized and the brow shaved, the face and forehead are thoroughly cleansed with a bichloride wash. An assistant then inserts under the upper eyelid a horn shield, and with his free hand steadies the skin of the brow, as directed by Panas. The operator then makes in the upper lid, at or slightly above the upper convex margin of the tarsal cartilage, an incision which commences at the inner side and includes the middle third of the lid. From the inner extremity of this incision another is made extending down to the ciliary border, and a third is made in like manner from the outer extremity of the first. The integument enclosed by these three incisions is dissected from the underlying tissue, down to the ciliary border of the lid, making a flap. A final incision is made in the brow, parallel with the first incision in the lid, but slightly longer. The integument between these two horizontal incisions is then undermined in such a manner as to make a bridge. The parts are carefully cleansed, the flap is passed up under the bridge and secured by stitching its upper margin to the upper margin of the incision in the brow. This is accomplished by means of five interrupted silk sutures. The outer and inner extremities of the final incision (*i.e.*, the outer and inner extremities of the incision in the brow after the flap has been stitched in

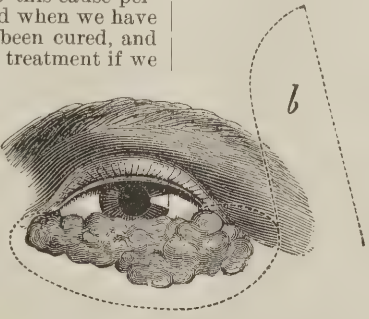

FIG. 2072.

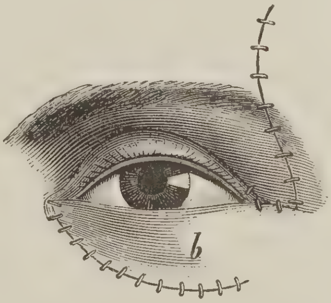

FIG. 2073.

place) are sutured, and the whole is covered with sterilized vaseline and bichloride gauze, and bandaged. The bandage is not to be removed for two days, after which it should be removed daily for a week, when the stitches can be taken out and the dressing discontinued. The epithelium of the flap becomes macerated and exfoliates, and the true skin unites with the under surface of the bridge, of which it becomes a part, or perhaps disappears.

It is not well to make the flap too narrow; it may even be made to include more than the middle third of the lid. Its length should vary with the degree of ptosis to be overcome. Sometimes after the operation the eyelids may not close in sleep, but this is only temporary. Another point to be considered is the tendency of the bridge to curl, causing a scar in the brow. This can be avoided by including the upper edge of the bridge in the sutures which unite the flap to the skin of the brow. The epithelial surface of the flap may also be scarified slightly, to hasten its union with the under surface of the bridge.

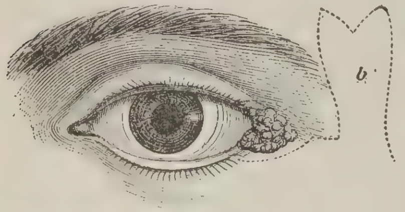

FIG. 2074.

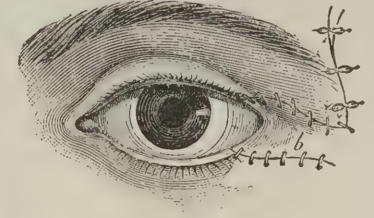

FIG. 2075.

This modification differs from the original operation of Panas in that the lines of incision are straight, and extend only through the integument, whereas Panas recommends that they extend down to the periosteum, which must necessitate a longer time in healing, and adds to the operation the danger of wounding deeper tissues, as, for example, the supra-orbital nerve.

The object of this operation is to make the occipito-frontalis muscle take the place, or do the work, of the levator of the lid; the flap, uniting by first intention with the upper edge of the incision in the brow, becomes a part of the skin controlled by the contractions of the occipito-frontalis, quite as much as it would if the incisions were deeper. The two lateral sutures advised by Panas to prevent ectropion are not necessary in the modified operation (see Figs. 2066 and 2067).

Blepharospasm is a spasmodic contraction of the orbicularis muscle, present in inflammatory conditions of the eye or the conjunctiva. Occasionally, when it persists and interferes with the treatment of the underlying inflammatory condition, it may be necessary to perform the operation known as canthotomy, which we have already mentioned. Blepharospasm may also be associated with the affection known as tic douloureux. If the cause of the tic can be ascertained, the treatment will suggest itself. In some cases nothing seems to afford relief, and we are compelled to resort to operative procedure, namely, stretching or dividing the trigeminus, or even extirpation of the Gasserian ganglion. Even these extreme measures often fail to give relief. The writer now has a patient under observation who has facial tic with blepharospasm, and who has become an opium victim, whose ganglion was removed many years ago. When last seen this patient was taking sixteen grains of morphine sulphate daily to relieve the pain.

Nictitation, or winking of the eyelids, is due often to local troubles, as conjunctivitis and trachoma. Even uncorrected errors of refraction may be the cause. When due to these conditions, the removal of the cause will effect the cure. At times a general nervous derangement seems to be the cause, when tonics are indicated. One must not expect, however, to cure all these cases, especially when the patients are markedly neurasthenic.

Ecchymosis of the eyelids occurs as the result of traumatism or of paroxysms of coughing, as in whooping-cough in children and in chronic bronchitis in older persons, or it may occur without apparent cause.

When ecchymosis of the eyelids occurs in elderly people without apparent cause, we should be suspicious of atheroma of the blood-vessels, and the interior of the eye should be examined for hemorrhages. We should also bear in mind that a hemorrhage of this character may be the precursor of cerebral hemorrhage. Extremely hot applications are recommended by some authorities as giving the best results in ecchymoses due to traumatism, while others recommend iced applications. The writer prefers the ice for the reason that it is easier to apply, and is therefore likely to be more efficiently applied than hot applications. Either very hot or very cold applications, if resorted to as soon as the traumatism is received, will prevent extensive discoloration of the skin, but neither will accomplish much if the application is delayed. Warm fomentations are not to be advised.

Aside from painting the integument of the eyelid to hide the discoloration, time is the best remedy.

Almost every conceivable injury which can happen to the integument of the body elsewhere can occur about the eyelids. The writer has seen a patient whose eyelid was nearly torn off in a street fracas, and has also seen an eyelid split by the branch of a tree, and by being caught on a butcher hook. Any of these injuries can be repaired while still fresh by carefully cleansing the parts and bringing them together, retaining their apposition with sutures. Larger and older wounds may require extensive plastic operations, the extent and nature of which will depend on the wound.

Burns of the eyelids are not uncommon, and especially gunpowder burns. It is well in powder burns to remove, as thoroughly as possible, all particles of powder which may be in the skin. The only way in which this can be accomplished is to pick the particles out, one at a time, with a forceps or spud. It may take hours of patient work to do this, but the result amply repays the time so spent.

In many, perhaps most, powder burns, only the epithelium of the lid will be injured. When this is the case, it is only necessary, after the powder specks have been removed, to apply a bichloride vaseline, bandage the parts, and keep them clean.

Where more than the epithelium has been injured, it may be necessary to stitch the lids together and resort to skin grafting in order to prevent the deformity which the cicatricial contraction will produce. The method of skin grafting which gives the best results is the Thiersch method.

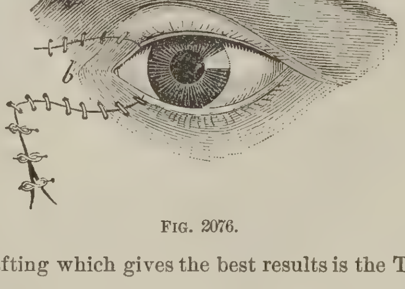

FIG. 2076.

The repair of damages to injured eyelids, and the relief of deformities occasioned by cicatricial contraction of wounds caused by injuries and burns, will give opportunity for the display of all the ingenuity and skill an operator may possess.

It is impossible to lay down definite rules as to when deformities are to be remedied by skin grafting, and when it may be necessary to resort to extensive plastic operations and the transplantation of large pieces of skin from the forehead and face. As a rule, it is better to reserve the Thiersch method for those cases in which the damage is so extensive that it is impossible to secure enough sound skin from the face or forehead to repair the damage—a condition sometimes found after scalds and burns. There may be times when both the transplantation of skin and the Thiersch method may be employed.

An eyelid, or both eyelids, on one or both sides, may be required to be replaced by skin taken from the forehead or cheek, or even from some other part of the body, as the arm. The necessity for taking a flap from the arm happens infrequently, and can be considered only when a cicatricial condition of the face or forehead makes it impossible to secure it from these parts. To remove a large piece of skin in toto and transplant it on some other part of the body would result, as a rule, in the speedy death of the part so transplanted, unless it remained attached to its original situation by a pedicle. In order to transplant a flap of skin from the forearm to the eyelid, and still retain the attachment of the flap to the forearm by a pedicle, would necessitate bandaging the arm to the head in a firm, immovable position for at least forty-eight hours. This has been done,—indeed, such a transplantation has been successful without a pedicle,—the pedicle being severed when the flap has united. Generally, however, it is possible to obtain enough sound skin from the face, except, as we said above, when there is extensive cicatricial contraction. A few general rules are necessary in order to secure a good result in plastic operations. When the margins of the lids are widely separated or everted, by cicatricial contraction, the first step must be to divide the cicatrices and bring the lids together, holding them in proper position with sutures. Every contraction which draws in any way on the margins of the lids should be freely loosened. We shall then have exposed the whole denuded surface which it is necessary to repair.

The next step must be to secure the flap with which to cover this denuded surface. Undoubtedly we have selected the spot from which this is to come before we began our operation, and have been influenced in our choice by the necessity of obtaining a strip of skin large enough to fill in the denuded surface, from a place where it is possible to secure also a healthy pedicle. The flap should be as nearly as possible devoid of cicatricial tissue, and it is even more important to have the pedicle of healthy skin. We have seen transplanted flaps thrive when they included superficial cicatrices, but when it is possible to utilize only healthy skin it is better to do so.

The flap should be large enough to prevent any tension on it or the parts to which it is sutured, when *in situ*, and it should be as free as possible from adipose tissue. The pedicle by which it retains its continuity with the surrounding tissues should be as broad as it is possible to make it, and should lie as flat as possible. A slight twist in the pedicle is not fatal to a good result, but any twist which is likely to interfere with the circulation of blood in the flap is to be avoided. In attaching the flap to the skin with which it is desired to secure union, fine iron-dyed black silk is to be preferred. The sutures should be close together, should not be very deep, and should not be tied too tightly. The writer does not recommend the use of harelip pins, believing that when they are necessary there is apt to be too great a tension on the flap to permit of union by first intention. A fatal mistake in plastic operations is to unite the parts before all bleeding has ceased. Severed arteries which persist in bleeding despite torsion should be tied with catgut ligatures, and the oozing of capillaries can be arrested by the application of hot water, or by gentle pressure; we must not use so much hot water that we destroy tissues and cause sloughs. The writer believes in the frequent washing of the parts with a weak bichloride solution during the operation.

After the parts are stitched in place, the spot from which the flap was taken must be repaired. This can be easily accomplished anywhere about the face, because of the looseness with which the integument is applied, by freely undermining the edges and bringing them together. Here is a consideration which must be taken into account when choosing a site from which to take a flap. We must be sure that the bringing of the parts together after the flap has been removed will not create a tension on the edges to which the flap is stitched after it is in its new position.

Flaps should not be taken from the cheek of a man whose beard is heavy and placed on the eyelid. The writer has seen this done, the flap producing a thick growth of hair which was annoying as well as disfiguring.

When the flap has been stitched in place, and the parts have all been adjusted to our satisfaction, a dressing of bichloride gauze should be placed over the wounds and a bandage loosely applied. This can be removed in two or three days, the parts cleansed if necessary, and the dressings reapplied. It is desirable to disturb the wounds after plastic operations as little as possible. The stitches can be removed, a few at a time, in from three days to a week. (Figs. 2068–2076.)

Epicanthus is a congenital defect characterized by a flatness of the bridge of the nose, and by the presence of crescentic folds of skin over the inner canthi. The defect is remedied by removing an elliptical piece of skin from the bridge of the nose and bringing the parts together. (Fig. 2077.)

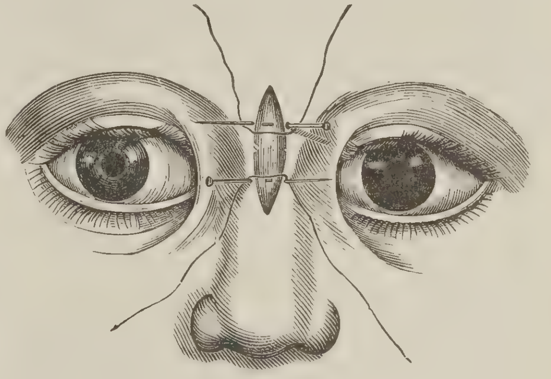

FIG. 2077.

Coloboma of the eyelid may also be congenital, and is remedied by paring the edges of the coloboma and sewing them together.

Nævus, another congenital defect, assumes a variety of forms. A simple reddened spot which varies in the intensity of its hue, often is seen in the eyelids of the newborn infant. Frequently these spots disappear in the first few months of life. Sometimes an intensely livid spot may cover the whole lid, or even the whole side of the face as well; when marked, these spots do not disappear, and very little can be done for them. Sometimes the distorted and enlarged blood-vessels may form distinct and irregular tumors. Treatment will be excision by means of the knife, or destruction of the blood-vessels by means of hot needles plunged into them. At times it may be possible to destroy a telangiectatic tumor by tying of the blood-vessels. The variety of these tumors renders it impossible to go into their treatment in detail in this article. Sometimes the results obtained are very satisfactory, and at other times, unfortunately, they are not satisfactory.

Frank Van Fleet.

EYE-STONES.—The opercula of certain species of gastropod mollusks. These organs are horny or calcareous valves, situated in the so-called foot of the mollusks, and serving to close the apertures of their shells when the animals withdraw themselves into them. They are of different shapes and variously developed in different species—in many species they are absent altogether. Those which are used as eye-stones are hard, stony, plano-convex bodies, about as large as split peas, 0.005

to 0.01 metre in diameter ($\frac{1}{6}$ to $\frac{1}{3}$ inch), rather longer than broad, with a smooth but rather dull plane, and a very smooth and shining, convex surface. The former has an excentric white nucleus, from which a brown, right-handed, spiral line reaches the edge in about two turns; the outer portion of this surface is variegated with light-brown markings, and finely striated with numerous lines running in the opposite direction. The convex surface is slightly asymmetrical, the thickest point being nearly opposite the nucleus of the spiral just mentioned. It is brownish flesh-colored in the centre, shading to white at the margin. Many specimens are much worn by the action of the sea; these are white as coral, and the spiral structure is difficult to make out. Eye-stones are composed mostly of lime carbonate, and perform entertaining movements occasioned by the discharge of carbonic acid from the surface when placed with the flat side down, in a vessel containing dilute acids. They have long been a popular resource in treating foreign bodies in the eye, for which one is placed under the lid, where it is carried around by the movements of the eye. When it comes in contact with the mote, this is carried along with the "stone" by capillary attraction, and is finally expelled with it. They are a clumsy means of doing what a small amount of skill will accomplish with far more certainty, and are deservedly nearly obsolete. The belief that they are alive and move themselves about in the eye, until they "find" the mote, is a popular fallacy. The demand for them now is very limited, and confined to the ignorant. The supply is also small and uncertain, those of this port (Boston) coming mostly in little lots from sailors who bring them from the Bahamas and elsewhere, as curiosities or private ventures. "Crab's-Eyes," lenticular concretions found in the lining membrane of the stomach of the crawfish, look much like eye-stones, and are described for them by several authors. The description just given will easily distinguish them.

W. P. Bolles.

EYES, ARTIFICIAL. See *Artificial Eyes.*

FACIAL NEURALGIA. See *Neuralgia.*

FACIAL PARALYSIS (Bell's Palsy).—Etiology.—In a large proportion of cases, peripheral facial paralysis is the result of so-called rheumatic influences, such as exposure of one side of the face to a draught, working in a damp room, or sudden chilling of the body while in a state of perspiration.

The disease may also be produced by a large number of organic lesions, which may be situated in the cranial cavity, in the course of the nerve through the Fallopian canal, or after its exit from the mastoid foramen.

The lesions within the cranial cavity which may give rise to this disease include basilar meningitis, tumors or exostoses situated at the base of the brain, syphilitic lesions in this situation, and aneurisms of the vessels of the base of the brain.

Within the Fallopian canal the paralysis may be the result of caries of the petrous portion of the temporal bone, otitis media, tumors which extend into the canal from adjacent parts, fracture of the base of the skull extending through the temporal bone, syphilitic deposits within or near the nerve, or an accumulation of wax in the external auditory canal.

After the exit of the nerve from the mastoid foramen, the paralysis may be produced by direct violence to the nerve (a slap on the face, fall, etc.), pressure upon the nerve, for example, the pressure of the forceps during parturition (a few cases have also been reported in which facial paralysis occurred during difficult and tedious labor, although the forceps had not been used), extension of inflammation to the nerve from adjacent parts (tuberculous abscesses of the glands situated near the angle of the jaw, parotitis, incised wounds during operations in this region, etc.). A case has also been reported in which the disease was produced by leukæmic infiltration of the nerve.

In comparatively rare cases facial paralysis follows certain of the infectious diseases, such as diphtheria, smallpox, erysipelas, typhoid fever. Gowers and others report cases of facial paralysis after tonsillitis, and Halschek has seen a case of double facial paralysis after mumps. This symptom has also been observed as a part of multiple neuritis. Many writers regard the disease as usually infectious in its origin. Several cases have also been reported in which the disease occurred during the secondary stage of syphilis, and was attributed to the direct action of the syphilitic virus. von Burski reports two cases in which the paralysis developed ten weeks after syphilitic infection, during the roseola.

The disease is more frequent in males than in females. It occurs very rarely during childhood and infancy.

Some writers believe that there may be a neuropathic predisposition to the disease. Browning reports the following case which bears on this point: A girl had facial paralysis after a cold; a few years later an older sister had a similar attack. The younger sister had two daughters; one of these had facial palsy after a cold, the other had a similar attack during childbed, from sleeping at an open window.

Clinical History.—Facial paralysis is almost always confined to one side of the face. In very rare cases it is bilateral (diplegia facialis), and in such cases the paralysis sometimes appears on the two sides at different times. Sometimes a similar cause operates upon both facial nerves (usually the so-called rheumatic influences); sometimes one lesion acts upon one nerve, an entirely different lesion upon the other nerve. Diplegia facialis is also a symptom of certain bulbar affections, but the consideration of the symptoms which distinguish the peripheral from the central variety will be reserved for the section on diagnosis.

Ordinary peripheral facial paralysis may begin suddenly, or it may be preceded for some time by a feeling of fulness and puffiness in the face, and by peculiar gustatory sensations on the affected half of the tongue. Rare prodromes consist of tinnitus aurium, dizziness, and pain in the face. Gowers has observed fever and temporary albuminuria. In Hoffman's case the paralysis was preceded by severe pains in the right side of the neck and face, and was attended by unconsciousness. Hence this writer believed that the attack was constitutional in origin. The paralysis may occur suddenly and completely in all branches (in rheumatic cases from a couple of hours to one or two days from the action of the exciting cause), or it may spread from one group of muscles to another (when it is the result of compression by a slowly growing external tumor or other lesion which acts in a similar manner). In the majority of cases all the muscles are affected in an approximately equal degree.

The appearance of the face is well shown in Fig. 2078. The patient, whose photograph is here shown, was directed to contract all the muscles of the face, but, as is evident from the illustration, power over the left facial muscles is entirely lost. The left eyebrow is slightly elevated, the palpebral fissure is enlarged, the naso-labial fold is effaced, the angle of the mouth droops slightly and is drawn nearer to the median line (this is observed even when the face is in repose), the mouth is kept a little open on this side, and the tip of the nose deviates slightly to the healthy side.

A patient suffering from complete facial paralysis is unable to wrinkle or corrugate the brow, on account of the paralysis of the frontalis and corrugator supercilii muscles. On making a vigorous effort to close the eyelid the globe is rolled upward and inward (or rarely outward), so that often only the sclera remains visible. But the upper lid descends a little, even when the nerve appears to be completely paralyzed. The descent of the eyelid has been attributed to a partial relaxation of the levator labii superioris, but it must be confessed that this explanation is not very satisfactory. On account of the paralysis of the orbicularis palpebrarum the puncta lachrymalia are no longer kept applied to the globe, and consequently the tears cannot make their way into the lachrymal canal and nasal cavity. Hence, the patients suffer from overflow of tears. The paralysis of the orbicularis also prevents winking and the closure of the eye during sleep. The consequent irritation of the eyeball may give rise to conjunctivitis and keratitis, though this does not happen very often. The lower lid may become everted.

The ala nasi on the paralyzed side cannot be distended so vigorously as on the healthy side, and hence smell is somewhat impaired. This impairment of smell is increased still further owing to the fact that diversion of the tears from the nasal cavity causes dryness of the Schneiderian mucous membrane.

The angle of the mouth droops a little, and is drawn slightly toward the median line. This phenomenon is increased upon bringing into play the muscles which are inserted into the opposite angle of the mouth, as in the act of laughing. The lips cannot be closed on the affected side, and hence whistling is rendered impossible. The pronunciation of labials may be interfered with, but in many cases articulation is undisturbed. The cheek on the paralyzed side flaps loosely when the patient attempts to puff it out. Mastication is also interfered with to a certain extent, on account of the paralysis of the buccinator muscle. The food is apt to accumulate between the cheek and teeth, and must be dislodged frequently by the patient's finger. In a considerable proportion, perhaps the majority, of cases taste is impaired upon the anterior third of the tongue on the paralyzed side, and sometimes the patient complains of peculiar subjective sensations in this locality. This is owing to the fact that the chorda tympani nerve, which supplies the anterior third of the tongue with gustatory fibres, joins with the seventh nerve during its course through the Fallopian canal. Some doubt still attaches, however, to the anatomical and physiological relations of this nerve.

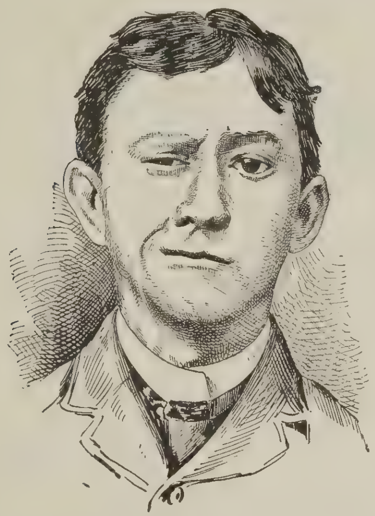

FIG. 2078.—Well-marked Facial Paralysis of the Left Side. (From a photograph taken at the moment when the patient was told to contract all the muscles of his face.)

The tongue is protruded in a straight line, but, on account of the displacement of the oral fissure toward the healthy side, there is an apparent deviation of the organ toward the paralyzed side.

In certain cases (*vide* the section on diagnosis) the palate and uvula are found to be paralyzed. Upon inspection the paralyzed velum palati is seen to hang lower than on the opposite side, and the uvula may be deflected to one or the other side (the latter phenomenon is sometimes observed in healthy individuals). These parts also remain almost motionless during phonation, or when reflex action is excited by irritation of the fauces. Deglutition is also interfered with to a certain extent, so that the patients often swallow the wrong way. Some writers deny the occurrence of an affection of the velum during facial paralysis. Lermoyez comes to the conclusion that the velum is innervated almost entirely by the pneumogastric.

As a rule, the sensibility of the integument remains unaffected, but in a few cases the patients complain of a feeling of numbness of the skin. In these cases, however, we have never been able to detect any objective evidences of disturbed sensation. The symptom in question is probably the result of an implication of some of the recurrent fibres of the trigeminus in their course along the facial nerve.

Hearing may be affected, sometimes as the result of the lesion which gave rise to the paralysis, sometimes as the result of the paralysis itself. In the latter event the patient suffers from hyperacusis (also called oxyokoia), *i.e.*, increased sensitiveness to auditory impressions. This has been explained by the paralysis of the stapedius muscle (which is supplied by the facial nerve), and the consequent predominance of the action of the tensor tympani (supplied by the fifth nerve). Herpes zoster is sometimes seen. Klippel distinguishes febrile zoster (infectious disease) combined with facial paralysis from the accidental herpes eruptions, which, like the accompanying facial paralysis, are due to definite lesions of central parts or of the peripheral nerve. In the former event, the eruption may be present only on the paralyzed side of the face or also in other parts, or it may not be located in the face at all. Remak reported a case, complicated with zoster of the anterior two-thirds of the tongue on the paralyzed side. The zoster recovered during the first week of the paralysis.

In some cases the muscular and nerve irritability remains normal throughout the course of the disease. Such cases usually recover spontaneously and with great rapidity.

Many cases present various stages of transition from normal electrical excitability to the complete form of degeneration reaction. Indeed, we find not infrequently that one case presents various conditions of electrical excitability in different muscles and branches of the nerve.

If the patient does not recover from the disease, the electrical irritability of the muscles gradually diminishes, and is finally abolished.

Experimental investigations have shown that the degeneration reaction is the result of certain lesions of the paralyzed nerve and muscles. When the degeneration reaction is at its height, it is found that the axis cylinder has disappeared, the medullary substance has undergone fatty degeneration, and the nuclei of the sheath of Schwann are increased in number; the interstitial connective tissue and nuclei undergo proliferation. At the same time the muscular fibrillæ are diminished in size and their nuclei increased in number; the transverse striæ are less distinct or absent, and the interstitial connective tissue is increased in amount. If recovery ensues all these changes gradually disappear.

Flatau reports a case of left facial paralysis due to chronic tuberculous otitis media, with total degeneration reaction (D.R.). Death occurred within a year from tuberculosis. The central portion of the nerve was found degenerated in its intramedullary and basal course; the cells of the left facial nucleus were swollen, misshapen, etc. The degeneration extended to the intranuclear facial fibres, the left ascending root, the efferent root, etc. These findings show that Waller's law of degeneration is no longer tenable as first laid down. The peripheral motor nerve is dependent on the cell, but is only part of a coherent, indivisible entity (the neuron), and the destruction of any part of this unit leads to changes in the entire neuron.

In another case of paralysis from middle-ear disease, Darkschewitsch and Tichonow found, on autopsy, the neurilemma unaffected; the lesions were those of purely parenchymatous neuritis.

In a few cases recovery is not complete, and spasms and contracture of the muscles are left over as sequelæ. These conditions may exist separately, but they are usually associated with one another. The spasms consist of short, quick contractions of the muscles, occurring irregularly, and very much resembling facial tic. These spasmodic movements are unattended with pain and are often unnoticed by the patient.

Contracture is observed particularly in the levator palpebræ superioris alæque nasi and zygomatici muscles, and causes retraction of the angle of the mouth upward and outward. It thus tends to overcome the original deformity produced by the paralysis. When the contracture is very marked, the deepening of the naso-labial fold to which it gives rise may create a deceptive appearance of paralysis upon the opposite side of the face. An error in diagnosis may be obviated by directing the patient to laugh, whereupon it becomes evident that the contractured muscles remain motionless, while those on the healthy side contract normally.

Gowers thinks it probable that contractures and clonic spasms are due to changes in the facial nucleus, caused by continued interruption in the nerve tracts and constant irritation of the centre during attempts to move the facial muscles. The cell resistance is diminished and hence the cells react with abnormal facility.

If complete paralysis of the muscles remains permanent, the muscles will undergo atrophy, so that the affected half of the face looks smaller than the other side.

Oppenheim has described a rare combination of peripheral facial paralysis with hysterical symptoms, viz., hysterical hemianæsthesia on the same side. The paralysis persisted but the hemianæsthesia disappeared in a short time.

In diplegia facialis the face presents a remarkable appearance inasmuch as it is absolutely devoid of expression, and even the most violent emotions are experienced by the patient without the slightest change of countenance. The lower lip droops, and saliva is constantly flowing from the mouth. Articulation and deglutition are interfered with to a very marked degree.

Diagnosis.—The differentiation of peripheral from central facial paralysis is usually quite easy. In the latter affection the muscles of the forehead and eyelid are very slightly involved. As a rule, however, on directing the patient to close only the eye on the paralyzed side, it becomes evident that this is done with less vigor and promptitude than on the healthy side. The affected muscles present no changes of electrical excitability, however profound the paralysis may be. It will also be noticed that the voluntary and the reflex contractility of the paralyzed muscles are often in marked contrast to one another, the latter being much greater than the former. Furthermore, the clinical history of the two affections is usually decisive. In the cerebral variety the facial paralysis is almost always associated with paralysis in some other part of the body, usually of the arm and leg upon the same side. In addition, cerebral facial paralysis generally develops after an apoplectic seizure, which is usually accompanied by unconsciousness.

In a certain proportion of cases the disturbance of gustation on the anterior portion of the tongue, the paralysis of the velum palati and uvula, and the history of a previous disease which may have produced a lesion of the seventh nerve, will aid us in clearing up any possible doubt in diagnosis.

In rare cases, however, facial paralysis produced by lesions of the pons Varolii presents most of the characteristics of peripheral facial paralysis. If the lesion is situated in the lower half of the pons, the facial paralysis is associated, as a rule, with hemiplegia of the opposite side of the body. When the lesion is situated in the upper half of the pons (before the decussation of the seventh nerves), the face and limbs are paralyzed on the same side of the body. The frontalis and orbicularis palpebrarum may be entirely paralyzed, as in ordinary peripheral paralysis, and, in addition, there may be marked changes in the electrical excitability of the facial nerve and muscles. But a mistake in diagnosis is usually obviated by the presence of other symptoms of a pons lesion, such as contraction of the pupils, marked difficulty in swallowing and articulation, and paralysis of various cerebral nerves (trigeminus, abducens, hypoglossus), etc.

After the diagnosis of the peripheral character of the disease has been made, we should also endeavor to determine its location more accurately. As a rule, this can be done with great certainty on account of the peculiar anatomical relations of the nerve.

If the lesion is situated above 5 (Fig. 2079), the patient will suffer from paralysis of all the facial muscles, of the uvula and velum palati, and from disturbances of hearing, but gustation will be unimpaired. This is owing to the fact that the chorda tympani nerve enters the facial nerve, in all probability, at the ganglion geniculatum through the petrosus superficialis major nerve, *psm* (from the trigeminus). The chorda tympani leaves the facial nerve between 2 and 3, *cht*, and then joins the lingual branch of the trigeminus.

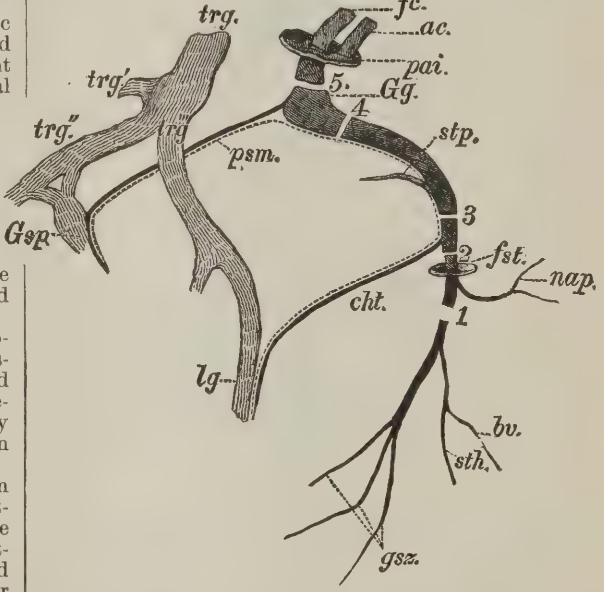

Fig. 2079.—Schematic Representation of the Ramifications of the Facial Nerve. (After Eichhorst.) *fc*, Trunk of facial nerve; *ac*, trunk of acoustic nerve; *pai*, internal auditory foramen; *gg*, ganglion geniculatum; *psm*, nervus petrosus superficialis major; *stp*, nervus stapedius; *cht*, chorda tympani; *fst*, styloid foramen; *nap*, posterior auricular nerve; *bv* and *sth*, nerves to the digastric and stylo-hyoid muscles; *trg*, *trg'*, *trg''*, *trg'''*, trunk and branches of the trigeminus; *gsp*, spheno-palatine ganglion; *lg*, lingual nerve.

If the lesion is situated between the ganglion geniculatum and the point at which the nerve to the stapedius muscle, *stp*, is given off, the symptoms will consist of paralysis of all the facial muscles, disturbances of hearing, and impairment of taste on the anterior third of the tongue. The velum palati is unaffected in this case, probably because its motor fibres are given off at the ganglion geniculatum, *Gg*. If the lesion is situated between the origin of the stapedius nerve and the point at which the chorda tympani, *cht*, leaves the facial nerve, the symptoms just mentioned will be present, with the exception of the disturbances of hearing. A lesion below the point at which the chorda tympani is given off will simply produce paralysis of the superficial muscles.

It must be remembered, however, that these remarks hold good only in those cases in which the lesion is of such character as entirely to destroy the conductibility of the nerve at the affected part.

Prognosis.—The prognosis depends chiefly on the character of the lesion which has given rise to the paralysis, and therefore varies according to that of the primary disease. When the nerve is involved directly, as in cases of rheumatic origin, or those due to infectious diseases, etc., the prognosis may be determined, in great measure, by the changes in electrical excitability.

When the excitability of the nerve and muscles is unchanged, the disease will usually recover spontaneously in from two to four weeks. If complete degeneration reaction is present, recovery cannot be looked for in less than from three to six or nine months. But the case should not be regarded as absolutely hopeless, even if the electrical excitability is abolished for a short period.

The development of muscular spasms and contracture is a very unfortunate event. In no case of this kind which has come under our observation has recovery occurred. The contracture usually continues to increase in severity, and after a while the muscles undergo a certain amount of atrophy. These two factors may give rise to considerable disfigurement of the face.

As a rule, the disease runs a longer course in those cases in which the lesion is situated within the Fallopian canal.

Treatment.—The causal treatment varies with the nature of the primary disease (affections of the middle ear, syphilitic lesions, tumors, etc.). The use of leeches, blisters, and the administration of strychnine, which are strenuously recommended by some writers, have been attended with such unsatisfactory results in our hands that we now rely exclusively upon electrical treatment.

In those cases in which the electrical excitability of the paralyzed nerve and muscles is unchanged, treatment is unnecessary, since recovery occurs spontaneously.

When complete degeneration reaction is present, electricity should be applied to both the nerve and the muscles, and in the case of the nerve the galvanic current alone should be employed. A small electrode, the anode, is placed immediately over the mastoid foramen (between the mastoid process and the lobe of the ear) on the affected side, the cathode (with a similar electrode) over the opposite mastoid foramen. The current will therefore pass through the petrous portion of the temporal bone, and act upon the nerve in its passage through the Fallopian canal. It should not be strong enough to produce a feeling of pain or vertigo, no interruptions should be made, and the sittings should be held for three or four minutes every other day. With this method we may combine labile galvanization of the muscles. One medium-sized electrode (usually the cathode) is placed upon the back of the neck, the other small electrode is slowly passed over the affected muscles. The frontalis and corrugator supercilii muscles are brought into play by passing the electrode horizontally across the forehead, a little above the eyebrow. The levator labii superioris alæque nasi, zygomatici, and buccinator are brought into play by passing the electrode along the side of the nose (beginning near the inner angle of the eye), and then outward across the cheek, immediately below the malar bone. Labile applications may also be made directly to the orbicularis oris and chin muscles. In applications to the orbicularis palpebrarum, we are in the habit of placing a very small electrode upon the muscle, at the outer angle of the eye, and then interrupting the current (by means of an interruptor in the handle of the electrode).

In an apparently incurable case of facial paralysis due to a gunshot wound, Faure and Furet stitched the peripheral extremity of the facial nerve to the adjacent branch of the spinal accessory. The results in this case were not very satisfactory, but in view of the experiments made by various observers it is probable that surgical interference will prove useful in a limited number of cases.

In some cases the excitability of the muscles will be found to have sunk to such a low ebb that it becomes necessary to employ the intrabuccal method of galvanization. One electrode is then placed upon the muscle which we desire to stimulate, the other directly opposite upon the mucous membrane of the cheek.

After the nerve has recovered its electrical excitability, the faradic current may be employed, either upon the muscles themselves, or by simply passing the electrode along a vertical line immediately in front of the ear, in order to stimulate the pes anserinus as it spreads out in this locality.

We may attempt to relieve contractures by stabile galvanization of the affected muscles, the negative pole being applied to the mastoid foramen, the positive pole to the contractured muscle. Massage of the muscles has also been employed for this purpose.

In all electrical applications in this disease, the electrodes should be very thoroughly moistened, and the current should merely possess sufficient strength to produce visible muscular contractions. *Leopold Putzel.*

FÆCES.—The term "fæces" is applied to the excrementitious substance that normally leaves the body through the anus. The material consists of the waste from the intestinal walls and the unabsorbed residues of the various secretions into the alimentary tract, together with an admixture, in varying amounts, of undigested and partially digested food, and at times such adventitious substances as may be taken into the alimentary canal *per os* and which are not absorbed. The common idea that the fæces in health consist chiefly of food residue is not sustained by the results of recent investigations.

After the intestinal contents have passed the ileo-cæcal valve, they rapidly take on the characteristic consistence, color, and odor of fæcal matter, being altered by the absorption of the liquids and soluble substances, as well as, to some extent, by the continuation of putrefactive and fermentative processes and by admixture with the strongly alkaline secretions of the large intestine. The extent of these changes is largely influenced by the rapidity with which the contents pass through the colon.

Physical Characters.—The *quantity* passed in twenty-four hours varies greatly, but is estimated to average 120–200 gm., in a healthy man on a mixed diet. It is dependent to some extent on the quantity and quality of food eaten, but is influenced as well by the condition of the digestive organs as regard secretion and absorption, and the frequency of evacuation. As a rule the quantity of fæces increases with the relative increase in the amount of vegetable food in the diet. It is probable that this is due largely to the greater resistance of vegetable food to digestive action and the subsequent stimulation of peristalsis by the undigested residues, with a resulting diminution of absorption. In an infant fed on cow's milk the quantity is regularly considerably greater, even up to ten times, than the amount passed by a breast-fed babe. This is due not alone to difference in digestibility, but to a considerable extent to the much larger quantity of milk given in artificial feeding, which both adds to the quantity of undigested food residue and increases the residue from intestinal secretion and waste. The quantity of fæces evacuated is occasionally increased by pathological products, including mucus, blood, pus, and serous fluid.

The *color* is normally derived from the intestinal secretions, notably from the bile, and under certain conditions is also very considerably influenced by the food, the stools of a mixed diet usually being a medium shade of brown, those of a meat diet dark to blackish-brown, and the evacuations following the exclusive ingestion of vegetable food being a light brown. The stools of an exclusive milk diet vary in color from orange to light yellow. The dark color is due to hæmatin, and to some extent to the compact, dry condition of the fæcal matter. In particular instances the color may be modified by special coloring matters ingested with the food, as, for example, chlorophyl, derived from large quantities of green vegetables. Adventitious ingesta as, *e.g.*, certain medicaments, may determine the color. Thus, calomel may cause a green coloration, probably by causing the presence of biliverdin, and bismuth or iron may each be reduced or may exceptionally appear as the black sulphide. Again, unusual changes in the intestinal contents may modify the color, as the growth of bacteria, producing pigment, notably green, or, as occurs frequently in infants, there may be a production of unusually strong alkalinity in the upper intestinal tract, causing the presence of biliverdin in the fæces in quantities sufficient to impart a green color. Finally, there are the clay stools after complete suppression of the bile and the similar appearance in cases without jaundice due to the presence of excessive amounts of fat.

The *odor* of the fæcal matter of adults is characteristic and is to be attributed to the presence of skatol and indol, and probably to other aromatic products formed by the putrefaction of the intestinal contents. When the passage through the intestines is rapid there may be little or no production of skatol, as in the rice-water stools of cholera, which are almost or quite odorless. The stools of an infant do not normally have a putrid odor, but if strongly acid they may have a rancid smell.

Normal stools are cylindrically *formed* and have a definite consistence. When the passage through the large intestines is rapid or the secretion into the bowels unusually abundant, they may become soft or even watery, while under opposite conditions they may be considerably hardened and assume the form of balls or very thin cylinders, these hardened masses being known as scybala. The so-called lead-pencil form is in no way indicative of intestinal stenosis, but is the rule when there has been complete abstinence from food, and may be caused by spastic or paralytic conditions of the large intestines.

After the exclusive ingestion of soft food the *structure* is usually homogeneous, while in fæces of the various mixed diets hard and undigested portions of food may be distinguished—as, for example, seeds, fragments of fruits and vegetables, or fibrous tissue. Adventitious admixtures of foreign substances are occasionally observed, such as fragments of wood, pieces of quill, buttons and pins. The appearance in the stools of bits of food tissue, recognizable to the naked eye, sometimes results from digestive insufficiency, either mechanical or chemical. Insufficient mastication is the most frequent mechanical fault. A failure of the chemical processes of gastric digestion is followed by the appearance of bits of connective tissue, while insufficient pancreatic digestion leads to the presence of undigested muscle fibre. Either biliary or pancreatic insufficiency may be followed by the appearance of much fat. Food fragments are more abundant in diarrhœal discharges, the material in some instances passing the entire length of the alimentary tract in a few hours and almost unchanged. In such stools pieces of meat may be seen or milk clots of various shapes and sizes. As a rule, the inner portion of formed stools is more recent than the outer, the passage through the intestines following the ordinary rule of flow, being more rapid in the centre and retarded at the periphery.

Fæcal matter has a certain *coherence.* If it does not contain evident food residue the mass usually does not crumble readily, when stirred with water, as do stools in which much food residue is present, particularly plant tissue and undigested casein. A large amount of fat increases the coherency, as does also in some instances much mucus, though possibly this is due to the accompanying fat.

Inspection of the alvine discharges occasionally reveals the presence of *pathological admixtures.* Blood, if from the lower bowel, is recognizable to the unaided eye, but, if changed by contact with the digestive juices, it merely imparts a dark color or tarry consistence to the stool. Likewise pus is recognizable only when it has been discharged into the lower part of the large intestine. The normal stool may contain on its surface visible mucus, but not in any considerable amounts. In catarrhal conditions of the intestines, however, the amount of mucus may be greatly increased, appearing either as a glassy layer surrounding the fæcal matter, as in diseased conditions of the lower portion of the bowel, or mixed with soft fæces, in which case the mucus adheres to a glass rod dipped into the evacuation; or, finally, it appears in watery dejecta as small floating particles, readily recognized. In membranous enteritis mucus is passed in long strings or as a continuous, tubular membrane, sometimes dense and opaque so as almost to appear fibrinous. In cholera and to a less extent in some other conditions great quantities of serous fluid, a true transudate, are evacuated with the intestinal contents.

MICROSCOPIC CHARACTERS.—Microscopic examination of fæcal matter reveals a mass of bacteria and detritus in which is embedded a greater or less number of recognizable morphological and crystalline elements, some being residue of food or adventitious ingesta, others being products from inhabitants of the intestinal tract, while still other such elements are those derived from the body itself and its secretions.

Vegetable cells and fibres of variable form may be encountered, some containing starch granules or masses of chlorophyl. Occasionally, especially in diarrhœal stools and where there is a failure of pancreatic digestion, starch granules more or less unaltered are recognized in considerable number. They turn blue in contact with a solution of iodine. Rosenheim states that he could not detect 0.6 per cent.; hence it appears that less than one-half per cent. of starch cannot be detected with certainty by microscopic examination.

Of the residues from *animal food,* connective tissue may be present in variable amount, being increased when this class of food is ingested in large quantity, and when there is a deficiency of gastric digestion. Where such food has been sparingly eaten, the appearance of areolar fibres in notable numbers is nearly always indicative of deficiency of the chemical processes of gastric digestion. Elastic fibres, except to a very limited extent in the instances in which they come from swallowed tuberculous sputa, are derived from the food and are not indicative of any condition of disease. Partially digested bile-stained muscle fibres are nearly always found in the stools, still preserving their transverse striæ so as to be recognizable, though the general appearance of the fibres may be much altered. They are not rendered more numerous by gastric deficiency, but they are apt to remain bound together by bands of undigested connective tissue. A large increase on a limited meat diet is indicative of deficiency of intestinal digestion. Undigested milk clot is at times present in the excrement of adults, and is frequently seen in the stools of infants. They are recognized by the absence of structure, the presence of fat globules and proteid, as indicated by microchemical tests, and the solubility of the coagulated proteid in dilute alkali and its reprecipitation by acetic acid.

Fat, in the form of globules and as fat tissues, is occasionally seen, but is commonly present as needles, single or in clusters. These are probably fatty acids in combination with calcium and magnesium, alkali-earth soaps. They are present in enormous numbers in acholic stools and are regularly increased when there is a deficiency in the absorption of fat.

Cholesterin *crystals* rarely appear in the stools, this substance not being a normal constituent of fæcal matter. Since it is usually present in meconium, in the stools of starvation, and in evacuations when digestion is arrested, its appearance in crystalline form is to be looked for in these conditions. Stercorin, into which cholesterin is normally converted in the intestinal tract, crystallizes in thin delicate needles and hence is distinguished with difficulty from alkali-earth soaps. Whether this substance appears in crystalline form in the stools is unknown.

Phosphate crystals are regularly seen in the microscopic examination of fæces, either as wedge-shaped prisms, single or in clusters, of the neutral calcium salt or as the triple phosphate in its various forms (see under *Urine*). They are without pathological significance.

Calcium oxalate crystals are frequently recognized in fæcal matter. They are in many instances derived from the food, but there is reason to believe that oxalate is at times formed in the fermentative and putrefactive processes of alimentation. In the light of our present knowledge its occurrence in crystalline form cannot be considered significant of any pathological process.

Crystals of other organic salts of calcium are described as occurring in stools, the lactate in the discharges of children, appearing as sheaves of radiating needles, and the acetate and butyrate in the discharges of gastric and intestinal catarrh. The occurrence of amorphous particles or dumbbell crystals of calcium carbonate and of prisms or dumbbell-shaped amorphous masses of calcium sulphate is exceedingly rare and probably devoid of pathological significance. After the administration of bismuth black crystals appear in the stools; in shape they closely resemble hæmin crystals.

Charcot-Leyden crystals are occasionally seen, most frequently when intestinal parasites, particularly worms, are present. They are also seen in typhoid fever and in catarrhal conditions of the bowel.

Of the *morphological elements* derived from the body epithelial cells are most frequently seen, as they are always present. Squamous epithelia come from the region of the anus, and are the least changed. The columnar variety is less frequently recognized, being much altered by partial digestion and abstraction of moisture. If in great numbers they point to intestinal catarrh, but are of no further diagnostic importance. The possibility of the presence of bits of neoplasm should always be borne in mind, but their recognition when such a growth exists is only occasionally possible. The casts of mucous enteritis and colitis frequently seem to be fibrinous, but microscopic examination shows that they consist of dense, more or less transformed mucus. Portions may be infiltrated with large numbers of small round cells. Blood, unless present in large amount, is recognized from the red corpuscles only when it comes from the lower portion of the rectum. Hemorrhagic stools frequently, however, contain reddish-brown hæmatoidin, sometimes presenting a somewhat crystalline structure, the crystals appearing in some instances after a hemorrhage had occurred several days before the stools were passed. In black tarry stools the presence of blood can be proved only by chemical tests (see Vol. II., page 74). Pus corpuscles occur in dysentery, ulcerative processes, and where an abscess has emptied into the bowel. Leucocytes are usually much degenerated and, if present in considerable numbers, are usually significant of ulceration.

Parasites.—Fæces contain lower forms of vegetable life which von Jaksch divides into two classes according to the manner in which they stain with iodo-potassic-iodide solution, viz., those that stain brown or brownish-yellow, and those that stain blue. The latter occur in relatively small numbers in health. Moulds are rarely present in fæcal matter, only the thrush fungus being occasionally seen, and then in children with thrush. Yeast cells are very common, being present even in the stools of breast-fed infants. They are more abundant in the acid stools of children. The fission fungi, chiefly bacteria, probably in most instances constitute the greater portion of the bulk of fæcal matter, occurring in enormous numbers, the figures obtained by different observers who have attempted to enumerate them ranging from 15,000 to 80,000 or even higher as an average for each milligram. Animals thrive in the absence of these forms of life in the intestinal contents, and they are not present during fœtal life, yet their presence is probably not without benefit. On a strict milk diet the number rapidly diminishes. In the stools of infants the bacteria commonly present are the Bacillus coli communis and the Bacillus lactis aerogenes; they give rise to acid fermentation with the production of acetic and higher fatty acids and occasionally formic acid, but they do not occasion a true putrefactive process. The varieties in the stools of adults are very numerous, more than fifty species having been identified, a number that does not at all adequately express the many species that probably are present under all possible conditions. It is generally accepted that the colon bacillus is the most constant inhabitant of the lower bowel, and with it are several of the different species active in putrefactive processes. For an account of the individual species and of the pathogenic bacteria, see the article on *Bacteria* and those that treat of the various diseases. Animal parasites of various description at times inhabit the intestinal tract, and may be passed with the stools. They include various protozoa, many species of worms, and not a few insects. For an account of these see the article on *Parasites.*

CHEMICAL COMPOSITION.—Normal fæces contain *moisture and volatile* substances to the extent of from sixty-eight to eighty-two per cent. of their weight, the water comprising about five per cent. of the total amount lost by the body through the various channels. In soft and watery stools the amount of water may increase to ninety-seven per cent. or more, while in hard stools it may diminish considerably. The other volatile constituents present in relatively small amounts are volatile fatty acids, phenol, indol, and skatol.

On ignition fæces usually yield an amount of *ash* equal to about one-eighth or less of the total solids, but this does not represent the condition of the mineral matter in the fresh material, since the acids of the ash are to a considerable extent formed from the organic matter in the process of combustion. Avoiding this error, Grundzach found in a normal adult, living on a mixed diet, that the bases were chiefly calcium and in smaller amounts potassium and magnesium, with still less of sodium and a very small amount of iron, and that twenty-two per cent. of these bases were combined with inorganic acids, chiefly phosphoric, but with small amounts of sulphuric and hydrochloric, and that the remaining seventy-eight per cent. were combined with organic and carbonic acids. In stools containing much serous transudate the quantity of chloride is greatly increased. Studying the secretions of the large intestine in a patient with an artificial anus in the lower ileum, Kobert and Koch found that on an average one-fourth of the solids is ash, about one-half of this in one examination being phosphate. It is evident, then, that the inorganic solids are derived from the intestinal and other secretions as well as from the food residue. The quantity of iron is usually found to vary between 2 and 25 mgm. in twenty-four hours, but it has been found to be 50 mgm. or more in malarial infection with much destruction of hæmoglobin.

The chief class of organic substances in the fæces is the *proteids,* the most important of these, the albuminoid bases of intestinal mucus, forming the chemical basis of fæcal matter. This is not mucin as was formerly supposed, but a phosphorus-containing, albuminous substance, probably identical with, or closely allied to, nucleo-albumin. True mucin is not regularly present in fæcal matter. It is, however, the chief substance imparting to human bile its mucilaginous character, and presumably may at times pass from the bile into the fæces, as well as from the saliva in which it is an important constituent, and from the food; but it has not been proved to be a regular constituent of human excrement. Appreciable quantities of albumins and globulins are present in pathological conditions only, namely, when there is serous fluid present, or when the food has passed through the body so rapidly as to escape complete digestion, and less frequently when the digestive function itself is not properly maintained. Thus in typhoid and dysentery albumins may be found; in the rice-water stools of cholera they are constantly present; they have likewise been found in stools deficient in bile. Since microscopic bits of bile-stained meat fibres can always be recognized in stools after a meat diet, it is presumable that myosin is present at the same time; but the quantity under ordinary conditions is hardly appreciable. Another class of proteids not present in the fæces of health is the products of digestion, the proteoses and peptones. They are constantly present whenever pus is found in the stools, and irregularly in certain other conditions. Nucleins are stated to be commonly present in fæcal matter. Whether in most instances they are true nucleins derived from the food or are paranucleins from mucus and nucleo-albumins of the food residue is uncertain, but it seems probable that in many instances they are paranucleins. Leucin and tyrosin are not present in the evacuations of health, and in diseases only when the passage through the lower bowel has been so rapid as not to permit of absorption. Hence they are to be looked for, and are frequently found in the stools of cholera and other conditions characterized by watery movements. Crystals of calcium and magnesium soaps were at one time believed to be tyrosin crystals, but their true nature is now recognized.

An important class of substances appearing in the fæces in greater or less quantity is the *fats* and their derivatives, consisting chiefly of neutral fat and soaps with some free fatty acids. The total quantity of these in an adult on an average mixed diet in health is only exceptionally as high as twenty-five per cent. of the dry solids of fæcal matter, the soaps and free fatty acids usually present making up three-quarters of the amount, with perhaps rather more soaps than free acids. The absolute quantity is influenced by the character of the food, only to a limited extent. In starvation and on some diets the fat of the excrement even exceeds the quantity ingested, while it has been observed that increasing the fats of the diet as much as twenty times only doubles the amount in the stools. When 100 gm. are ingested not more than from 4 to 6 per cent. of this amount should be contained in the fæces. It is interesting that the fat of lower melting-point is more readily absorbed, the fatty acids recovered from the stools usually melting seven degrees higher than those of the food. With diminished absorption the difference is less, and in diarrhœa may be almost inappreciable. The presence of free fatty acids in the ingested fats likewise favors absorption and correspondingly diminishes the amount excreted. In obstructive jaundice the total quantity of fat is greatly increased, the amount in some instances reaching seventy-five per cent. or more of the dry solids, without there being any considerable relative increase of neutral fat. With a failure of the pancreatic secretion, either with or without obstruction of the bile, there is likewise an increase in the fats excreted, but with a marked relative increase in the neutral fat. When the fats are thus increased, whether from insufficient bile or pancreatic fluid, the stools take the gray-white color and soft consistence that characterizes the so-called acholic stool. Mention should be made of the enormous, thick, pulpy stools of a dirty dark gray color and greasy appearance sometimes seen in diabetics. They contain a large quantity of neutral fat and other food residue, and are to be attributed to a diminution or absence of pancreatic fluid, from extensive lesion of the pancreas, which in these cases is the primary cause of the diabetic condition. Other conditions, in which an increase in the excretion of fats has been observed, are fevers, though usually not typhoid, and some cases of anæmia.

Carbohydrates appear in the fæces only when they are ingested and escape digestion and absorption. If they are easily soluble their utilization is usually complete, being determined entirely by the motor and absorptive functions, while starch demands the action of diastatic ferments for solution, and starch granules enclosed in cell walls are dependent still more on this latter function, and also call into exercise the action of bacteria to dissolve or decompose the cell cellulose. These facts are in accord with the observation that raw starch is more apt to appear in the stools than cooked and soluble carbohydrates. Considerably smaller quantities of starch can be detected by the fermentation test than by microscopic observation of the iodine reaction, by the former method 0.1 per cent. in one instance having been readily indicated, while by the latter 0.6 per cent. was not recognized, though it does not seem improbable that here the structural form was lost, and even that the starch was present in the soluble condition. Dextrin and gums may sometimes be detected in the stools, but even in diabetes dextrose is not present, though secretion into the intestines be induced by purgation. Of the pentoses rhamnose readily appears in the stools, xylose less readily, and arabinose only after its ingestion in large quantities. Cellulose is not dissolved by the digestive ferments, but to a slight extent is decomposed into methan and carbon dioxide by bacterial action. A large percentage is evacuated unchanged.

Of the *bile derivatives* the most important is the pigment. Under ordinary conditions bilirubin is reduced in the intestines to the color constantly present in fæces, known as hydrobilirubin, and to certain colorless closely allied substances capable of ready oxidation into pigment. The name "stercobilin," used by Vanlair and Masius, who supposed the color to be formed from bilirubin by oxidation, is still used by some writers rather than Maly's term, which expresses the true chemical relationship. The average amount contained in the twenty-four hours' evacuation was found by one observer to be 0.36 gm., not including the colorless products capable of yielding pigment by oxidation, of which a very considerable amount may be passed. Under certain conditions, as has been seen, the usual change in bile pigment does not occur, and biliverdin is present, giving to the discharge a green color. In the gray "acholic" stools, either bile pigment is absent or it is obscured by the presence of excessive quantities of fats. In the latter instances, the residue of fæces will be seen to be colored, when the fatty matter has been extracted with alcohol-ether. Biliary acids are to a large extent absorbed from the intestinal tract, either as such or after decomposition. Cholalic and choleidic acids are regularly present in the fæces, but not in large amount. Taurin is likewise present, but it has been found that the quantity in twenty-four hours is only 0.32 gm. When the passage through the intestines is very rapid, so as not to permit either the usual chemical changes or absorption, the bile acids or the products of their decomposition appear in the fæces in greater amount.

Lecithin is not present in more than traces, being either decomposed or absorbed as such; of the products of its decomposition the fatty acids are in part excreted with the fæces. It has been already stated under what conditions cholesterin is present and that ordinarily this substance is reduced, during its passage through the intestines, to stercorin. This discovery of Flint has received abundant confirmation in the last few years, and it is now established that normal fæces of the adult do not contain cholesterin. The amount of stercorin is usually one gram or less in twenty-four hours. This substance differs from cholesterin, not only in crystalline form but in chemical composition, its formula being $C_{27}H_{48}O$ (cholesterin $C_{27}H_{46}O$), and in chemical behavior. The chloroform solution gives with concentrated sulphuric acid a yellow coloration which on long standing changes to deep yellow and finally deep red. It does not form halogen addition products. The crystalline needles melt at 95–96° C. Little need be said of the fats and soaps of the bile, since they meet the same fate as these substances in food. That they appear in the fæces in part is indicated by the passage of fat in starvation, and also with a fat-free diet.

The volatile substances of fæces include volatile fatty acids and aromatic products of decomposition. Of the former three-fourths consist of acetic acid and the remainder of butyric, isobutyric, valerianic, and caproic acids, and perhaps traces of others higher in the fatty acid series. These bodies are formed very largely as a result of putrefying and fermenting of the intestinal contents. Lactic acid should be mentioned in this connection since it is regularly present in the acid stools of infants on a milk diet. The aromatic decomposition products phenol, indol, and skatol are present in the putrid fæces of the adult. Occasionally hydrogen sulphide, ammonia and other volatile bases contribute to the odor. In the milk stools of infants decomposition products are usually absent, though occasionally indol may be found. Indol and skatol are colorless crystalline solids formed in the large intestines from albuminous substance by putrefaction and possessing a disagreeable pungent odor. Indol has the formula $C_8H_6.NH$, while skatol is methyl indol, $C_8H_5CH_3.NH$. Each of these substances may be absorbed and is then eliminated in the urine or sweat, after undergoing slight oxidation and entering into ethereal combination either with acid potassium sulphate or with glycuronic acid, the indol in this condition appearing as indoxyl, the indican of the urine. In the fæces the quantity of these substances is small, but sufficient to give character to the excrement.

The *nitrogenous substances*, usually excreted by the kidneys, at times leave the body in the fæces in considerable amounts. Thus both urea and ammonium salts may be present in uræmia in notable quantities, while it appears that the purin bases, xanthin and hypoxanthin, are in leukæmia excreted through this channel to the extent of 1 gm. a day, which amount is even greater than leaves the body in the urine. Since these substances are present in small quantities in health, they must be considered normal constituents of the fæces. They are not increased in gout. Uric acid has not been found in the fæces of man

Mention should be made of the components of intestinal flatus. They consist of carbon dioxide, hydrogen, nitrogen, and methan. Ad. Schmidt concludes that the amount of nitrogen decreases with an increase in the tendency of the material to undergo fermentation, which condition depends on the amount and degree of digestion of the carbohydrate of the food. The quantity of methan varies in the same way.

There are present in the fæces substances that render this material poisonous. Regarding them and the poisonous products in the various diseases the reader is referred to the article on *Auto-intoxication*, and he is also reminded of the probability that the fæces will at times contain the toxins produced by the bacteria that are active in the intestines during the formation of the fæces.

An account of the chemistry of the fæces is incomplete without mention of the *chemical reaction*. In the adult it is alkaline, the acid contents of the upper intestinal tract being more than neutralized by the abundant secretion of sodium carbonate by the large intestine, and furnishing conditions favorable for ammoniacal fermentation. In typhoid, ammonium carbonate is present in unusual quantity, giving an increased alkalinity. After a diet rich in vegetables the fæces may be slightly acid; when bile is wanting they are strongly so. They are usually acid in infants, and in adults as well are markedly so in acute indigestion, the acidity being due to lactic and butyric acid fermentation.

Finally, mention should be made of certain *ferments* usually present in fæcal matter. A diastatic ferment is constantly present, derived apparently from the lower part of the small intestine, the amount varying inversely with the solids, being greatest in diarrhœa. It is not influenced by the character of the diet. Invertin is said to accompany diastase in the stools of infants. A proteolytic ferment, which is apparently trypsin that has escaped destruction in its rapid passage through the bowel, is reported to be present in diarrhœal discharges.

In the study of the digestibility or utilization of a definite food or dietary, it is important to distinguish the fæcal matter containing the residue from this particular ingested material. The *separation of the stools* thus becomes an important part of the experimental observation. This is accomplished by the ingestion, at the beginning and end of the experimental period, of material which so marks or characterizes the fæcal discharge as to render possible a mechanical separation, both from the fæcal matter preceding and from that immediately following. A considerable number of substances have been employed for this purpose, including in dogs bone, silica, and cork, and in man lampblack, milk, and carmin. Perhaps the most satisfactory procedure is to limit the meal immediately preceding the period of the special dietary, and also the meal immediately following, to milk, with which, at the same time, several gelatin capsules containing lampblack are to be taken. In the separation advantage can then be taken both of the salve-like consistence of milk stools and the dark color imparted by the lampblack. In many instances this separation is very satisfactory, but in diarrhœa, and particularly in constipation with formation of scybala, the boundary line is not always well marked.

After the fæces corresponding to a definite period have been obtained, it is then desirable to distinguish what portion of the material is residue from the ingested diet, and what is waste from the intestinal tract. The distinction between the *metabolism residue*, as these products are called, and the food residue is a matter of extreme difficulty, and although it has received much attention, there is no method known at the present day that serves to accomplish this end, except under definite and restricted conditions. The procedure of estimating the metabolic products in the fæces of starvation and deducting this amount from the total is inapplicable, since the metabolic products are increased with the ingestion of food and are dependent upon its character and amount. In many instances no effort is made to distinguish between metabolic and food residues, the total fæces being deducted from the amount of food ingested and the difference, instead of being termed "digestible" food, being called "available" or "utilized" food, and the factors deducted being termed "coefficient of availability" or "coefficient of utilization." Evidently these factors represent the net gain to the body rather than the digestibility of the food.

The fæces are at times the subject of special examination to ascertain the condition of the intestinal processes. The macroscopic appearance alone may indicate a diminution of the chemical or an increase in motor function, by showing an excess of fat or particles of food residue; but the microscopic appearances are of greater service to this end. When more exact knowledge is desired, the coefficients of availability of the nutrients of a given dietary of known amount and composition may be determined and these results compared with the coefficients in health. Ad. Schmidt and Strasburger have recently recommended different procedures that promise to be of some value in determining the utilization of carbohydrates. At the outset, after the ingestion of 0.3 gm. carmin, the patient is put on a special diet, known as No. 2, consisting daily of milk, 1,560 c.c., four eggs, 100 gm. zwieback, one plate barley soup (40 gm. barley), one plate flour soup (25 gm. flour), 375 c.c. bouillon, all containing 20 gm. sugar, in combination with the more common diet of 60 gm. chopped beef, and 250 gm. mashed potatoes (potatoes 190 gm., milk 60 gm., butter 7 gm.). In diet No. 1 the chopped beef and mashed potatoes are omitted. No. 3 consists of 1,690 c.c. milk, 2 eggs, flour soup, bouillon, and mashed potatoes as in diet No. 2, sugar 10 gm., milk rolls 225 gm., meat (cutlet) 150 gm. The diets are seen to contain carbohydrate in increasing amounts from 1 to 3 and successively in more difficultly utilizable form, as well. For most cases either or both 1 and 3 will be found advantageous in addition to 2. After the disappearance of the carmin, usually after an interval of three or four days, during which the diet is continued, the fæces are submitted to a fermentation test, as follows: The fresh stools are mixed with water (usually two parts) to the consistence of a thick fluid, and the mixture is put in a fermentation tube of about 30 c.c. capacity and left at body temperature. The formation of gas in twenty-four hours to one-third the capacity of the tube is a weak reaction; to two-thirds moderate, and more than this strong. Five conditions determine the development of the reaction, namely, the presence of (1) starch, (2) nutritive material, (3) obligatory bacteria, (4) a diastatic ferment, and (5) the absence of a high grade of acidity. A late appearance of gas is due to putrefaction of the material, and is not to be given the same consideration as the early fermentation. Strasburger concludes that early fermentation with diet 1 is always pathological; with diet 2, is on the boundary, but is more frequently pathological; with diet 3, is normal, yet in the majority of normal stools does not appear. Only positive results are of diagnostic value. Under most conditions carbohydrate is the variable factor, and it is apparent that Schmidt's method is primarily directed to the estimation of the utilization of this class of nutrients. The same investigator has devised a method of measuring the bulk of undigested meat fibre in the fæces after the ingestion of these same dietaries. The method consists essentially in determining the reduction in volume which the residue in the fæces undergoes when submitted to the action of pepsin-hydrochloric acid. The value of the procedure remains to be determined.

Ernest Ellsworth Smith.

FAHRENHEIT AND CENTIGRADE SCALES.—The following table, showing the value in degrees, tenths of a degree, and hundredths of a degree, according to the Fahrenheit scale, of every tenth of a degree of temperature from 44° to 32° Centigrade, while perhaps belonging more properly in the article entitled *Thermometer*, is introduced in this place for the reason that such early introduction is likely to prove a convenience to many readers of the Handbook. In the determination of the limits of this short table only the needs of the clinician have been considered.

FAINTING. See *Brain, Anæmia of*, and *Syncope.*

FALKENSTEIN, GERMANY.—There is nothing remarkable about the climate of Falkenstein which would warrant any extended account of it as a health resort. The name "Falkenstein," however, has become famous in connection with the renowned sanatorium situated there, and this demands notice as being one of the best exponents of the sanatorium treatment of pulmonary tuberculosis in the world.

Nine miles out of Frankfort is the picturesque village of Cronberg in the Taunus Hills, where resided the late Dowager Empress of Germany for a good part of the year. A walk of about forty minutes up the hill from here brings one to the tiny village of Falkenstein, commanding an extended view over the valley of the Main with Frankfort in the distance. Here, in a location protected on the north, west, and east is situated the sanatorium, 1,300 feet above sea-level. The institution consists of a main building with two wings joining it at an obtuse angle and enclosing a large terrace, and two annexes united to the main building by covered promenade galleries. The terrace enclosed by the wings of the main building and looking toward the south, has a continuous broad veranda of glass, provided with sun blinds and curtains, where upon cushioned reclining chairs one sees long rows of patients lying rolled in rugs, taking the rest cure, some reading or writing, others conversing, and a few sleeping. There are also, near by, pavilions, some revolving, affording further opportunity for the same treatment. The climate is that of central Germany, its principal characteristic being a pure atmosphere free from dust, which, from Dettweiler's point of view, is the chief consideration in the climatic treatment of phthisis, provided it can be utilized continuously. Only about half the days in the month are sunny.

The internal arrangements are similar to those in the other large sanatoria: A large, well-ventilated dining-hall accommodating two hundred persons; reading, music, and billiard rooms; post and telegraph office; bacteriological and analytical laboratory; throat and douche rooms; various offices and consulting rooms. Each sleeping-room has a special ventilating flue and the usual simple furnishings; linoleum floors, washable walls; they are never swept but cleaned with damp or wet cloths. The windows are always open. Near by are the dairy and stable, gas-works, and a disinfecting apparatus. As in most of the other sanatoria the system of drainage is on the principle of chemical precipitation with cleansing basin. The large corridors for rest treatment (*Liegehallen*), which were first introduced as a means of treatment at Falkenstein, have a powerful gaslight between the heads of every two chairs, permitting the patients to read as they lie out in the evening. Blue-glass spittoons containing water are distributed in the halls on brackets, smaller ones in the rooms, and white crockery ware ones on the grounds. Each patient is required to carry with him the Dettweiler pocket spit-cup, and expectoration except in these receptacles is absolutely prohibited—handkerchiefs or cloths not being allowed. The compliance with this law seemed to be perfect. The sputum is disposed of by throwing it into the waste water or by burning.

The *jour médical* for an average patient, as told by one of them, is as follows:

7 A.M. Rubbing—dry or wet—or a douche.

8. Breakfast, consisting of coffee, tea, or chocolate, with rolls, butter, honey, and milk.

Until 10, the rest treatment in the reclining chairs.

10. Second breakfast, of bread, butter, milk and soup, with wine or cognac. (Upon this latter Dr. Dettweiler places a high value.)

10:30 to 1 P.M. The rest treatment again.

1. Dinner: soup, fish, vegetables, several kinds of meat, fruit, dessert, and coffee.

2 to 4:30. The rest cure again.

4. Milk.

4:30 to 7:30. Rest or walking.

7:30. Supper, consisting of soup, hot and cold meats, salads, preserves.

After supper the rest treatment until 10, with milk at 9.

10. Retire.

It will be seen from the above that the rest treatment in the open air (*Ruheluft-Kur*) occupies most of the day, and herein is a marked difference between Görbersdorf and Falkenstein. Dettweiler lays great stress upon *rest* in the open air, while Brehmer puts the emphasis upon methodical *hill-climbing.* Dettweiler so insists upon this system of open-air rest treatment that the most of his patients spend from seven to eleven hours daily in the open air in spite of rain, fog, or snow, and of cold, even to 12° below zero. As Ransom observes: "This form of treatment is almost independent of weather." Each patient on admission is carefully studied, not only his physical condition, but his temperament and will power, and his intelligent and willing co-operation with the physician is obtained. His plan of life is then arranged in all its details. He is constantly under the eye of the physicians, and always sees them at the principal meals. To this skilled watchfulness and care, the hygienic-dietetic measures, and the hyperaëration is due the success attained in such an institution. Here, as at the other sanatoria, the treatment of fever is continued rest, physically and mentally, and this applies to all patients who have a temperature of 37.5° to 38° C.

(99.5° to 100.4° F.) or over. At some sanatoria, as at Hohenhonnef, the patient is not even allowed to lie out in the *Liegehallen*, for fear the moving and excitement may keep up or increase his fever, but is kept absolutely quiet in his room. Generally this treatment alone, with some Hungarian wine or cognac, suffices in a short time to reduce the temperature to normal. Knopf explains this disappearance of fever after a short sojourn at a sanatorium by the almost total absence of pathogenic microbes, especially the streptococci, in the pure atmosphere.

I was struck with the appearance of the patients as I saw them at dinner; they hardly differed from the persons one would see in the dining-room of an ordinary hotel, and presented only to a slight degree, if at all, the appearance one usually associates with a consumptive. During the entire meal I hardly heard a cough. Moreover, it was as contented and happy-looking an assemblage as one would see anywhere. The average length of residence is about three months.

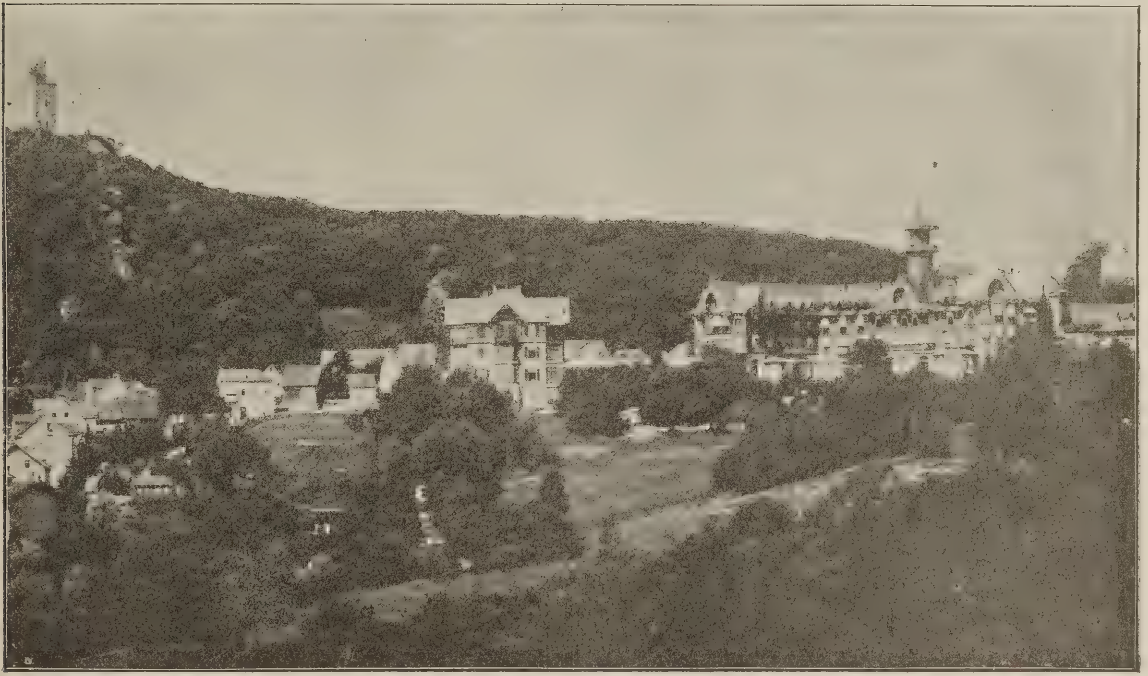

FIG. 2080.—The Sanatorium at Falkenstein, as seen from Adolfsfelsen.

The results at Falkenstein, from 1876 to 1886, of the patients who have been kept under observation since their discharge, is 13.2 per cent. of complete cures, and 11 per cent. of relative cures (disease arrested), a total of 24.2 per cent.; 60 per cent. or more are improved. The expense here, as at most of the other sanatoria, is from $20 to $25 a week.

One cannot leave Falkenstein without carrying away a lasting impression of its founder and guiding genius, Dr. Dettweiler. It was my good fortune to ride up to the sanatorium with him from his modest home in Cronberg. It was a chilly, disagreeable morning in May, much like our March weather, which perhaps suggested his remark that it was not so much a climate as a method; tuberculosis could be cured in any climate. He told me of his early struggle with tuberculosis in his own case, when it seemed that he could not live. But the struggle was successful, and now he is a man of middle age or more, and has accomplished an immense amount of work, and is still the inspiration of his sanatorium. He is a man of great simplicity and sympathy, inspiring enthusiasm, and well illustrates the power of the personal factor in the success of the physician. He makes his patients love him, and in consequence they readily yield to his will and guidance. "In him," as Dr. Thorne says, "reason, science, and long experience are correlated into action by discrimination, adaptability, sympathy, and unbending will. In both of the senses in which the term can be employed, he is a presiding genius."

Edward O. Otis.

FALLOPIAN TUBE. (ANATOMICAL.)—See *Generative Organs, Female.*

FALLOPIAN TUBES, DISEASES OF.—ANATOMY.—In order to comprehend completely the nature of the diseases and neoplasms of the Fallopian tubes or oviducts, a thorough knowledge of their anatomy and embryology is requisite. The oviduct has a common origin with the vagina and uterus from the Müllerian ducts. The upper portion of these ducts remains open externally and that portion forms the pavilion of the tube. The occurrence of secondary pavilions, or ostia, may be explained by supposing that the canal of Müller is not completely closed in all its extent at that period of embryonic life when the two borders of the gutter which give origin to it are turned toward each other to transform the channel into a tube. The Müllerian ducts unite lower in their course to form the uterus and vagina, and the limit of this union is the insertion of the round ligament. The similarity in structure and the continuity of mucous membrane explain how readily disease of vagina and uterus extends to and involves the tubes. These structures are veritably the excretory ducts of the ovaries and are placed, one on each side of the uterus, to permit the passage of the spermatozoid toward the ovary and to transmit the ovule from that organ to the uterus. They are in the upper folds of the broad ligaments, and their average length is from 10 to 12 cm. Their length may be unequal and is subject to considerable variation, as in cases of ovarian tumors, when it may be very much increased. The tube consists of three coats, the incomplete peritoneal, the longitudinal and circular muscular, and the mucous. It is divided into the isthmus, the ampulla, and the fimbriated extremity. The uterine extremity, or isthmus, is its narrowest portion and will barely admit a bristle. The ostium abdominale is surrounded by a number of fimbriæ which are formed by the outward bulging of the mucous membrane. These fimbriæ are lined upon the inner surface by mucous membrane and externally by the peritoneum, so that there is a direct continuity of mucous and serous membranes at this point. No distinct glands, such as are found in the cervix and uterus, have been observed in the tubes. The mucous crypts formed by the folds of the mucous membrane are probably glandular in character and secrete an albuminous fluid. This membrane has a single layer of ciliated columnar epithelium upon two or three layers of supporting cells which are round or pyriform. The cells abruptly terminate at the ends of the fimbriæ, where the margin between the columnar and pavement epithelium is distinctly marked.

Malformations.—Malformations of the Fallopian tubes are rare. One tube may be longer than the other. Sometimes the lumen of the tube is increased. The abnormality which is most likely to attract attention is the presence of one or more accessory abdominal ostia. They are usually situated near the abdominal end of the tube, in the upper part of its wall, and are surrounded by fimbriæ. Ferraresi found six openings upon one tube, all of which were surrounded by fimbriæ. These openings are probably due to failure in closure of the groove in the germinal epithelium, or to splitting of the Müllerian duct after it has closed. There may also be accessory tubes, either as cystic diverticula starting from the tube, or as independent tubes with fimbriæ starting from the mesosalpinx. The tubes may be absent on one or both sides, which absence is due to a destruction of the corresponding part of the Müllerian ducts in the embryo. Very often a small pedunculated cyst, about the size of a hazelnut, is found attached to the fimbriæ or to the outer aspect of the tube. These cysts are called hydatids, or cysts of Morgagni. They are said to occur in eight per cent. of adults, and are not of surgical interest.

Diseases of the Fallopian Tubes.—The diseases of the Fallopian tubes may be either *inflammatory* or *neoplastic*. The inflammatory changes produced in the Fallopian tubes are variously classified according to the extent of involvement. Salpingitis is the ordinary term applied to inflammation of the oviducts. Perisalpingitis is inflammation of the peritoneal covering of the tube, a condition which occurs only as a part of a more extended pelvic peritonitis. Endosalpingitis is the term applied to inflammation of the mucous lining of the tube. Hydrosalpinx indicates an accumulation of serous fluid within the structure. If it is distended with blood, it is termed hæmatosalpinx; or, when a purulent collection is present, the term pyosalpinx is applicable. Hydrops tubæ profluens is the term applied to an accumulation of fluid in a tube in which the uterine end remains permeable, and, as the fluid increases, permits the excess to be drained through the uterine canal. The open tube acts as a safety valve, preventing the overdistention of the oviduct which occasionally completely collapses after evacuation. Tuberculosis will be discussed under infections of the tube, and the neoplasms affecting the tube will be considered later.

Etiology.—A knowledge of the causation of salpingitis is requisite for its prophylaxis and treatment. According to Noeggerath gonorrhœal infection is the most usual cause of inflammation of the tubes. Polk believes that puerperal endometritis is the most *frequent* cause of salpingitis, while the most *destructive* form is that produced by gonorrhœal infection. Salpingitis is hardly ever a primary disease, being as a rule secondary to inflammation of the uterus or peritoneum. The inflammation may follow the mucous membrane by a direct extension, or be propagated from the uterus through the lymphatics of the broad ligament. It may be due to infectious and exanthematous disease. Malposition of the uterus, neoplasms affecting the uterus, or stenosis of the uterine os with retention of secretion in its cavity, may produce tubal inflammation. Exposure to cold, too frequent coition, or violent exercise immediately before menstruation are causative factors. Puerperal infection following labor or abortion under septic conditions may be placed among the chief causes of inflammation of the appendages. Unfortunately, in many cases unwise surgical interference, intra-uterine exploration, the introduction of the sound, and the employment of stem pessaries, are to be classified among the sources of tubal infection. Too often the gynecologist is called upon to perform sacrificial operations upon the adnexa to relieve the patient from the results of gynecological tinkering. The practice of some physicians, now fortunately nearly obsolete, of making intra-uterine application of caustics or astringents with routine introduction of the sound, is responsible for endometritis and a secondary salpingitis. There is a direct relationship between the diseases of the endometrium and tubal affection. Salpingitis cannot be considered an uncomplicated entity; it is invariably associated with more or less metritis or ovaritis, and there is the constant danger of the process involving the pelvic peritoneum. The various micro-organisms that have been identified in tubal affections are the gonococcus, the staphylococcus, streptococcus, and Bacillus tuberculosis. In a few cases the presence of the Bacterium coli commune has been demonstrated. Frommel and Witte have found the pneumococus in puerperal salpingitis. One of the saddest things to contemplate is the possibility of the innocent, newly married woman being infected with the gonococci, and yet this is observed over and over again and emphasizes the necessity for complete cure of men contemplating marriage. The ravages of gonorrhœal infection and the dire results produced upon the appendages demand plain speech and earnest teaching upon this point. Another cause of these diseases is the neglect of proper attention being paid to the pubescent girl. Engelmann in a tabulation of 5,000 cases among school girls found that 66 per cent. were afflicted with more or less menstrual suffering; and no doubt a large proportion of these cases presented more or less symptoms of tubal congestion.

Pathology.—Many classifications have been presented of the various forms of tubal disease; but here simplicity is the secret of lucidity. Like inflammations of other structures, salpingitis may be either acute or chronic and it may affect one or both tubes. As it becomes chronic, or the infection increases in severity, the various changes noted occur, such as the formation of hydro-, hæmato-, or pyosalpinx.

Acute Salpingitis.—In the first stages of acute salpingitis the disease is confined to the mucous membrane of the tube, whence it quickly extends to the muscular and peritoneal coats. The whole tube is soft, congested, and friable. In early salpingitis a prominent feature is small-celled infiltration of the plicæ which causes them to become thick and club-shaped. Blood-vessels, at first dilated, soon appear narrower than in health. The folds become œdematous and hyperæmic. The epithelial cells are swollen, show slight increase in the size of their nuclei, and vacuoles form in their protoplasm. The secretion is increased and contains mucus, albuminoids, and epithelial débris. This secretion exudes from the abdominal ostium when the tube is squeezed. When the infected material escapes into the peritoneal cavity, the danger of pelvic peritonitis is great. The direct channel established by the tubes between the uterine and peritoneal cavities facilitates peritoneal infection. But the frequency of this is diminished by nature's provision in producing occlusion of the abdominal ostia of the tubes, which closes these orifices. Many cases of acute salpingitis undergo resolution and the tubes are restored to their normal condition. This is particularly true of the milder forms of catarrhal salpingitis.

In *chronic salpingitis* there is an extension of the inflammation and the formation of adhesions with more definite changes in the tubal structure. Many cases are either subacute or chronic from the beginning; that is, they never present violent or acute symptoms. The lesions produced are numerous. The tube may become enlarged and more tortuous than normal, its muscular coat more extensively involved, producing interstitial salpingitis. As it progresses, the cilia of the lining cells disappear, the wall of the tube becomes thicker and harder, with an increased amount of connective tissue. The conservative closure of the abdominal ostium is of much importance, because it prevents leakage of the septic material through this channel and consequently diminishes the danger of peritonitis. When the inflammation extends from the tubal mucous membrane to the peritoneal covering, the fimbriæ retract and become invaginated in the tube; and this opening, instead of being surrounded with protruding, divergent fimbriæ, becomes rounded and smaller. The process continues until the edges finally meet and unite by peritoneal adhesions, causing complete closure of the opening. As the tube increases in size and weight its position is frequently changed and it becomes adherent to the uterus, ovaries, or the pelvic peritoneum. Usually there is obstruction of the uterine extremity of the tube, which is produced by swelling of the mucous membrane in the narrow isthmus, by cicatricial contraction, or by a sharp flexure along the course of the tortuous tube. The greatest distention is at the outer extremity of the tube so that it assumes a pear shape. If the tube be brought into connection with the ovary, either by agglutination of the fimbrial extremity to the surface of that organ or by burrowing between the layers of the broad ligament, the tissue intervening between the cavity of the tube and the cyst of the ovary may be absorbed or perforated, and the two cavities thrown into one, forming a tubo-ovarian cyst; or, if infection has occurred, a tubo-ovarian abscess.

Hydrosalpinx.—The fluid of a hydrosalpinx may be colorless, slightly yellow, or brownish when colored by the presence of blood. As the accumulation increases, the walls of the cyst atrophy and become very thin; the epithelium and the mucous membrane in time disappear until nothing but a thin-walled sac remains. The size of the tube varies from that of the finger to that of a fœtal head. In a case reported by the writer, the hydrosalpinx was the size of a cocoanut and was mistaken for an ovarian cyst. As a rule the fluid from a hydrosalpinx is sterile, unirritating to the peritoneum, and readily absorbed.

Hæmatosalpinx.—True hæmatosalpinx rarely occurs. Extra-uterine pregnancy is the most common cause of an accumulation of blood in the Fallopian tube and should not be termed hæmatosalpinx. [The subject of ectopic gestation is treated elsewhere.] Hæmatosalpinx may occur, however, when hemorrhage takes place into a tube previously closed by inflammatory action. Such an accident may result from traumatism or by the torsion of the pedicle of a tubal cyst, or when there is an obstruction to egress of menstrual fluid. The writer has never seen a case of tubal hemorrhage in which ectopic gestation could be excluded. Although the positive evidence of impregnation may not be present, yet undoubtedly the vast majority of these cases are of such origin.

Pyosalpinx, or a collection of pus in the closed Fallopian tube,[1] produces a gradual thinning of its wall. This thinning predisposes to rupture and the escape of the pus into the peritoneal cavity. The pyosalpinx often becomes adherent to the posterior wall of the uterus, to the rectum, or to the small intestine. The contents of the sac are usually at first clear, non-odorous pus; but proximity to the bowel frequently causes this to assume a more offensive character. The possibility of a pyosalpinx being evacuated through the uterus has been asserted by some authorities. This, however, is a very unusual occurrence, and it is probable that in such cases the escaped fluid has been retained uterine secretion. The pus of a pyosalpinx varies greatly in character. In the early stages of the disease it is actively septic; but later the micro-organisms become inert, die, and disappear. According to Penrose, out of 133 cases of acute and chronic suppuration of the uterine appendages in which the pus was examined bacteriologically, no organisms whatever were found in 82 cases; in other words, the pus was sterile in about 61 per cent. of the cases. Out of 116 cases Wertheim found that in 72 there were no bacteria at all; in 32 there were gonococci; in 6 there were streptococci, and in 1 staphylococci. It is only when the pus is in contact with an absorbing surface, or escapes into the peritoneal cavity, that general inflammation or septic symptoms develop. It is surprising what a quantity of pus may exist in cases in which there has been no deviation of the pulse or temperature from the normal. In this connection it is well to call attention to the frequent coexistence of appendiceal and adnexal disease. Adhesions will be found between the appendix and the tube and ovary in about fifteen per cent. of all cases of tubal disease. The proximity of the appendix to the right appendage and the frequent coexistence of inflammation in both are often perplexing to the diagnostician.

Symptoms.—In acute salpingitis the patient usually complains of pelvic pain and tenderness which is most marked in the ovarian regions. The temperature is elevated, the pulse rapid, and the knees are often drawn up as in peritonitis. There are no pathognomonic symptoms. A chill may occur. Bimanual examination reveals marked tenderness upon pressure in the vaginal fornices, and there is a sense of fulness in the region of the tubes. If the pelvic peritoneum and cellular tissues are involved, the whole vaginal vault will feel resistant. If the patient is thin and the abdominal walls are sufficiently relaxed, the enlarged, tender tube may be palpated by the conjoined method. When the disease becomes chronic, with more extensive pathological changes, the symptoms vary and may in part be attributed to associated ovarian disease. Pain is generally continuous, but may be relieved by the recumbent posture. It is increased by exercise, coition, and during defecation. It may be felt in one or both ovarian regions or in the sacral region. It often has a colicky character due to the contractions of the inflamed muscular coat. It may be dull and aching, or at times sharp and lancinating, and is very much worse at each menstrual period. The dysmenorrhœa in salpingitis is usually characteristic, beginning several days before the flow and lasting throughout the whole of the period. While the disease is quiescent there may be no acceleration of the pulse or increase of the temperature. The patient frequently has marked exacerbation of the pain and sometimes acute attacks, with symptoms of local peritonitis. Her life is in constant jeopardy, as there is the ever-present possibility of intraperitoneal rupture, with escape of septic material and consequent peritonitis. Leucorrhœa is common, more or less constant, and may vary from a slight, thin watery to a profuse, purulent, or sanguinolent discharge. Menorrhagia or metrorrhagia is frequently present. The general health suffers, the patient loses flesh and strength, and marked nervous and reflex symptoms develop. Sterility is the rule in these cases, as the disease of the mucous membrane and destruction of the ciliated epithelium render the passage of the ovum into the uterus difficult. A careful study of the history of the patient will aid in diagnosis; but our chief reliance must be upon our bimanual examination. If the diagnosis is obscure and the patient's abdominal walls are rigid, it is wise to employ an anæsthetic. For this purpose the bromide of ethyl is convenient. The small amount of anæsthetic required, the rapidity of its influence, and the quick return to consciousness make this anæsthetic of distinct value where a brief period of anæsthesia is desired. By bimanual examination the tube may be felt lying beside the uterus or behind it in Douglas' pouch. The shape of the tube and its connection with the uterus may be traced, and it will appear tender, thickened, and often distorted. Fluctuation may not be elicited even when there is a large amount of fluid, if the sac is much thickened. If the inflammation has been extensive and the disease is bilateral, the tubes, ovaries, and uterus may form one conglomerate mass filling the true pelvis. Usually the uterus is pushed forward in the pelvis and the appendages occupy the recto-uterine space. Frequently the appendage primarily diseased becomes prolapsed first, and the other appendage rests upon it and may be felt by the abdominal examining hand. Recto-abdominal examination should also be practised. Disease of the tubes may be mistaken for cellulitis, oöphoritis, or pelvic hæmatocele. An adherent, retrodisplaced uterus must also be differentiated. In women with very thick abdominal walls physical examination is unsatisfactory, but the history of the case and the symptomatology usually justify the diagnosis.

TREATMENT.—The treatment of tubal disease is *prophylactic, palliative,* and *surgical.* In order to prevent disease of the tubes attention must be paid to the woman's health from puberty to the menopause. At puberty the young girl should be carefully advised by her parents or physician in regard to the menstrual function. The false modesty which keeps her in ignorance of her sexual physiology is responsible for untold suffering. During menstruation she should avoid exposure or violent exercise and should evacuate the bladder whenever the desire is present. Proper clothing should be worn at all times; and corsets, if worn at all, should support rather than compress the viscera; but they should be positively interdicted until complete development has occurred, since it is reprehensible to compress the waist of a growing girl by anything tight or constricting. In married women tubal trouble may be prevented by the rules of health already mentioned, by careful attention after abortion or labor, by repair of all lacerations of the cervix or perineum which do not heal immediately after labor. If gonorrhœa develops, energetic treatment will often prevent the disease extending from the vagina and uterus to the appendages. Whenever there is metritis or endometritis, palliative measures should be used. Careful antisepsis in the treatment of abortion or during the puerperium will diminish the frequency of salpingitis. As gonorrhœa and sepsis are two great causes of inflammation in these organs, our attention should be devoted to their prevention. In all necessary intra-uterine exploration there should be the same rigid asepsis as though the peritoneal cavity were to be invaded; for the tube is a direct channel of communication between the uterus and that important serous membrane, the peritoneum.

Palliative Treatment.—When a patient is suffering from *acute salpingitis* in its early stages, the treatment should be expectant: 1. Absolute rest in the recumbent position. 2. The administration of saline purgatives: from one to two drachms of Rochelle salts every two hours until the bowels have moved freely; or four to six ounces of liquor magnesiæ citratis may be given in the same manner. It is far better to keep the bowels open by such drugs as these than to keep the patient under the influence of opiates. Hot vaginal douches of some antiseptic solution such as corrosive sublimate, creolin, or lysol, of a temperature of from 100° to 110° F., and not less than one gallon in quantity, should be employed two or three times a day. Much relief will be afforded by the use of ice-bags over the lower abdomen. In fact the cold applications are preferable to hot fomentations, as the cold relieves the pain and has a tendency to prevent the extension of inflammation. If there is elevation of temperature, with a rapid, high-tensioned pulse, tincture of aconite in small doses is indicated. If there is a tendency to abdominal distention, high enemata of sulphate of magnesia, glycerin and water, or of the milk of asafœtida, will favor peristalsis and the expulsion of gas. All examinations should be made with great care and gentleness and no oftener than is essential to determine the progress of the disease. The patient should be carefully watched, and if the temperature and pulse rate decrease and the tenderness is subsiding, the palliative treatment should be continued; but if the symptoms are increasing in severity and the possibility of peritonitis or abscess formation is at hand, operation is demanded for the purpose of removing the source of infection. In some cases of acute salpingitis with virulent infection fatal peritonitis will result in three or four days after the onset of the attack. On the other hand, in a great number of these cases the closure of the abdominal ostium of the tube prevents extension to the peritoneum; but the tube itself is badly damaged by the disease and remains in a condition of chronic catarrhal or purulent salpingitis.

The treatment of *chronic salpingitis* varies somewhat from that of the acute. It must be borne in mind that tubal disease is almost invariably associated with metritis and oöphoritis, and that these must be considered if effective treatment is to be given. The patient's condition and the degree of suffering experienced are to be our guides in deciding whether we shall employ palliative treatment or surgical interference. Curative measures should be directed to any accompanying endometritis. If this is chronic, aseptic curetting is the proper remedy; but it must be used with great caution, as intra-uterine manipulations are apt to produce an acute attack of the tubal trouble. For chronic salpingitis hot, germicidal solutions should be daily employed; and vaginal tampons of sterilized lamb's wool saturated with fifty-per-cent solution of boroglyceride in glycerin, or a fifteen-per-cent. solution of ichthyol in glycerin, should be inserted two or three times a week. The tampon improves the pelvic condition by raising the uterus to a higher level and maintaining it there. The tampon may be left in position twenty-four hours; and, after its removal, a copious vaginal douche of the antiseptic solution should be used twice daily, with the patient in a recumbent position. The same attention should be paid to the bowels, diet, etc., as in acute salpingitis. Rest at the menstrual period, the avoidance of exposure to cold, and abstinence from coition will aid in relieving the symptoms. Internally, preparations of viburnum, hydrastis, or ergot may be given. In some cases of chronic salpingitis beneficial results have been derived from the use of pelvic massage as advocated by Thure Brandt. It produces a rapid alteration in the inflammatory accumulations, setting free the uterus and its adjacent organs. It may be employed in subacute or chronic inflammation unassociated with pus formation. American physicians, however, have not secured the same brilliant results by massage as have been reported by European gynecologists. The writer has found that patients were unwilling to undergo the discomfort of the prolonged séances of pelvic massage necessary to secure definite results.

Surgical Treatment.—When palliative methods have failed and the woman experiences suffering constantly, or at the menstrual periods, and is unwilling longer to lead the life of an invalid; then it is necessary to consider surgical interference. When there are gross tubal lesions such as hydro-, hæmato-, or pyosalpinx, or retrodisplacements of the uterus with adherent tubes and ovaries, nothing but operation will afford permanent relief. One of two routes may be selected according to the individual preference of the surgeon. These are the vaginal and the abdominal; but no fast rule can be laid down as to which route should be preferred, as the choice depends upon the condition of the patient, the environment in which the operation must be performed, and the skill of the surgeon. Often both routes will be employed in the same operation, as in the evacuation and irrigation of a tubal abscess per vaginam prior to its removal by abdominal section. If the patient is very weak, the pulse rapid, and the abscess bulging into the vagina, a vaginal cœliotomy may be rapidly performed, the pus evacuated, and drainage introduced without anæsthesia or with a very brief period of it. In a great many cases of vaginal section the patient will so far recover her health as to obviate the necessity for abdominal cœliotomy. The technique of the vaginal operation is as follows: After complete evacuation of the bowels and the necessary anæsthesia, the vagina should be thoroughly scrubbed with a solution of creolin or lysol, ʒ i.; tincture of green soap, ℥ i.; hot water, O.i.; after which it should be irrigated with sterilized water and alcohol. A curvilinear incision is then made through the posterior vaginal wall and the finger, or a pair of scissors, is carefully pushed into the tubal mass. The pus or blood is evacuated, the cavity being constantly irrigated with hot normal salt solution. Care should be taken that all accumulations be evacuated and that no injury be done to the viscera. After the cavity has been perfectly cleansed, it should be packed with iodoform gauze, which by its pressure controls any slight oozing that may occur and serves as a vaginal drain. If the vagina is capacious and the adhesions are not too firm, salpingo-oöphorectomy, if indicated, may be done through this incision. The gauze packing is allowed to remain for three or four days, and after its removal vaginal douches of normal salt solution, or of a 1 to 2,000 formalin solution, should be given. The advantages of the vaginal route are the absence of abdominal incision, less shock, less danger of hernia, and more rapid convalescence. There is, however, always the possibility of a secondary operation being required.

The operations which may be done by the abdominal route are: salpingotomy, salpingostomy, and salpingectomy. In all of these the same general preparation is to be observed as in other abdominal operations. *Salpingotomy,* or resection of the Fallopian tube, is the result of conservative evolution; and it has been proved that, after the resection of a diseased portion of the tube, regeneration may take place and the tube continue to functionate. Dudley, of New York, has reported some splendid operative results and has resected the tubes even when gonorrhœal pyosalpinx was present. The success in these conservative operations depends upon the careful selection of cases and the skill of the individual surgeon.

Salpingostomy is the establishment of a new opening in the Fallopian tube when the normal one has been closed by some inflammatory process, and is particularly indicated when it is desirable to retain the child-bearing function. The new opening in the tube may be sutured directly over the ovary so that when the Graafian follicle ruptures the ovule may pass directly into the tube. In all conservative surgery upon the tubes care must be taken thoroughly to cleanse that canal and to protect the peritoneal cavity from its contents.

Salpingectomy.—In nearly all cases requiring removal of the tubes, the ovary demands extirpation also. Salpingectomy is required when the symptoms are marked and the tube is irreparably diseased. There must be danger to life or serious impairment of health before this operation is resorted to. The exact nature and the extent of the operation depend upon the disease for which it is performed, the age and social condition of the patient, and the ability of the operator. In performing salpingectomy the abdomen is aseptically prepared, and an incision, from two to three inches in length, is made in the median line, midway between the umbilicus and the pubes. An examination is made to ascertain the position, extent, and strength of adhesions. When the pelvic viscera are found in one conglomerate mass, it is well first to find the fundus of the uterus and then proceed to the tubal enucleation. The intestines and general peritoneal cavity should be walled off by gauze pads. The use of the Trendelenburg position is of great advantage, as it permits the operator to see as well as feel the visceral adhesions. In old cases in which the adhesions are firm and organized, great care must be taken to prevent visceral injury. If the tubal sac in a pyosalpinx ruptures during removal, gauze pads should be at hand to catch the escaping fluid and the cavity should be irrigated with a large quantity of normal salt solution. After the appendages have been freed, chromicized catgut ligatures should be applied to the pedicle in small sections rather than *en masse.* A supporting button should be left beyond the ligature to prevent its slipping and the possibility of secondary hemorrhage. If the interstitial portion of the tube is involved, it is often wise to remove the fundus of the uterus also. Frequently there will be denuded peritoneal surfaces which require suturing to control oozing. A careful examination should be made to find whether the rectum, sigmoid flexure, or small intestine has been injured. Drainage is not so often employed as formerly, as it has been shown by Clark that by thorough irrigation and postural drainage the use of tubes or gauze is unnecessary. If there is an extensive raw oozing surface or fear of infection, then the pelvic cavity may be packed with iodoform gauze, one end of which is carried through a posterior vaginal incision into that canal. The great advantages in such vaginal drainage are that drainage takes place from the most dependent portion of the pelvis and there is no danger of a ventral hernia or abdominal fistula along the drainage tract. After the appendages have been removed and a most vigilant examination has been made to see that all bleeding is controlled and all injuries are repaired, the abdominal incision should be closed and the patient treated according to the usual methods employed in abdominal surgery. These, however, cannot be discussed here for lack of space.

Tuberculosis is more apt to affect the tubes than any other part of the genital apparatus. They are involved in nearly all cases of genital tuberculosis, which is much more common than was formerly supposed. According to Penrose and Beyea, it is present in eighteen per cent. of cases subjected to the operation of salpingo-oöphorectomy; while Williams found that in one out of every twelve operations for the removal of the tubes and ovaries that were the seat of inflammatory disease, this infection was present. It may be either primary or secondary, but is usually the latter. The infection may take place through the blood from the peritoneum or the uterus. Coition with men affected with genito-urinary tuberculosis may be an occasional cause. This disease may involve the tube long before puberty. Chaffey has described a case in which a child aged four died with tuberculosis in the lungs and abdominal organs, and the tubal walls presented caseous nodular masses. Silcock has detected a similar condition in a child aged five.

Tuberculosis of the tube may be divided into three classes: *miliary, chronic diffuse,* and *chronic fibroid* (Penrose). Miliary tuberculosis of the tube may be a part of a general condition, or it may belong primarily to the tube, when micro-examination shows giant epithelioid cell tubercles scattered through the mucous membrane. This is the first stage and the process may progress no further or may be converted into one of the other varieties. In the chronic diffuse tuberculosis the mucous membrane is infiltrated with epithelioid cells, miliary tubercles, and areas of caseation. The tube may be filled with cheesy material or with pus, and in time the mucous membrane becomes entirely destroyed. In the chronic fibroid variety, there is a great increase of connective tissue between the tubercles, the lumen of the tube is distorted, and a few miliary tubercles are found scattered through the mucous membrane. This form advances very slowly and not infrequently terminates in a spontaneous cure. The symptoms of tubal tuberculosis resemble those of salpingitis and are not at all characteristic. The diagnosis is often obscure, but occasionally it may be made by careful bimanual examination, by an inquiry into the question of hereditary predisposition, and by finding other signs of it, especially in the lungs. Most cases of tubal tuberculosis have been discovered unexpectedly at the time of operation or autopsy. The treatment is prophylactic, hygienic or medical, and surgical. If the condition of the patient permits, salpingo-oöphorectomy should be performed; and if there is any evidence of disease of the uterus it should be removed at the same time. The presence of tuberculous peritonitis indicates rather than contraindicates operation. The curative action of cœliotomy in these cases is probably due to a combination of the peritoneal traumatism during the operation, thermic influence, penetration of air into the abdominal cavity, and the action of light. Therefore such operation offers to the patient the best chance of cure.

Neoplasms of the oviducts are exceedingly rare except as the result of inflammatory changes. *Cysts* varying in size from a pea to a walnut are found in all the walls of the tube but most frequently beneath the peritoneum. Sänger divides these cysts into three classes: 1. Serous cysts, which arise from the accumulation of serous fluid between the lamellæ of the mucous membrane. 2. Lymphangiectatic cysts. 3. The hydatid of Morgagni, which is a physiological cyst at the end of the tubal fimbriæ. *Myoma.*—Notwithstanding the fact that fibroid tumors of the uterus are of such common occurrence, myoma of the tube is very rare. Bland Sutton reports a case in which an interstitial myoma, the size of a Tangerine orange, was found in the walls of the tube at the juncture of the uterine and middle thirds. Most of the reported myomata of the tube are pedunculated and of the subperitoneal class. In Sir J. Y. Simpson's case the tumor was "of a size equal to that of a child's head"; but usually the growths are so small as to create no disturbance. Many observers have mistaken a collection of tuberculous matter and inflammatory changes in chronic salpingitis for minute fibroids. *Cancer.*—Carcinoma of the tube may be either primary or secondary, though the latter is more frequent and results from involvement of the tube in cancer of the uterus or ovaries. The disease is generally confined to one tube. Until recently it was asserted in text books that the secondary was the only variety, but at least seventeen authentic cases of primary carcinoma of the tube have been described. The cancer in nearly every case assumed a villous or papillomatous appearance. *Sarcoma* has also been noted. Montgomery refers to a case reported by Kahlden in which the tube formed a sausage-shaped mass filled with soft, cauliflower-like material. Under the microscope it showed various degenerations such as round-cell and spindle-cell sarcoma and a papillomatous structure wanting in connective tissue. *Lipomata*, or fatty tumors, from the size of a bean to that of a walnut, have been found in connection with the tubes. Parona reports a case in which the lipoma weighed a little under three ounces and measured three and a half inches in the longest diameter; traces of the wall of the tube with characteristic ciliated epithelium were seen through the adipose tissue of the lipoma. *Deciduoma malignum.*—Two cases of this remarkable disease have been described, both in Sänger's opinion quite authentic; and if we can have the malignant degeneration of a portion of the placenta or chorion within the uterus, it is not surprising that a similar malignant change may occur in the tubal sac of ectopic pregnancy. Sänger claims that this is an additional argument, not only for active interference in cases of extra-uterine pregnancy, but also for the extirpation of the appendages in which tubal abortion has occurred. *Papillomata.*—According to Doran papilloma is the term applied to an exuberant morbid growth which lies in the interior of the Fallopian tube. Sutton, however, classifies such tumors as adenomata. Doran considers that these tubal papillomata are allied to the condylomata and warts seen on the external genitals irritated by venereal discharges. These ordinarily are innocent but may undergo malignant degeneration. Sänger divides them into two forms: simple cystic and hydropic. *Dermoids.*—According to Doran there is no sound evidence that a dermoid tumor of the tube has ever been seen. *Enchondromata* are small, semitransparent, cartilaginous masses, occasionally situated on the ends of the fimbriæ (Montgomery).

The *general treatment* for all these tubal neoplasms is salpingectomy. They are rarely differentiated, as subjective symptoms throw no light upon the diagnosis and examination reveals merely a tubal mass without any determination of its character. *Wilmer Krusen.*

FARCY. See *Glanders.*

FARMVILLE LITHIA SPRINGS.—Prince Edward County, Virginia.

Post-Office.—Farmville. Boarding-houses.

Access.—Viâ Norfolk and Western Railroad to Farmville, thence one-half mile to springs. Farmville is a thriving town of 4,000 inhabitants, located 55 miles east of Lynchburg and 72 miles south of Richmond. The railroad depot is within convenient walking distance of the springs, but carriages are at hand for all those who prefer to ride. There are many features of interest in this historic region. The springs are beautifully situated about 550 feet above the sea-level. The surrounding country is very pleasing to the eye, and on every hand the visitor is met by names and locations of familiar memory. Not far from the springs are found the battlefields of Chancellorsville, Appomattox, Rapidan, Five Forks, and others of lesser note. The climate here is bracing, the temperature ranging from 40° to 50° F. in winter and from 80° to 90° F. in summer. The springs are eight or ten in number, and yield about fifty gallons of water per hour. The following analysis is by Prof. E. T. Fristoe, of the Columbian University, Washington:

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	5.30
Sodium sulphate	3.59
Potassium sulphate	.18
Calcium sulphate	1.81
Lithium bicarbonate	3.76
Calcium bicarbonate	1.33
Magnesium carbonate	2.71
Ferrous carbonate	1.26
Manganous carbonate	Trace.
Alumina	2.52
Silica	3.92
Iodine	Trace.
Sulphuric acid	Trace.
Organic matter	Small quantity.
Total	26.38

Carbonic acid gas, 74.20 cubic inches.

It will be observed that this water contains a fair proportion of the bicarbonate of lithium. It is also abundantly charged with carbonic acid gas, and contains sufficient sulphate of sodium to give it a mild laxative action. The water has come into wide use as a corrective of the uric-acid diathesis, and is sold in all parts of the country. Its best effects have been observed in gout, renal and vesical calculus, Bright's disease, and dyspepsia. The iron in the water gives it also excellent properties as a ferruginous tonic. *James K. Crook.*

FAT NECROSIS. See *Pancreas, Diseases of.*

FATTY DEGENERATION; FATTY INFILTRATION. See *Lipogenesis.*

FAUQUIER WHITE SULPHUR SPRINGS.—Fauquier County, Virginia.

Post-Office.—Fauquier White Sulphur Springs. Hotel.

Access.—From Washington viâ Virginia Midland Railroad to Warrenton, 56 miles southward, thence a drive of six miles to the springs. The visitor to this favored locality is pleasantly impressed during the forty minutes' ride from the picturesque town of Warrenton to the springs. The drive is over a fairly graded road through a country where the well-stocked farms and handsome residences are indicative of an advanced degree of thrift and refinement. The springs are charmingly situated among the foothills of the Blue Ridge at an elevation of 1,000 feet above the sea-level. The surrounding grounds comprise an area of 400 acres in a high state of cultivation and abounding in shaded walks and drives through hills and valleys. Being sheltered on the west by wooded hills, the location admits of invalids enjoying the open air with safety almost daily throughout the year. The clear waters of the Rappahannock River border the western boundary of the park and sweep along the base of the mountains, where the huntsman or the disciple of Izaak Walton will find an ample reward for his tramp among the hills or his patience by the waterside. The waters of these springs have been well known for upward of seventy-five years. As early as 1834 a company was formed of well-known men from Maryland and Virginia, and two large hotels and a number of cottages capable of accommodating 1,000 persons were built. So attractive were the resort and its surroundings that the Legislature of Virginia held a summer session there in 1849. At the beginning of the war the place was in the full blast of prosperity. In August, 1862, it was the scene of a fierce fight between the Federal and Confederate forces, and the two hotels were burned. In 1877 a company was formed for the purpose of restoring the famous old resort to public uses. The present accommodations consist of an elaborate and commodious fire-proof hotel fitted with all modern improvements. There are besides a number of cottages, capable of accommodating 500 guests; they are located in a fine grove of elms convenient to the main hotel.

The following analysis of the spring water was made in 1878 by Prof. Thomas Antisell, of Washington, D. C.:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Calcium bicarbonate	7.88
Magnesium bicarbonate	2.47
Sodium chloride	3.75
Calcium sulphate	3.39
Iron phosphate Iron sulphate	2.14
Sodium and potassium sulphate	1.63
Calcium and magnesium phosphate	.64
Gaseous matter, etc	.10
Total	22.00
Gases.	**Cu. in.**
Carbonic acid	11.00
Sulphureted hydrogen	Small quantity.

Temperature of water at springs, 55° F.

The source of the mineral ingredients of the springs lies in the country rock, which is an aluminum slate, the beds of which lie nearly horizontal, or with a slight slope, and hold between their layers sandy, ferruginous seams, in which are embedded crystals of iron pyrites with some hydrated oxide of manganese. The water is properly classed as a sulphureted alkaline-chalybeate, possessing alterative, tonic, and diuretic properties. It has long been recommended in the various forms of dyspepsia, in intestinal disorders and in liver complaints. Its diuretic properties are utilized in dropsical affections due to renal and cardiac diseases, as well as in the early stages of Bright's disease. In the condition known as neurasthenia, produced by overwork, anxiety, or other causes, a course of this water has been found to be markedly advantageous. In certain female complaints, notably in menstrual disorders due to anæmia, its action is prompt and permanent. *James K. Crook.*

FAVUS. See *Tinea.*

FEBRICULA (diminutive of *Febris*, fever).—(Synonyms: Simple fever, Simple continued fever.)

Febricula is a convenient term which finds its justification in ignorance rather than in knowledge.

A pyretic state lasting from one (*ephemera*) to ten days, in which the temperature probably does not rise above 102° F. except temporarily, nor the pulse usually above 100 to 120, accompanied by a white, furred tongue, constipation, loss of appetite, by headache which may be sharp; but without other derangement of the bowels than constipation, without any exanthem, without any distinguishable internal or external local lesion, inflammatory or otherwise; ending in sudden resolution and rapid, easy recovery—this is febricula, and we agree to call this general condition, whatever may be the cause, by that name for want of a better, and because it requires some designation.

Febricula has no pathology, because it always ends in recovery. Febricula ending in death takes on another name. Abortive typhoid, typhus, or relapsing fever; scarlet fever or measles without their rash; tonsillitis with an inappreciable tonsillar affection; acute rheumatism or erysipelas without localization, may all conceal themselves under the term febricula.

On the other hand, the same symptoms—as shown in a mild or short continued fever—may result from exposure to extremes of temperature, from exhaustion, from digestive disturbances, from derangement of the nervous centres.

The *febris ardens* of the tropics, various degrees of which are encountered in the United States during the occasonal hot "waves" of our summer months, belongs more appropriately under insolation, or heat- or sun-fever.

The DIAGNOSIS of febricula can be reached only by exclusion, and should only be made subject to ready revision.

The TREATMENT is simple and consists of a saline laxative, diuretics, diaphoretics, or refrigerants, as indicated in the particular case. *George B. Shattuck.*

FEEDING, FORCIBLE.—Forcible feeding means the introduction of food into the organism against (or without) the will of the individual. It is employed in two groups of cases: (1) In patients exhibiting a comatose or semi-comatose condition for a considerable period of time; and (2) in patients afflicted with brain troubles (insanity, melancholia), when they refuse nourishment.

The insane form the largest contingent of cases in which forcible feeding must be resorted to. Here it is the most important measure not only to prolong life but also often for the establishment of a cure, whenever this is possible.

In some instances small quantities of liquid or semi-liquid food are introduced into the mouth of the patient and the latter is told to swallow. In case this procedure is effective, enough nourishment may be slowly ingested in this way. But if this means fails, as it often does, or in patients who are not accessible to our exhortations, the principal measure of forcible feeding consists in the artificial ingestion of nourishment. The latter is performed in three ways: (1) Gastric alimentation by means of a tube inserted into this organ; (2) rectal alimentation; (3) subcutaneous alimentation.

By far the most frequently employed and the most efficient method of forcible feeding consists in the first measure. It seems that the stomach pump was used for this purpose long before its application in gastric affections as a therapeutic measure (Kussmaul, 1867); for in 1857 William Hamilton[1] mentions the stomach pump as a well-known procedure in the feeding of the insane. The same writer had also introduced a new means of gastric alimentation by inserting a tube through the nostril into the œsophagus and providing it with a funnel. This method is still used nowadays, and I may, therefore, be allowed to cite Hamilton in full. He says:

"Acting upon a method advised, in cases of trismus, of introducing into the nostrils a tube to the posterior fauces, through which nourishment may be passed to a point beyond voluntary muscular control, an instrument was constructed which was efficaciously employed on the 24th of June last. It consists of an elastic tube, twenty-four inches long, the size of a catheter, at the open end of which a funnel is attached. Near its end the tube is slightly curved. The curve is maintained by the introduction of a silver wire, two inches in length, one end being bent upon itself to preserve it in position, to prevent its impinging at right angles upon the posterior wall of the pharynx during the first stage of the process, and, during the second, keeps the tube from interfering with the glottis. The tube being adjusted, the operator pours through it nutritious or medicated liquids, which are immediately, by automatic action, conveyed into the stomach. This operation is not disturbed, owing to the length and flexibility of the tube, by any considerable motion of the patient's head."

Forcible gastric alimentation is performed in the following manner: A soft-rubber tube (regular stomach tube), provided with a connecting glass-piece at the outside end, is introduced, either by way of the mouth (when this is possible, or after keeping the mouth open by a gag) or by way of the nostril, into the stomach. A rubber tube with funnel attachment is next slipped over the glass-piece, and the apparatus is then ready for the reception of food. The latter, in liquid or semi-liquid form, is poured from a pitcher into the funnel, which at first must be somewhat lowered, in order to prevent the entrance of too much air into the stomach, and then afterward raised to about the level of the patient's face, until the whole quantity desired has been ingested. Then the entire apparatus is quickly removed after compressing the tube with the fingers in such a manner that no contents may escape from it while in the pharynx. It will be readily understood that assistance is oftentimes required during this procedure, especially when we are dealing with maniacal patients. The arms and feet of such a patient must sometimes be kept quiet by strong assistants.

The amount and kind of foods to be introduced into the stomach can be varied. The principle is, to introduce liquid and semi-liquid food in sufficient quantity for the maintenance of life. As a rule a combination of milk and eggs beaten up together is the most important and most frequently used form of nourishment. F. Jolly[2] recommends using one quart and a half of milk and three raw eggs for each feeding, twice daily. The milk can also be combined with cream, with somatose, or with plasmon, or indeed with any of the beef juices in use. A tablespoonful or two of sugar and some table salt may also be conveniently added. In the same manner meat powder, purée of brain, peas, etc., can be mixed with water or milk and introduced into the stomach.

Inasmuch as forcible gastric feeding permits us to utilize a great variety of foods, and especially a considerable quantity of them, it lies within our power not only to keep the patient in balance, but also sometimes to make him gain in flesh. Forcible gastric feeding is therefore the means par excellence for forcible feeding. The other two methods mentioned above—rectal alimentation and subcutaneous feeding—play here but an unimportant part. Rectal alimentation may be for a time combined with gastric alimentation when it is very difficult, on account of the patient's struggles, to introduce the tube into the stomach. Subcutaneous alimentation is still less important, as the amount of nutritive value introduced in this way hardly amounts to anything. William H. Murray[3] recommends subcutaneous injections of olive oil (10–20 c.c.) twice daily. *Max Einhorn.*

FEES, LEGAL RULES GOVERNING THE COLLECTION OF.—As far back as history goes we find mention of physicians; physicians' fees are probably nearly as ancient, but the privilege of being able to recover these fees in a court of law is, in countries other than our own, of quite recent date. In the United States the law has never made any distinction between the professional man who works with his brain and the laborer who works with his hands. *Honoraria*, with their interesting history and subtle legal evasions, are unknown here; and the rules governing the collection or recovery of physicians' fees are, in the main, the same as would be enforced in any other vocation. But still, there are a few peculiarities arising from the nature of the services rendered, or from the circumstances that attend the need of these services; also there exist in many minds certain superstitions or fallacies with regard to a physician's services and remuneration. Hence a few general rules on these topics may be of value. At the outset it must be premised that only a very general sketch can be given; on points of detail the various States differ considerably among themselves, and even in the same State diverse decisions have been rendered on a single point. This article is intended to be for physicians what an article of similar length in a "Family Medicine Book" might be for lawyers, *viz.*, a guide till proper professional advice can be obtained. A physician ought to know enough law to avoid being his own lawyer.

A physician's right to receive compensation for his services is based upon a contract either express or implied, and this same contract will form a basis for an action to recover that compensation in a court of law. If there is an express agreement between the parties (1) as to the amount or rate of compensation, and (2) as to the person or persons to be considered responsible for the same, then no difficulty is likely to arise. But this is seldom the case, and as a rule an *implied* contract will be inferred as existing between the physician and either the patient or some one representing the patient. In this implied contract the *physician* will be expected to treat his patient with reasonable skill, judgment, and experience, according to the standard prevailing in the locality in which he practises, he will pay such visits as he may deem necessary; and the *patient*, by his acceptance of these services, undertakes to obey the physician's instructions and to pay a reasonable remuneration. What constitutes a reasonable remuneration will depend upon the usual rate of charges for similar services in the neighborhood. Here it may be remarked that failure to cure will be no bar to the physician's recovering his fee. The physician as a rule does not guarantee a cure; but should he undertake a case on the distinct understanding that "no cure no pay" shall hold, he will be required to abide by it. A patient will not be allowed to allege that he got no benefit from the physician's treatment provided the physician uses reasonable care, skill, etc.; but it has been held that where the treatment was such that it could under no circumstances effect any possible benefit, the patient might allege this as a reason for non-payment. If the services were intended to be gratuitous, and the physician so declared, no action will lie for recovery; but if the physician intended his services to be free, and did not at the time declare such intention, an action for recovery will lie; and in any case the law will presume the existence of liability on the patient's part, and it will be for him to prove that such services were intended to be without charge. But an implied contract can exist not only with the patient, but in some cases with a person or persons who stand in such relation to the patient as to be legally liable for necessaries furnished. Thus, in medical services rendered to a child under age, the parent is held by the implied contract to pay; so, too, is the husband for services rendered to his wife, and the guardian for services rendered to his ward. It is very necessary that the proper person be held responsible, and the physician will do well to ascertain the individual to whom he should present his account. Thus, where a married daughter was taken ill in her father's house, and received a physician's services, the father acquiescing, the father was not liable, but the husband, and it was held that even if the father had sent for the physician it would have made no difference. With regard to parent and child under age, it may be said that as a rule the father is liable, even if the child is away from home, provided he is absent with his father's consent, but not if the child has run away or left without the father's approval. If the father is dead, the mother is liable only so far as the child has a separate estate, and if the child has no separate estate she is not liable. In the case of husband and wife the husband is liable; and if the wife be divorced, the husband will still be liable unless the physician is made acquainted with the fact. So, too, where the husband declines to be responsible for debts incurred by his wife, it is incumbent on him to furnish this information to the physician, or else the courts will uphold the physician in recovering his fee from the husband.

"There are two cases in which, in the absence of an express contract, the physician may recover if either husband or wife has property. The first is the case in which a physician renders services to a woman not knowing her to be married. Here the husband is liable as an undisclosed principal, but the wife is also liable as an agent who has made a contract without disclosing the fact of agency, and either could be sued notwithstanding a previous judgment against the other for the same cause, if it has not been satisfied." "The second is the case in which a married woman, who has been abandoned by her husband, or is living apart from him for good cause, renders him liable for necessaries furnished to herself and her children. Here the debt is that of the husband, and the wife may not be sued directly. But a judgment against the husband may be enforced against the wife's separate property, by an action instituted for that purpose" (Willard A. Mitchell, in *Medical Record*, 1894, vol. xlv., p. 98).

In the case of a third party other than the parent, husband, or guardian, what are the liabilities of such third parties for the payment of the physician's fees? When a physician depends on the promise, express or implied, of a third party, it is necessary to understand whether that third party promises as for himself or as a guarantor. In the former case he is liable, and the physician can recover from him. In the latter case it is necessary that such promise should be in writing. The Statute of Frauds declares that "no action shall be brought . . . whereby to charge the defendant upon any special promise to answer for the debt, default, or miscarriage of another person . . . unless the agreement upon which such action shall be brought, or some memorandum or note thereof, shall be in writing, and signed by the party to be charged therewith, or some other person thereunto by him lawfully authorized." To take a few illustrative cases: (1) A asks a physician to attend X, and says, "I will pay," or "I will see you paid"; A is liable, and the physician can recover from him. (2) A asks a physician to attend X, and says, "If X does not pay you, I will"; unless this is in writing the physician cannot recover from A. (3) A says to a physician, *after* services have been rendered to X, "I will pay"; A is not liable. In Case 1 above, there is an ordinary contract, and the transaction does not come under the Statute of Frauds because it is an independent promise. Case 2 is covered by the Statute of Frauds. In Case 3 there is no consideration upon which to found a contract, and therefore, whether oral or written, such a promise has no legal value. But, in the large majority of cases, although third parties are ready enough to call a physician for a friend or neighbor, they are singularly reticent on the subject of remuneration. If the third party avers that he is merely an agent, he has no responsibility; but where he does not state that he is acting as an agent the courts differ as to the question of liability. This subject of agency has been condensed as follows: "It is a general principle of the law of agency that one who procures services to be done for another is not himself chargeable as the debtor, unless he omits to make known his principal, or erroneously supposes that he has authority, or exceeds his authority, or expressly or implicitly engages to be answerable either by directly promising to pay for them if rendered, or by doing or saying something which justifies the person who is to perform them in supposing that the one who applies to him engages to pay for them" (Judge Daly, in Buck *vs.* Amidon). In dealing with corporations, such as railway companies, the physician will do well to remember that unless he has an *express* contract with the corporation, an *implied* contract is with the person who receives his services. Thus, in a railway accident, a conductor asks a physician to attend X; the company is not liable. Doubtless there is in every corporation some officer whose acts will bind the corporation; if such an officer requests professional services for an injured person, the company will be held responsible, but not otherwise; and it will be for the physician to prove that the officer who employed him had such authority, or else that the company subsequently ratified the action of an inferior officer. The question of the liability of corporations, with the various decisions, is far too large to enter upon here.

Having now seen how, in most cases, a contract is made, let us note the points necessary to success in invoking the aid of the law. In the first place—with regard to his own legal status—the physician must have fulfilled all the legal requirements of the State in which he practises, and of the county or counties in which he has an office. He must be legally qualified to practise. If there is any omission or flaw in this respect he cannot recover his fees in any State, with the possible exception of Missouri. And as with professional services so, too, with medicines supplied. Generally the physician will be presumed to have fulfilled all legal requirements, and the burden of proving that there is any irregularity will rest upon the defendant. The legally qualified physician can also recover for services rendered by students working under his direction, and also for a physician employed to assist him, even when this assistant is not legally qualified. But it would seem that a physician, being unable to attend a case, and sending in his place another physician not his assistant, cannot recover for that other physician. The patient is also liable for the expenses of a consultant, even when there is no express stipulation. Next, the physician will have to prove that he has rendered the services for which the charges are made. This is a difficult and delicate matter, and the physician must proceed cautiously, for the question of "professional secrecy" presents itself. In the States of Arizona, Arkansas, California, Colorado, Idaho, Indiana, Iowa, Kansas, Michigan, Minnesota, Missouri, Montana, Nebraska, Nevada, New York, North Carolina, North Dakota, Ohio, Oklahoma, Oregon, Pennsylvania, Utah, Washington, Wisconsin, and Wyoming a duly qualified physician is positively restrained from disclosing anything that the patient has confided to him professionally. In States not mentioned above, the physician may be allowed to testify in detail as to the services that he has rendered. In case the physician should be unlicensed the patient has no such protection, and a full account of the services may be given. Great diversity exists as to the interpretation of these rules, and chiefly as to what is included in the term "privileged communication." In the next place the account sent in will be scrutinized. The court will hardly recognize an account as vague as the "To professional services" so commonly rendered. While there is some difference in the requirements of the various States, the safest course is to present an account in which each item is specifically given under its proper date, and with its own charge against it. "The general rule that one who receives a bill or account, and retains it without objection, will be deemed to have acquiesced in its correctness, does not apply to a bill rendered for personal services without previous agreement as to rate of compensation. But where a part payment is made on such bill without protest, it becomes an account stated, which may be sued upon without giving evidence as to the value of the services rendered; and the bill need not have been an itemized one" (Willard A. Mitchell, in *Medical Record*, 1894, vol. xlv., p. 98). With regard to the value of the services rendered—in case this is disputed (and the defendant is likely to dispute everything)—the custom of other physicians in the locality, and the plaintiff's own custom in other cases may be cited; but it will be proper for the defendant to urge that the physician had on previous occasions charged him less for similar services. Expert opinion as to the value of the services may be given by physicians only; but juries are not bound to accept their valuation, and in case of different witnesses making different appraisals the lowest is most likely to be taken. Another possible defence is that the physician made more visits than were actually necessary; but the physician is recognized as the only judge as to the number and frequency of the visits required, and as a rule the physician remains in attendance on a case just so long as he deems it necessary, or until the patient dismisses him, or until he leaves by mutual assent. It may possibly be urged that the physician was intoxicated; this would be a good plea if the patient on this ground refused to allow the physician to treat him, but if the patient continues to receive that physician's services this defence will not be allowed. "Malpractice" is a common assertion; if proven it is a good defence; but to sustain this the defendant will have clearly to prove gross neglect or culpable lack of skill. With regard to "limitation of action," where there is only one item to the account, the matter is easily settled by referring to the Statute of Limitations for the particular State; but where, as is generally the case, there are several items, covering a number of years, with possibly certain payments made from time to time, the different States have decided differently on the question of this constituting a "mutual account." In this case proper advice must be sought. *R. J. E. Scott.*

FELL-O'DWYER METHOD OF INSUFFLATING THE LUNGS.—Insufflation of the lungs is evidently the most direct and instant method of restoring the suspended respiratory function, and yet until recent years it had been practically abandoned or forgotten by the medical world.

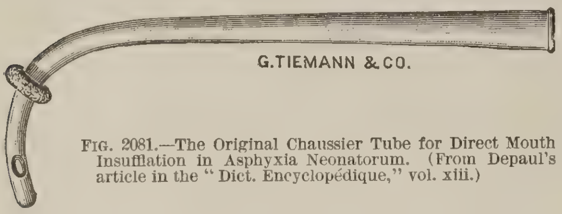

FIG. 2081.—The Original Chaussier Tube for Direct Mouth Insufflation in Asphyxia Neonatorum. (From Depaul's article in the "Dict. Encyclopédique," vol. xiii.)

Such was not, however, always the judgment upon it. It has an ancient and honorable history. Passing by the statement of Depaul that reference to it may be found in the Scriptures, and that Hippocrates considered it, he lets us know that Paracelsus (1493–1541) applied a bellows to the mouth and by its aid gently inflated the lungs, while Panarolus had recourse to the same procedure to revive the victims of charcoal fumes. Vesalius (1514–1564) demonstrated that in animals, after the thorax had been opened for observation, respiration could be maintained by the use of an insufflating bellows and tube.

In the latter part of the eighteenth century this method of relieving asphyxia was widely popular. It was in particular used to restore those who had been asphyxiated by drowning, and the numerous appliances, which were the product of the ingenuity of medical men in England and on the continent of Europe, were placed in the hands of life-savers and the police to be used at their discretion, or, too often, their indiscretion.

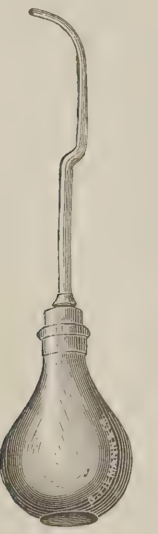

FIG. 2082.—Gairal's "Aërophore Pulmonique." (From Depaul's article.)

The names of many eminent physicians are connected with the invention of insufflating apparatus at this time. In all of these machines the air was supplied from a bellows or pump and injected into the lungs by means of a tube inserted into the mouth, the nostrils, or the glottis, or through a tracheotomy wound. In England William Hunter, Monroe, James Curry; on the continent, Des Granges, Hans Courtois, Fine, Pia and Garcy, devised instruments that were more or less widely adopted. And Lecat, Louis, Marc, Portal, Troja, and many others were warm in their praises of this method of treating asphyxia.

The indiscriminate use of these machines by ignorant persons resulted in bringing the method into disfavor. In 1829, Leroy d'Etiolles announced to the French Academy that the mortality from drowning had increased since this practice had become general. He contended that insufflation was dangerous to the integrity of the respiratory organs. Numerous experiments upon animals and upon human cadavers had convinced him that violent insufflation could produce emphysema and rupture of the air cells and smaller bronchioles. He therefore condemned the practice, and being supported in his conclusions by a committee, composed of Dumeril and Magendie, appointed by the Academy of Sciences to investigate the matter, the fate of insufflation was, for the time at least, sealed, in spite of the vigorous protests of Marc, the physician-in-chief of the life-saving service of Paris, and of other members of the Academy.

The sentence seemed final when, in 1845, Depaul started a propaganda in its favor for the resuscitation of the asphyxiated new-born. He demonstrated that insufflation was dangerous only when done by the inexperienced and with violence, and he proved that the human lung was more resistant than that of most of the animals used in Leroy's experiments.

Chaussier, who preceded him at the Maternité, in Paris, had, in 1806, recommended, for intralaryngeal insufflation, a tube which met the approval of Madame La Chapelle, and which Depaul adopted with some slight modifications.

The eminence of Depaul, the brilliancy of his argument, and the convincing character of his clinical evidence stimulated other inventors to attempt to improve upon his instrument. Gairal, in 1879, proposed an instrument which he called the "aërophore pulmonaire."

Ribemont, in 1877, presented a somewhat similar tube with *conical tip*, to which he too attached a rubber bulb.

Depaul, in his article, objects to these so-called improvements upon his method of insufflation, claiming that the operator's lungs are the safest form of bellows to use in filling the lungs of the new-born babe, and that the wedging of the conical tip of Ribemont might endanger the structures of the larynx.

Matas calls attention to the fact that Dr. Truehead, of Galveston, Texas, in 1869, described a complex machine of his invention for the purpose of inflating and aspirating the lungs. His article was contributed to the Berlin Obstetrical Society and appeared in their Transactions for 1869–72, but was never published in America.

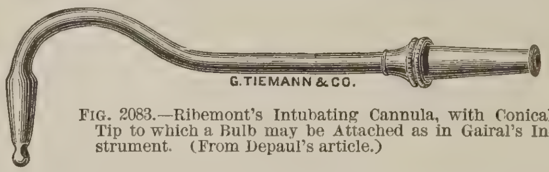

FIG. 2083.—Ribemont's Intubating Cannula, with Conical Tip to which a Bulb may be Attached as in Gairal's Instrument. (From Depaul's article.)

From this review, it is evident that the idea of combating asphyxia by means of insufflation was too fundamental ever completely to receive its quietus. Individual and original minds were attracted to it, but to the great body of the profession it was a discredited proceedure, when, in 1887, Dr. John R. Fell, of Buffalo, N. Y., after vainly trying every recognized method to maintain respiration in a case of opium narcosis, employed the tracheal cannula and bellows, used on dogs in the Buffalo Medical College, and succeeded, after carrying on respiration with its help for three hours through a tracheotomy opening, in saving the life of his patient. This success was followed by others, and in 1893, at the meeting of the Pan-American Congress in Washington, he was able to present a list of thirty cases whose lives had been preserved by the use of his instrument, which he had meantime modified by substituting a face mask for the tracheotomy cannula.

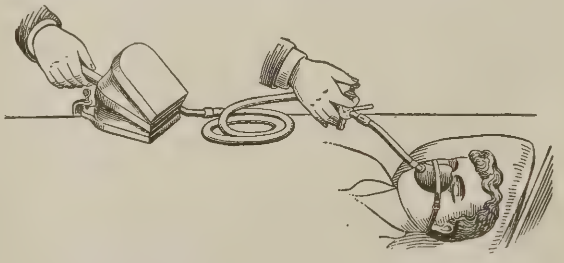

FIG. 2084.—Original Fell Apparatus, showing Face Mask and Air Valve Attached to Tube. (Truax's "Mechanics of Surgery.")

It is interesting in passing to notice that while the arguments of Leroy and his adherents had succeeded in discrediting insufflation for the relief of asphyxia in man, it had continued to be the universal custom in physiological laboratories to maintain respiration during

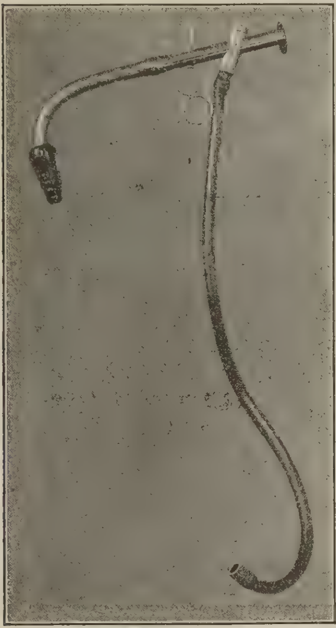

FIG. 2085.—Dr. Bloom's Latest Modification of the Intubator for Adults, with Automatic Ball-Valve.

vivisection experiments by injecting air through a tracheotomy tube by means of a bellows connected to it by rubber tubing.

The disadvantages of having to do a preliminary tracheotomy led Fell to substitute a face mask. But there were obvious objections to the latter, the chief of which was that part of the air was liable to pass down into the stomach and, by distending it, interfere with the descent of the diaphragm. Joseph O'Dwyer, whose experiments in intubation had admirably qualified him for the work, overcame these objections by the tubes which he constructed, for use with the bellows, and which he described in the *Annual of the Universal Medical Sciences* for 1894.

The tube and bellows, very properly called the Fell-O'Dwyer apparatus, have been in use in the Presbyterian Hospital, in New York, where they were introduced by Dr. William P. Northrup, since 1895, and in the Charity Hospital at New Orleans, for which they were purchased by Dr. J. D. Bloom, since 1896. Ample experience in the use of the apparatus in these two hospitals has demonstrated its great practical value. It consists of a foot bellows, connected by a long flexible rubber tube with the intubation attachment. The latter is of metal, is curved at the laryngeal end at a right angle, and has detachable conical tips, of various sizes to suit different ages, and designed to wedge in the larynx and prevent the escape of air alongside. The extra oral end has two branches, one to receive the tubing and admit the air from the bellows, the other to permit the escape of the air in expiration. The latter is stopped by the thumb of the operator during forced inspiration. No effort is made to aspirate the chest, it having been demonstrated during the days of Hunter and Monro that the elasticity of the lung is amply sufficient to expel the air. To give a better grasp on the instrument, a row of metallic rings is attached near the free end of the tube. These receive the fingers and give excellent control over the instrument.

Matas has recently modified the O'Dwyer tube by the addition of a pistol-shaped handle, and by adding a third branch, provided with a stopcock, through which an anæsthetic can be admitted without interfering with the continuance of forced respiration.

Since its introduction into the Charity Hospital, Dr. J. D. Bloom has made a number of improvements in the bellows, consisting of (1) a long lever to facilitate compression of the bellows; (2) a metal chamber, filled with cotton to filter the air on its way from the bellows to the lungs; (3) a similar chamber, through which oxygen can be passed into the bellows from a bag or cylinder, when deemed advisable.

For use in the asphyxia of the new-born, Dr. Bloom has had made a smaller tube, to which is attached the bulb of an ordinary atomizer, in place of the large bellows, thus preventing over-distention of the infant's lungs. In this small instrument the thumb of the operator is replaced by a ball valve, which automatically closes the exit tube when the bulb is compressed, and falls out of the way when the pressure from the bulb is stopped. (Fig. 2085.)

Since the days of Leroy the objections to the use of insufflating appliances have been: (1) That the instrument ignorantly or roughly used was capable of inflicting serious injury upon the larynx and upon the structures of the lungs themselves. To this it may be answered, as was done long ago by Depaul, that it is not intended to be either ignorantly or roughly used; that the same objections might be urged against any of the operations of surgery; and that extended experience in at least two great hospitals has demonstrated not only that it can be employed without danger to the integrity of the larynx and lungs, but that even after many hours of continuous insufflation by the Fell-O'Dwyer apparatus the voice is seldom affected.

(2) It is objected that it is difficult to introduce the tube into the larynx. It is true that a certain amount of dexterity is required, particularly in the infant, but the necessary skill is very quickly acquired. It is certainly far easier to introduce than the intubation tubes used in laryngeal diphtheria.

The instrument is introduced exactly as in the operation of intubation. The head of the patient is kept in the median line with the face pointing directly up. The mouth is kept well open by means of a gag, and the tongue is best pulled forward with a tongue forceps to bring the epiglottis well in reach. With the tube lightly poised in the fingers of the right hand the left index finger is passed along the tongue till the epiglottis and the opening of the larynx are felt. The epiglottis is hooked up by the

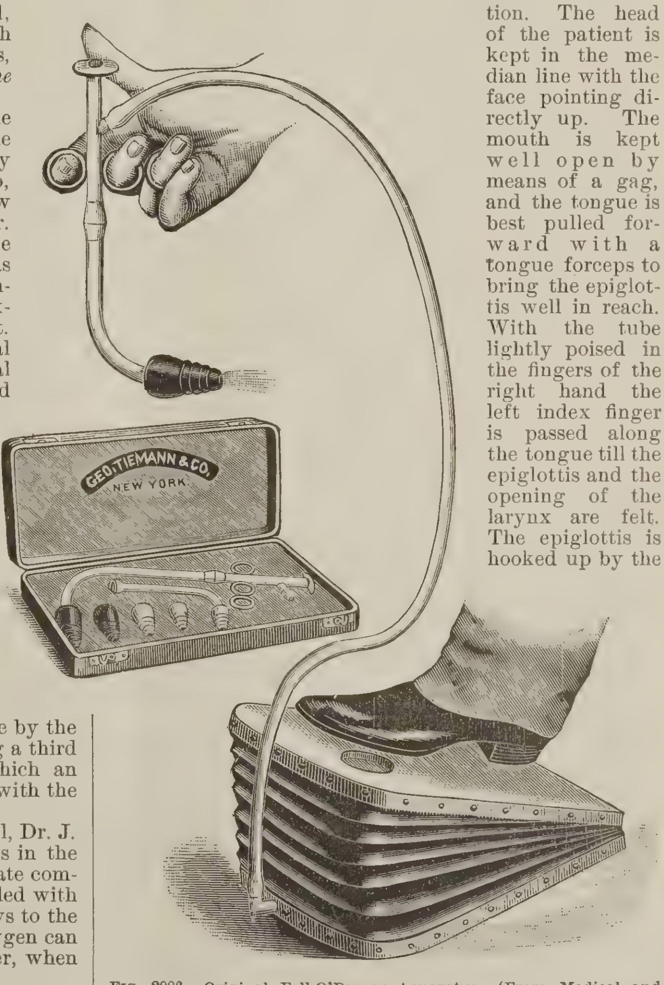

FIG. 2086.—Original Fell-O'Dwyer Apparatus. (From Medical and Surgical Reports, Presbyterian Hospital, of New York City, 1896.)

finger, which is slipped a little to one side. The tube is now passed alongside of the finger, exactly in the median line, till it reaches the tip of the finger. The handle is now sharply raised and the tube pressed home into the larynx. A gentle inflation from the bellows will cause the chest to rise and will be followed by expiration, if the tube is in the larynx. On the other hand, if it has passed down into the œsophagus, the chest will not rise, and in addition the air will be heard hissing in the throat. Occasionally the end of the tube gets blocked by the folds of the larynx. In these cases a little manipulation will generally clear it, or it may have to be withdrawn and again introduced. It is hardly necessary to say that these manipulations should be executed with gentleness and deliberation. The most common mistake is to see the operator frightened at a little delay in getting the tube in proper position and the inflow of air started. Seconds seem minutes in such cases, but it is very rare to see cyanosis develop which is not quickly cleared up when the bellows has been compressed once or twice.

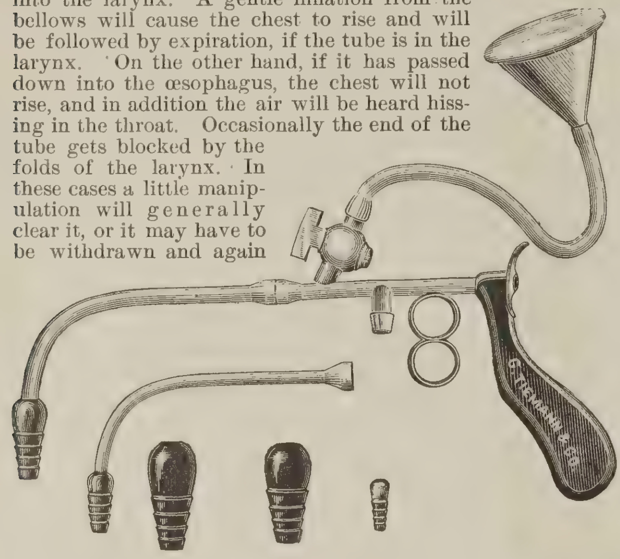

FIG. 2087.—Matas' Modification of O'Dwyer's Tube. (From his article on "Intralaryngeal Insufflation.")

The Fell-O'Dwyer apparatus is certainly the simplest and most efficient instrument so far invented for carrying on artificial or "forced" respiration. In 1897 Doyen ("Technique Chirurgicale") described an apparatus for insufflation, which he had devised for use in operations upon the thorax, to prevent the alarming symptoms of sudden pneumothorax. He was led to this invention by the experimental work of Tuffier and Hallion, Quenu and Longuet, who, recognizing the great danger from sudden pneumothorax, tried to find a way to prevent it. This they accomplished by insufflation, but they did not produce a suitable instrument. Doyen's apparatus is a credit to his inventive genius, but is manifestly inferior to the Fell-O'Dwyer apparatus.

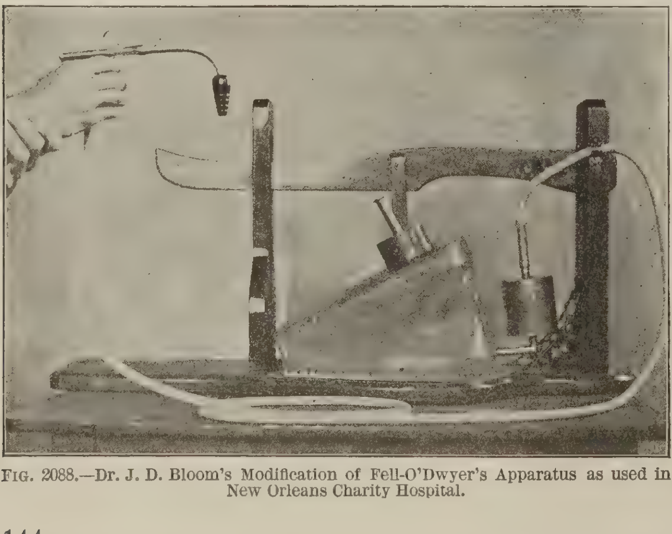

FIG. 2088.—Dr. J. D. Bloom's Modification of Fell-O'Dwyer's Apparatus as used in New Orleans Charity Hospital.

The latter is an admirably practical addition to our resources, and it is confidently recommended in the treatment of asphyxia in the following classes of cases:

1. In asphyxia neonatorum, by the use of Dr. J. D. Bloom's modification. The small size of the instrument permits its inclusion in any obstetrical bag. When its use is successful, the feeble and infrequent heart beat becomes more rapid and distinct. The skin loses its livid color and assumes the rosy hue of health, and even when no effort at independent respiration has been made by the infant the circulation appears to be perfectly normal. Generally a very short time elapses before the child can be left to carry on its respiration without assistance. I have myself now resuscitated too many asphyxiated infants with this instrument to feel any doubt of its superiority to any other method of meeting this condition.

2. In opium poisoning, with respiratory failure. This is the condition for which Fell originally recommended the method. Any one who has witnessed the transformation which occurs in the appearance of such a patient after the establishment of "forced respiration" with the Fell-O'Dwyer apparatus, and has compared its quiet efficiency with the strenuous and unsatisfactory effects of artificial respiration by Sylvester's and other methods, or with electrical stimulation of the respiratory function, will need no further argument to recommend it. Under its use the lividity of cyanosis is replaced by an unusually rosy color, the heart's action is improved, and, these two centres being kept going, the system has time to eliminate the poison. The use of the instrument is to be continued until, when the bellows is stopped, the patient breathes of his own accord at least twelve or fourteen times a minute and shows signs of being aroused from the narcotic stupor. We have frequently noticed that even after having regained consciousness these patients will lie quiet and permit the operator to carry on respiration for them. Sometimes after having regained the power to breathe for himself the patient will relapse and the tube will have to be again applied. At the Charity Hospital in New Orleans the apparatus has been used continuously for twelve or more hours, with ultimate success in saving the patient's life. It has undoubtedly saved cases which would have been fatal under other methods of treatment. It has markedly reduced the number of cases of post-narcotic pneumonia, which was formerly very frequent.

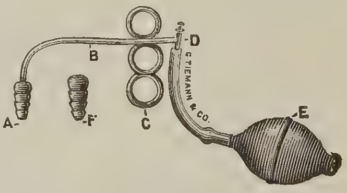

FIG. 2089.—Dr. J. D. Bloom's Adaptation of Fell-O'Dwyer's Apparatus for Use in Asphyxia Neonatorum. *A* and *F* are tips of different sizes; *D* is the ball valve to replace operator's thumb; *C*, metal rings into which the operator's fingers may be introduced; *E*, air bulb.

(3) In other cases of respiratory failure, as instanced by the following case: A young woman was brought into the Charity Hospital unconscious. She had been drinking long and heavily and appeared to be in a condition of alcoholic coma. No trace of opium could be found in either the stomach contents or the urine. The pulse was fairly good; respiration rapid and shallow. Suddenly the pulse became very feeble, the pupils became dilated and unequal, respiration practically ceased, and the skin quickly got blue. The pupils remained unequal for several hours afterward. Hypodermic stimulation and artificial respiration were at once resorted to, but she could not be made to

breathe. Death seemed imminent, when the Fell-O'Dwyer apparatus was introduced. In a few moments the pulse had slightly improved, and under the influence of the regular respiratory movements the cyanosis disappeared. After three hours she was sent to bed breathing for herself, and on the next day she was partly conscious. Total suppression of urine, however, terminated her life in coma.

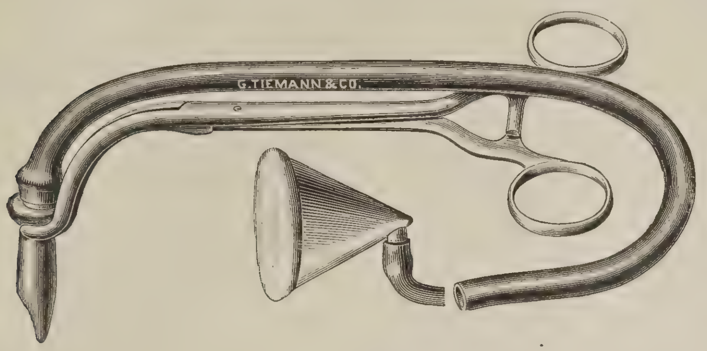

FIG. 2090.—Doyen's Intralaryngeal Tube and Rubber Connections, with Funnel Attached, for Laryngeal Tamponade and Chloroform Anæsthesia. The cut shows the special forceps used to introduce the tube. The intubating cannula may be used for direct air insufflation. (From Doyen's "Technique Chirurgicale," Fig. 43, p. 123.)

(4) In chloroform narcosis, when the respiration fails before the heart. Unfortunately, in most cases the heart fails along with the respiration, and then I believe nothing will save the patient.

(5) In the surgery of the mouth, to prevent the entrance of blood into the trachea and to secure free admission of air to the lungs, the anæsthetic being given through the tube; a very limited field of application, and one better met by preliminary tracheotomy.

(6) In thoracic surgery, when the pleura is widely opened and there is danger to life from the production of sudden pneumothorax, with collapse of the lung. As demonstrated by Parham at the Charity Hospital, in a case of sarcoma of the ribs, the frightful anxiety which attends this accident may be prevented by the use of the Fell-O'Dwyer apparatus, and the expansion of the lung quietly maintained while the organ is being secured to the chest wall by sutures.

There can be no doubt that the most brilliant future for this method of "forced respiration" lies in the field of thoracic surgery. Milton, of Cairo, has succeeded in doing some remarkable work upon the mediastinum with the assistance of insufflation, and Parham has, in this country, conclusively demonstrated its wonderful utility in forestalling the pneumothorax which has always been the bugbear of operative interference with the thoracic walls. *Erasmus D. Fenner.*

FENNEL.—FŒNICULUM. The fruit of *Fœniculum. Fœniculum* (L.) Karst. ("*F. capillaceum* Gilibert," U. S. P.—fam. *Umbelliferæ*).

From a perennial or biennial herb with a tall, smooth, green, branching stem, and pinnate, skeleton-like leaves, the latter consisting of but little more than straggling, branching midribs and veins, arising from broad, concave, half-sheathing petioles. Umbels compound, naked, many-flowered. Native of Southern Europe, Western and Southern Asia, etc.; it exists in several varieties, and has been long and extensively cultivated.

Of two separate or united carpels, each 0.5 to 1 cm. ($\frac{1}{5}$ to $\frac{2}{5}$ in.) long, about one-third as broad and one-sixth as thick, oblong or a little narrowed at the summit, more or less curved, bearing five very prominent and stout light-colored ribs upon the back, otherwise smooth, yellowish or brownish-green; pericarp containing an oil tube between each two ribs and two upon the flat side; odor pleasantly aromatic; taste sweet and pleasantly aromatic.

Sweet, or Roman fennel, with very large, long, light-colored, pale-greenish fruits, and a particularly pleasant odor and taste, from cultivated plants of southern Europe, is much the best. German, or Saxon, with shorter and proportionately thicker fruits, is cultivated in Germany. Wild, or bitter fennel, is from wild plants growing in the south of France.

Fennel contains about three and a half per cent. of an *essential oil* very much like that of anise, being composed of a large proportion of *anethol*, a smaller one of a hydrocarbon of the terpene series, etc.

Fennel is a mild aromatic of exactly the same medicinal qualities as anise. It is, however, less used in medicine than that, but is considerably consumed as a flavor in cordials, as a spice and in veterinary practice. It also enters, as a carminative, to prevent griping, into the compound infusion of senna, and its oil similarly into the compound spirit of juniper and the compound licorice powder. Both are often added to prescriptions, with this object. The dose of fennel is 0.5 to 2.0 gm. (gr. viij.–xxx.). *W. P. Bolles.*

FENNEL, OIL OF—a volatile oil distilled from the above—is thus described in the Pharmacopœia:

A colorless or pale yellowish liquid, having the characteristic, aromatic odor of fennel, and a sweetish, mild, and spicy taste.

Specific gravity: not less than 0.960 at 15° C. (59° F.).

Between 5° and 10° C. (41° and 50° F.) it usually solidifies to a crystalline mass, but occasionally it remains liquid at a considerably lower temperature.

Soluble in an equal volume of alcohol, the solution being neutral to litmus paper; also soluble in an equal volume of glacial acetic acid.

The oil is not colored by the addition of a drop of ferric chloride T. S. (absence of some foreign oils containing *phenols*, and of *carbolic acid*).

If the oil be dropped into water, without agitation, it should not produce a milky turbidity (absence of *alcohol*). It should contain about sixty per cent. of anethol. The relatively higher temperature at which crystals of this substance begin to separate indicates its percentage and of course determines its quality. Another substance present in it is *fenchone*, with pinene, phallandrene, etc. Its properties and uses are precisely like those of oil of anise, and the dose is ♏ i. to v. The official water (*Aqua Fœniculi*), having a strength of one-fifth of one per cent., is usually employed as a vehicle, but is carminative in doses of 8 to 30 c.c. (fl. ℥ $\frac{1}{4}$ to 1). *Henry H. Rusby.*

FENUGREEK.—FŒNUM GRÆCUM. The seeds of *Trigonella Fœnum-Græcum* L. (fam. *Leguminosæ*), a very ancient food and drug of India, produced upon a cultivated and wild erect, branching herb. The seeds are about one-eighth inch long and nearly as broad, and a little more than half as thick. They are irregularly rhomboidal, with rounded edges, and grooved diagonally, on both sides. They are of a peculiar brownish-yellow, sometimes grayish-yellow, smooth, peculiarly and not very pleasantly odorous, and of similar fatty and bitter taste. About one-fourth of their weight is gum, nearly as much albumin, and there is seven per cent. of ash, with six of a disagreeable smelling and tasting fatty oil and a little resin. There are small amounts of *choline* (see *Hemp, Indian*) and *trigonelline* ($C_7H_7NO_2 + H_2O$). They are largely eaten as an albuminous food and are also regarded as tonic (doubtless due to the bitter alkaloid) and carminative. They are also very largely used in the ground state for poultices. The absorbable properties of the alkaloid, so applied, are unknown. They are very largely used as food and medicine for cattle, and this is almost their exclusive use in this country. The very young herbage is similarly used as a sort of *medicinal food*, much as are dock leaves and dandelion leaves. *Henry H. Rusby.*

FERMENTATION.—Fermentation is derived from the Latin *fermentatio*, which has the force of the root found in the Latin verb *fervere*, to glow with heat, to seethe, to boil—a good idea of which may be obtained from the English cognate *fervent*. The word was used to describe such processes as take place in a beer-vat or a jar of working preserves—processes which are marked by an elevation of temperature and the production of a scum or froth. (For a historical résumé of the work by which such processes were shown to be due to living organisms, see article *Bacteria*, this HANDBOOK, vol. i., pp. 677-680.) Later, the word came to be used in a wider sense to include putrefactive changes in general, and its use finally was extended to take in the processes which are now best known by the name of zymolysis (see article *Enzymes*, this HANDBOOK, vol. iii., p. 840). Fermentation, therefore, in its fullest significance may be said to include, on the one hand, those processes brought about by the lower vegetable organisms (bacteria, yeasts, moulds, etc.), which increase in growth as they produce the physical and chemical changes observed in the medium in which they grow; and, on the other hand, the term is sometimes stretched to include zymolysis or the changes produced by enzymes, which enzymes neither increase nor grow less as the process is continued.

It is interesting to note that while in Germany the word *Fermentwirkung*, of Latin origin, is used to apply almost exclusively to zymolysis, in England and in America the word fermentation is used to apply to exactly the other half of the field, viz., to those changes which are produced by the lower vegetable organisms.

In this HANDBOOK "Fermentation" has been practically treated by the articles on *Bacteria* and on *Enzymes*. As these deal respectively with each half of the subject, it will not be entered into *in extenso* here. There are, however, three classic theories, inseparably connected with the subject of fermentation, which have not been discussed in the articles referred to and which will therefore be taken up now. These are:

(*a*) Berzelius' theory of *catalysis*.
(*b*) Liebig's theory of fermentation.
(*c*) Pasteur's theory of fermentation.

Berzelius' theory of catalysis, while not advanced exclusively as part of a study of fermentation, was promptly seized upon to explain the action of enzymes, and is still so quoted—though rarely—at the present day. Prior to Berzelius' classic paper on this subject, it had been observed that certain substances such as finely divided platinum would cause the union of such stable elements as hydrogen and oxygen with the evolution of sufficient heat to cause the platinum to glow. Similarly such platinum would cause the oxidation of alcohol (in the presence of water) to acetic acid, and yet the platinum did not appear (as far as was known at that time) to enter into the reaction—at least it was not used up. Platinum was found, furthermore, to decompose hydrogen peroxide, and, what to Berzelius was still more striking, a flake or two of fibrin would have the same effect, the amount of hydrogen peroxide decomposed being considerable, while the platinum or the fibrin was little or not at all affected and apparently did not enter into the reaction (compare with illustration of nitric oxide, article *Enzymes*, this HANDBOOK, vol. iii., p. 839). To account for such phenomena Berzelius advanced the theory that certain substances could act simply by their presence and produce profound reactions, in which, *as far as he could see*, they took no part. Later investigations have shown there is probably no case in which a body acts in this way without taking part in the reaction and many severe criticisms of the Berzelian theory have been made, but it should not be forgotten that the theory was put forth only tentatively, and that Berzelius did not insist upon the discovery of a new force which could not be brought into line with other forces then recognized as active. This is clearly shown by the following translation from Berzelius' original paper (*Ann. de chimie et de physique*, 1836, vol. lxi., p. 150), in which he says: "This new force, which has been unknown up to the present, is common to both organic and inorganic nature. I do not believe it to be a force quite independent of the electrochemical affinities of matter; I believe, on the contrary, that it is only a new manifestation of these; but inasmuch as we are not able to see their connection and their mutual dependence, it will be more convenient to designate them by a separate name. I will call, then, this force, *catalytic force*. I will call, in the same way, *catalysis*, the decomposition of bodies by the force, just as we designate, by [the name] analysis, the decomposition of bodies by chemical affinity." From a comparison of this theory with the action of enzymes it may readily be seen how it was called in to explain zymolysis, but it need scarcely be said that the simple employment of the new word catalysis did not, in the slightest degree, explain the nature of the process.

Liebig went a step farther than Berzelius in attempting to show how ferments acted. He applied his theory to both organized ferments and enzymes. According to Liebig enzymes were albuminous in nature and possessed intramolecular movements or vibrations, which they tended to transmit to certain other (fermentable) substances around them. These fermentable substances, when they took up the vibrations in question, were shaken to pieces, and the atoms of which they were formed entered into new combinations. In the same way he supposed that the protoplasm of yeast cells, being highly complex and tending to break down, would transmit vibrations to non-living matter near them and cause it to break down.

Pasteur entered the field with a new theory, viz., that yeast cells, bacteria, etc., as a result of needs of their own in their life process, took from substances in solution around them what they needed—usually oxygen—and by this means destroyed the fermentable substance as such. The atoms which remained after the extraction of what the yeast cell needed then formed new combinations in accordance with their chemical affinities. This has often been compared to the yeast cell pulling out what might be called the keystone of the arch (comparing the molecule to an arch); the other stones of the arch, so to speak, would fall together in groups corresponding to the chemical affinities they possessed.

For a number of years the scientific world was interested in the discussion which followed between Liebig and Pasteur, until finally, by brilliant researches of his own and of others, Pasteur succeeded in making his theory the favored one. Among the many researches which might be quoted here was one by Dumas, which might almost be said to have given the *coup de grace* to Liebig's theory. Dumas showed that a thin film of collodion, not more than 0.1 mm. (about $\frac{1}{250}$ in.) thick, would absolutely prevent the action of an actively fermenting solution being transmitted to a fermentable solution on the other side. If Liebig's vibration theory was true, this was not what would have been expected, while it harmonized thoroughly with Pasteur's theory that the yeast cell would have to come in absolute contact with the fermentable substance in order to pull out the parts which it needed.

The theory of Pasteur, more or less modified as to the importance of oxygen in the process, might be said to be the one most generally held in favor, even at the present day; but more recent researches indicate that a new theory radically different will, not unlikely, take its place. This new theory is that the vegetable organisms so long identified with fermentation, and believed to be the efficient cause of the same, really act a secondary part—that is, they produce enzymes, and the enzymes bring about the changes to which we give the name fermentation or putrefaction. (See article *Enzymes.*) *George T. Kemp.*

FERN, MAIDEN-HAIR.—ADIANTUM. (*Venus-Hair Fern.*) *Adiantum* is a large genus of ferns, several of whose species have been used in medicine, more especially the *A. Capillus-Veneris* L. of Europe and the *A. pedatum* L., growing throughout North America, except the far North and the Southwest, and abundant also in parts of Asia. The herb is the portion used. It has an aromatic-bitter taste, due to constituents which have not been studied. Its use is historical, it having been employed mainly in the treatment of catarrhal affections, especially of the respiratory tract. At the present time it is largely used in the manufacture of some patent medicines, but scarcely in any other way.

Henry H. Rusby.

FERN, MALE.—ASPIDIUM. FILIX-MAS. "The dried rhizome of *Dryopteris Filix-mas* Schott and of *Dryopteris marginalis* Asa Gray (nat. ord. *Filicas*)" (U. S. P.)

The first-named of these species is a large, robust, and handsome fern. It is one of the commonest in the cooler parts of Europe, and abundant also in the temperate parts of Asia, in the northern and southern extremes of Africa, and in both North and South America. It is not found in the Eastern United States, but occurs in British America and in the Western States. Its employment as a tænicidal agent is of great antiquity, as it is mentioned by some of the earliest writers upon medicine. The introduction of the "oleoresin" (ethereal extract) dates from the recommendation of an apothecary of Geneva named Peschier, in 1825 (Flückiger). The horizontal or decumbent rhizome is collected and either dried and marketed in its natural state, or (as now usual) after stripping it of its dense coat of leaf bases and chaffy scales, then constituting the "Peeled Fingers."

DESCRIPTION.—Before being peeled, 10 to 15 cm. (4 to 6 in.) long by 5 to 7 cm. (2 to 5 in.) thick, including the densely imbricated, dark brown, cylindraceous, slightly curved stipe-bases and the dense mass of brown, glossy, transparent, soft, chaffy scales; when peeled, 1 to 2 or 3 cm. ($\frac{2}{5}$ to about 1 in.) thick, slightly curved or claw-shaped, somewhat narrowed toward one end, bearing several coarse longitudinal ridges and grooves, pale-green when first peeled, becoming pale-brown, or when too long kept, rusty-brown, smoothish (or somewhat roughly scarred with remains of the stipe-bases); texture rather spongy, pale-green, with age becoming gradually brown from the outside inward, the *Filix-mas* showing about 10, the *marginalis* about 6, steles in a loose and interrupted circle. The marginal hairs of the stipe-scales of *Filix-mas* consist each of two parallel, slender cells, neither of them glandular; those of *marginalis* are almost identical in appearance, being directed slightly more toward the apex of the scale, and their lower cell often a little narrower. Upon the older scales they are nearly wanting. Male fern has a disagreeable odor and a bittersweet, acrid, astringent, and nauseous taste.

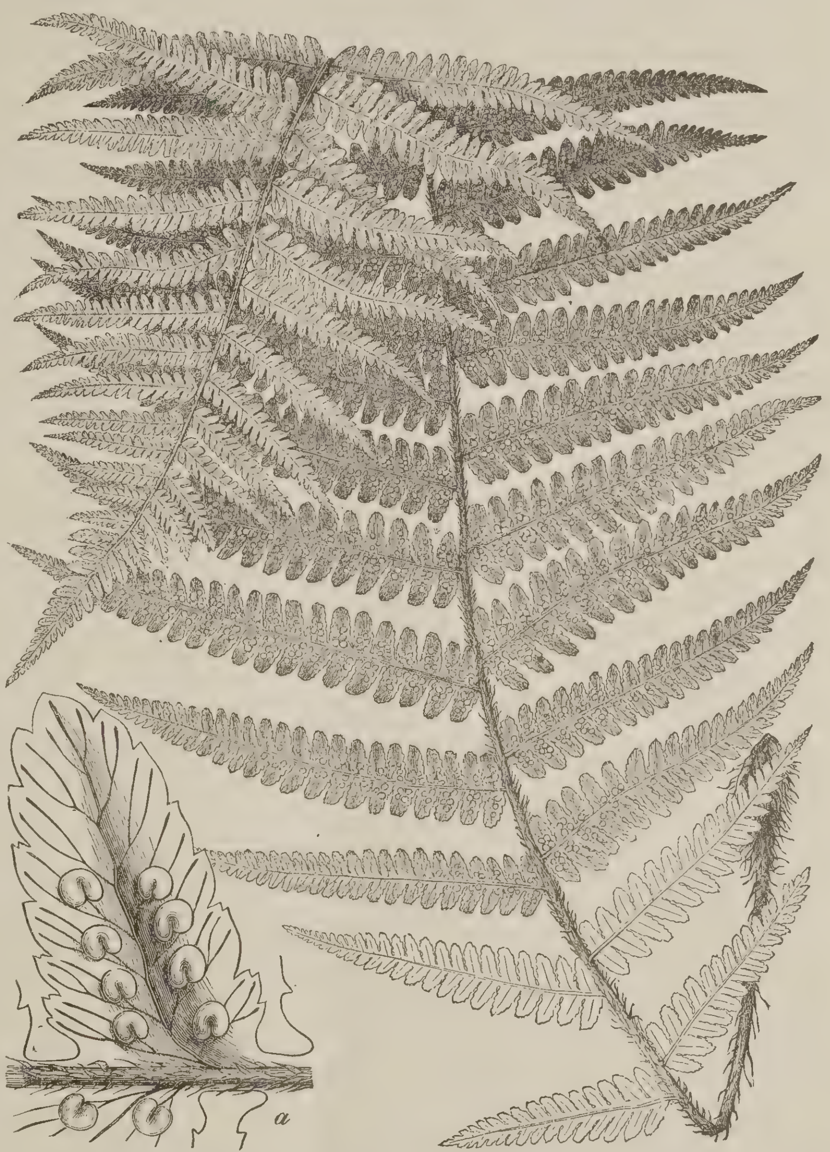

FIG. 2091.—Male Fern. Frond about one-third natural size; also a lobule (*a*) enlarged about four times, showing the round-reniform *indusia* covering the *sori.* (Luerssen.)

The chaff, together with the dead portions of the rhizome and stipes, should be removed, and only such portions used as have retained their green color. The powder should be freshly prepared and bright green.

Several, perhaps many, adulterants and substitutes have been and are sold. Some of these can be distinguished by their different numbers of steles, while the distinctions of others are microscopical and obscure. It is not indeed practicable, without a very elaborate description, to exclude all the possible adulterants. Some, not readily detected in the peeled drug, are so when the covering of stipes is present, a condition which is, for other important reasons, also to be preferred.

The second species occurs in Eastern and Northwestern North America. It is scarcely so large as the former.

Of late years, the market has afforded very much more male fern only a inch and a half in length by a quarter or a third of an inch thick, than of the larger sort. The size, however, does not appear to affect the quality greatly, except that the larger form retains its freshness longer.

Few drugs are more certain to prove effective than male fern of good quality and properly prepared, yet there are few whose preparations, as found in pharmacies, are more uncertain. The quality of the genuine drug appears to depend wholly upon its freshness and correct and careful preparation. The freshness is at once determinable by the color, and no pharmacist is excusable for accepting or using an inferior article. The outer surface at first loses its green, and assumes a very pale-brown, then a deep rusty-brown color. At the same time a similar change of color is occurring internally, beginning at the exterior and gradually working inward. The quality is in a general way proportional to the retention of the green color.

The composition of male fern is very complex and variable with the length of time that the drug is retained. Many compounds have been from time to time described and, being found to act more or less like the drug, have been credited as the active constituents. We are unable, however, to state positively to what the action is due. There appears to be little doubt that several of the constituents are active, upon both the system and the parasite. Filicic acid, which is certainly somewhat active, was long regarded as the chief tænicidal agent, but since it increases upon keeping the drug, while the latter becomes less effective, this view has become modified. Aspidin is more abundant in the fresh drug and has been proven to be active, as has aspidinin. With these substances occur six or seven per cent. of fixed oil, a variable amount of volatile oil and tannin, and various less known bodies. The 20% to 30% of *filicic anhydride* or *filicin* is not active.

In medicinal doses, 1 to 4 gm. (ʒ ¼ to i.) of the oleoresin, the preparation almost entirely employed, male fern ordinarily has a purely extraneous action, affecting only the parasite. But when very large doses are taken, or when absorption occurs, this being favored by the use of fats while the oleoresin is still in the intestine, for which reason castor oil is an ill-chosen adjuvant, poisonous symptoms may occur, and the results may be fatal. The symptoms of poisoning are those of great intestinal irritation and inflammation, purging and vomiting, convulsive movements and powerful depression, ending in coma. A favorable result from the use of male fern depends in great measure upon the method of administration. One of the most important points in its administration is the dietetic preparation of the patient. For ten or twelve hours before the first dose he should eat no solid food whatever, and the bowels if full should be emptied by a cathartic. Milk may be taken freely, or thin soup; then about 4 gm. of the oleoresin should be given at one dose; after several hours a second dose may be given, to be followed by a cathartic, if needed. The discharges should always be carefully examined for the head and upper portions of the worm. Unless these are passed the cure cannot be considered certain, and it may be found necessary to repeat the treatment. *Henry H. Rusby.*

FERN, SWEET.—This name has been applied to a number of plants; to some true ferns, because of their fragrance; and to some flowering plants with leaves resembling those of ferns, especially to the *Comptonia peregenia* (L.) Coulter (fam. *Myricaceæ*), also called Fern-Bush, Fern-Gale, or Sweet Bush. It is exceedingly abundant in rocky meadows, especially amidst blueberry bushes, in Northeastern North America. The leaves are peculiarly pinnatifid, with nearly semicircular segments alternating upon the two sides. They contain tannin, a small amount of an irritant glucoside, and a peculiar volatile oil, smelling like bay oil and somewhat like cinnamon. This oil has a specific gravity of 0.926 and solidifies at a freezing temperature.

The leaves are useful as a mild astringent of delightful fragrance, and are at the same time markedly stimulant, owing to the oil. The bark also contains tannin and is used as an astringent. The dose of the leaves is 1 to 2 gm. (gr. xv.-xxx.); of the bark, twice as much.

Myrrhis odorata Scop. (fam. *Umbelliferæ*) has also been called sweet fern. It is the sweet chervil of Europe and its root is used as a carminative. *Henry H. Rusby.*

FERNS.—(Nat. ord. *Filicineæ* or *Filices.*) This immense and interesting class of exquisitely beautiful plants has, unfortunately, but limited practical applications outside of decorative art. A few species yield extractible amounts of starch, while the rhizomes or young shoots of others are cooked and eaten. Dye-stuffs are yielded by a number, while several contain cumarin. There are many species which, although used to a large extent, and with good results, as domestic remedies, are not known to professional medicine. The commonest property, perhaps, is that of being anthelmintic, and many species of many genera, especially of *Pteris*, *Dryopteris* (incorrectly called "Aspidium"), and *Polypodium*, are so used. Many of these are poisonous, resembling in this respect the male fern. Next in importance are the astringent properties, due to tannin-like constituents, for which a very great number are in native use. In one or two cases, like that of *cibotium*, the hæmostatic effects are mechanical, after the fashion of lint. Many species are distinctly diuretic, and a few carminative, while a great number, like hart's-tongue or scolopendrium, are in use as pectorals. The gummy exudation from incisions in some of the South American tree ferns forms a most useful, permanent, and elastic protective covering to slight wounds. *Henry H. Rusby.*

FERNVALE SPRINGS.—Williamson County, Tennessee.

Post-Office.—Fernvale Springs. Hotel and cottages.

Access.—Viâ Louisville and Nashville Railroad to Franklin; thence 13 miles west to springs. Or viâ Nashville, Chattanooga, and St. Louis Railroad to Bellview; thence 12 miles southwest to springs. The location is 25 miles southwest of Nashville. This pleasant summer resort has been long and favorably known to the citizens of Nashville and the surrounding country. It has recently been thoroughly renovated, and it is said that guests as far away as Texas are beginning to find their way to Fernvale. Many attractions are afforded to the visitor in the picturesque hilly and wooded districts surrounding the springs. The situation of the resort is about 1,400 feet above the sea-level. The springs here are six in number, only three of which are mineralized. An analysis was made in 1836 by G. Froost, analytical chemist, and in 1879 by Prof. W. T. Lupton, of the Vanderbilt University. The former analysis is antiquated and incomplete. Following is Lupton's analysis:

One United States Gallon Contains:

Solids.	Grains.
Potassium sulphate	1.14
Sodium sulphate	13.76
Sodium sulphite	8.30
Sodium chloride	8.85
Lithium carbonate	Trace.
Calcium sulphate	27.63
Calcium carbonate	7.04
Magnesium carbonate	6.52
Iron oxide and alumina	.55
Silica	.05
Total	73.84
Gas.	**Cu. in.**
Sulphureted hydrogen gas	14.21

This water is very clear and not unpleasant to the taste. It has proved to be efficacious in skin affections of the squamous variety and in disorders of the alimentary tract and kidneys. It is also used locally in the treatment of sore eyes, chafing of the skin, superficial ulcerations, etc. *James K. Crook.*

FERRIS HOT SPRINGS.—(Formerly Matthews), Gallatin County, Montana.

POST-OFFICE.—Bozeman. Hotel. These springs are located on the east bank of the West Gallatin River, 7 miles west of Bozeman, from which place they are reached by coach. They were discovered over twenty years ago, but were not much improved until quite recently. The present proprietor has erected a handsome modern hotel, improved the natural charming surroundings, and placed the resort on a par with the most attractive in the West. The location of the hotel possesses unusual advantages. To the northeast and south a broad expanse of level country stretches out, dotted here and there with groves of cotton-wood and poplars, the intervening ground being occupied by fields of growing grain and verdant meadow lands. On the west the river sweeps along in magnificent curves, the line of tall trees conforming to the meanderings of the stream. Back of all, the grand old Rockies—snow-crowned, rock-ribbed, majestic—form an apparently unbroken guard to the enchanting scenes which lie in tranquil loveliness below. The location is 4,500 feet above the sea-level. Fish and game are found in great abundance and variety in the neighborhood. An analysis of the waters by Messrs. Riggs and Clark of the United States Geological Survey in 1885 resulted as follows:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Silica	4.61
Sodium silicate	6.40
Calcium carbonate	2.28
Magnesium carbonate	.21
Sodium carbonate	4.37
Potassium chloride	.78
Sodium chloride	4.12
Sodium sulphate	11.51
Loss	.06
Total	34.34

The analysis shows sufficient sulphate of soda to give the waters a laxative effect when taken in considerable quantities. They are recommended, both for internal use and for bathing, in the diseased conditions to which hot saline waters are applicable. *James K. Crook.*

FEVER. See *Calorimetry.*

FEVER, CLINICAL SIGNIFICANCE OF.—By fever we understand an abnormal elevation of the temperature of the body continued for a number of hours, or if not continuous, at least intermittently repeated, due to some infection or to some local inflammatory process, or to some unexplained disturbed state of the nervous system.

No symptom of disease was more carefully studied by the ancients than the temperature, and from the time of Hippocrates to the eighteenth century it was estimated by the rate of the pulse. Early in the eighteenth century Boerhaave began to use the thermometer in fever cases, but the thermometer did not come into general clinical use until Gavarret, in 1839, and twenty years later Zimmermann, Traube, and Wunderlich urged its advantages.

During the next twenty-five years the prognostic value of the height of the temperature became more and more over-estimated, but during the last fifteen years its prognostic importance has become much better understood, and to-day its greatest significance lies in its diagnostic advantages as a day-to-day indicator of the progress of the disease.

To understand well the pathology of fever, it is necessary to remember the normal mechanism of animal heat. The sole cause of this heat is a process of combustion of food substances by the oxygen absorbed. About four-fifths of the total body heat is produced in the skeletal muscles through an oxidation whereby oxygen is absorbed and carbonic acid given off, though the processes passed through are probably much more complex than mere oxidation. The other one-fifth of the animal heat is furnished by the secreting glands and the alimentary canal during digestion, and the liver, the largest gland of the body, contains the warmest blood. The internal temperature will be higher during the digestion of a meal than before.

During active fevers glandular activity and digestion are at a low ebb, and almost the entire heat production in these conditions is due to oxidation or changes in the muscular system; hence the loss of weight. Any muscular or mental activity or the taking of food will slightly raise the temperature, but external surroundings do not much affect the temperature of adults. But the adult during convalescence from a severe sickness is easily made colder or warmer by sudden changes in the external air or by any internal disturbance, the heat-regulating apparatus having become temporarily impaired. The babe, also, has its temperature easily raised or lowered by external or internal conditions because its heat-regulating apparatus is undeveloped.

Strychnine, caffeine, cocaine, and atropine all raise the temperature by increasing muscular and cerebral activity, the latter by reducing heat loss by preventing perspiration. Alcohol, nicotine, and morphine diminish temperature, the first two by relaxing the blood-vessels and increasing perspiration, and the latter by preventing all glandular and muscular activity.

Clinically, then, with high fever we should stimulate with alcohol, but with depression we should stimulate with strychnine.

A word as to the physiology of heat regulation. The equilibrium of the body temperature must be governed by the relation of the heat loss to the heat production, and as the one increases, so must the other, and all of this mechanism must be under the control of some finely adjusted nerve governor. The theories which have been offered in explanation of this are very various; they range from Macalister's three centres, namely, a thermogenic or heat-producing centre, a thermolytic or heat-dispersing centre, and a thermotaxic or heat-controlling centre, to Schaefer and Moore's belief that the vaso-motor mechanism in the medulla oblongata is probably the regulator of the relations of heat loss to heat production. Ott's cortical heat centre and Reichert's corpus striatum centre have not been proved, no structural difference having been discovered before and after the heat-regulating power has developed. But this power appears to be associated with the control over the skeletal muscles and blood-vessels.

As to the pathology of fever, its cause must be an over-production of heat, or a diminished loss of heat, or both. This may be due to anything that interferes with the vaso-motor regulating apparatus, or to anything that increases chemical activity, be it glandular, muscular, or metabolic.

Probably most fevers are due to poisoning from some source, the character of the fever, of course, depending upon the kind of poison. Anything that irritates or excites the brain may interfere with heat regulation and cause fever. This is especially noticeable in convalescents and in infants in whom too much excitement, over-eating, etc., cause a return of fever in the convalescent, or a febricula in the infant.

The purest kind of nervous pyrexia is seen in hysterical fever. This may be caused by hyperfunctional activity of some of the control centres, or we may have such a nervous shutting up of the peripheral blood-vessels as greatly to diminish the heat loss. Also the unceasing muscular activity present in some hysterical explosions, either as muscular or as simple fibrillar contractions, increases the heat production without adequate increase of heat loss.

A malarial paroxysm is perhaps the best type of immediate stoppage of heat loss and the consequent enormous sudden rise of the temperature. As the infected red blood corpuscles burst from the pressure of the matured plasmodia the first impression on the nervous system is to cause a sudden irritation of the vaso-motor centres and the resultant contraction of the peripheral vessels, and the symptom is a chill more or less severe. The internal temperature, perhaps partly from the toxin, perhaps largely from the obstructed heat loss, rises rapidly and often to a great height, which is sustained until the now superheated skin and over-stimulated sweat glands begin to pour out a profuse perspiration and heat loss first exceeds and then equals heat production, and the normal equilibrium is once more established. A period without fever, the intermittent stage, then follows, its length depending upon the type of plasmodium with which we are dealing.

In the same individual may be found mixed varieties of malarial parasites, maturing at different and at irregular times, and one set so overlapping the other that we have the so-called remittent fever—a malarial fever with remissions but without any marked intermissions. A frequent use of the thermometer, however, will generally show some short period of intermittency.

Our best type of a continued fever, of course, is typhoid. This fever undoubtedly becomes in time a mixed affair. Very soon in the course of this fever, unless laxatives and bowel antiseptics are freely given, fermentation and decomposition occur in the intestines, and we have an increased temperature due to the absorption of toxins from these processes, and the infection is then double.

This same double infection occurs in diphtheria, when added to the mild fever caused by the diphtheria bacillus we have fever from the absorption of the putrefactive products from decomposition of the diphtheritic membrane. The same is true of scarlet fever with decomposing membranous exudation on the tonsils.

In acute colds, follicular tonsillitis, measles, and chickenpox the fever is short-lived unless some complication occurs. The specific germs may so shock the nervous system as to produce the premonitory chill, and this in turn will be followed by a fever which, however, soon terminates unless some focus of pus formation develops, or the secretions undergo putrefaction, or the fæces become impacted.

The hectic fever of chronic tuberculosis is a pus fever, that is, a streptococcus fever, and is not caused by the tubercle bacillus.

Of all irregular and intangible fevers la grippe heads the list. The germs of this disease can cause a typical chill which is followed by a high fever that lasts two or three days and is followed by more or less nervous depression and by catarrhal symptoms; but the vaso-motor system is profoundly affected, often for a long time, and irregular chills, shiverings, hot flashes, and even hemorrhages from the mucous membranes may occur. In no fever is the insomnia so noticeable as in influenza, undoubtedly due to the inability of the blood-vessels of the abdomen properly to dilate and thus relieve the cerebral congestion and produce sleep—in other words, a general vaso-motor ataxia is present.

Fevers are classified as: (1) Continued, (2) remittent, and (3) intermittent, according to the character of the temperature range.

A continued fever is one in which there is but slight deviation in the temperature line. A remittent fever is distinguished by intense paroxysms. In the intermittent type we have paroxysms of fever with absolute intermissions, or periods of apyrexia.

Fevers are also sometimes classed as dynamic or sthenic, and as adynamic or asthenic, in accordance with the tone of the heart and nervous system.

Sthenic fever is characterized by a hard, full pulse, a flushed face, and often active delirium. The crisis in these cases is generally positive and short.

In an asthenic fever the pulse is from the beginning feeble and compressible, the skin is pale and often moist, the respiration troubled, and if there is delirium it is of the low muttering type, and the patient seems to die rather from exhaustion than from the lethal power of the disease.

To study the range of temperature carefully in a given case of fever the thermometer should be used at perfectly regular intervals.

Fevers are often divided into four stages: First, a period of incubation extending from a few hours to a week; second, the stage of invasion; third, the fastigium, or stage of greatest power of the disease; fourth, the stage of declination or defervescence.

The stage of invasion may be ushered in by a chill or by shiverings, and in the case of children often by convulsions, or by vomiting, or by both. The surface of the body, especially the extremities, tip of nose, etc., is cold for a short period, this stage being soon followed by myalgias, constipation, loss of appetite, thirst, and a more or less heavily coated tongue. The stage following is one in which the temperature and pulse become higher and higher. This stage terminates either by crisis or lysis. In crisis the temperature falls in the course of from twenty-four to thirty-six hours to the normal, and the other symptoms undergo a similar decline. Such a sudden decline of the fever may be attended by shock; hence this period is one of considerable danger. At this time we may expect hemorrhages, diarrhœa, profuse perspiration, weak heart, and collapse. The course of a lobar pneumonia furnishes the best example of a fever ending by crisis.

When the declination is by lysis, several days are generally occupied in the process, the morning remissions becoming more pronounced from day to day and the evening rise being less than that of the day before. This is typical of the declination of typhoid fever.

A sudden fall of temperature at an unexpected time in the disease shows that something serious is taking place, and is almost always a bad omen. A sudden rise, on the other hand, generally shows that some complication has occurred, and the case must then be carefully studied.

Before we consider the necessity of treating a fever, —that is, of simply lowering the temperature of the patient's body,—we should analyze its cause and should carefully weigh the danger, if any, which threatens the individual. In the first place, it is a question whether the fever does not represent nature's method of combating the harmful influence of the toxic products of the disease germs. On the other hand, however, there must be taken into consideration the question of how much fever the human body can safely bear. It is permissible to state that the system can sustain for a short time a temperature of 105°, or even 106° F., without danger or damage, while a long-continued temperature of 101° F. or over seriously threatens the integrity of the heart, muscles, and nervous system. With a short-lived fever, as of a malarial paroxysm, or the grippe, or a cold, if the fever is high it may cause some symptoms that are very uncomfortable and may call for some treatment, but the temperature as such requires no treatment.

The symptoms of high fever are myalgia, especially backache, generally localized in the lumbar region, headache, rapid heart action, and quickened respiration. Delirium may or may not occur, according as the patient is or is not susceptibile to irritation from cerebral congestion. The tongue is dry, and the mouth and lips are parched, not only from the fever, but from the mouth-breathing that is present if the lungs are much congested by a disturbed circulation. The surface vessels are more or less contracted as shown by the dry skin and the tendency to hemorrhages manifested by the mucous membrane. The internal organs, especially the liver and spleen, generally become congested. The liver thus becomes impaired in its power to produce materials protective against the toxins, and hence is unable either to render the poisons of the specific germs innocuous or to neutralize the effects of the toxins which are absorbed from the intestines.

Furthermore, owing to its congested state, the liver will secrete a diminished amount of bile, and thus there will be established a tendency to constipation and to fermentation in the intestinal canal. These changes, coupled with those which follow the diminished production of hydrochloric acid in the stomach, may lead to vomiting and to intermittent diarrhœa.

Aside from the fact that it easily becomes congested we cannot state what effects are produced in the spleen by fever.

From what has already been stated it is apparent that no serious harm can come to the organism provided the fever be short-lived. Hyperæmias give place to normal vascular conditions, toxins are eliminated, and all that we need do is to hasten nature's cure by increasing the loss of heat through the employment of any measures which tend to relax the peripheral blood-vessels and to cause perspiration. It is also possible that, in the effort to secure this result, we may derive some aid from the administration of a cathartic or from cold applications to the head.

If, on the other hand, the fever is a continued one, or even continuous for a few days, then we must analyze the condition. If we decide that this amount of fever is due to the specific germ and its associated local inflammatory conditions, our duty is to keep the patient as quiet as possible. The importance of this becomes apparent when we consider that every excitement causes restlessness, and this in turn means muscle movements through which heat production is increased. Hence it will frequently be necessary to give hypnotics. The bowels should be daily moved, not only for the relief of the liver, but to prevent fermentation, decomposition, and the absorption of all of the products of bowel infection. A carefully regulated ingestion of iced or cold water also tends to diminish the temperature, but if the latter still keeps too high we can, in short fevers, reduce it by means of the coal-tar products, cautiously administered in appropriate doses, or, in long-continued fevers, by cold applications.

If the body-temperature is so high as to be dangerous to life, even though brief in duration, as occurs in insolation, no treatment is as successful as immersion in cold water made gradually colder by ice. If the heart can withstand the previous high temperature, under this treatment the vaso-motor system recovers and heat control is re-established.

If after careful survey of the case we decide that the fever is in excess of that due to the disease *per se*, we must search for the additional cause, and with each disease we know where to seek its local manifestations. In the varied local inflammations such an abnormally high body-temperature generally indicates the formation of pus, as in appendicitis, pleuritis, synovitis, or otitis media. In typhoid fever and dysentery it means ulcerations with decomposing membrane and sloughing, and the absorption of toxins and pus products. In tuberculosis it means some closed up or incompletely evacuated pus cavity,—*i.e.*, streptococcus fever. In diphtheria, in follicular tonsillitis, and in scarlet fever it means a putrid exudation, a decomposing membrane, and a poorly cleansed throat.

While it is good treatment to keep the bowels free from fermentation and putrefaction in all short-lived fevers, it is absolutely essential in typhoid fever, and any treatment that gives free daily movements of the bowels in this disease will favorably modify the course of the fever. In typhoid fever constipation keeps the partially digested milk or other nutriment long in the intestines, and the mucous deposits and ulcerative sloughs long remaining *in situ* become most productive culture grounds for all sorts of bacilli and cocci, and the colon bacillus is often stimulated to migrate. Also fermentation increases, gas is formed, and tympanites, with the danger of perforation and hemorrhage from distention, readily occurs. We then have secondary infection with high fever and cerebral toxæmia.

If every local inflammation that develops in the course of any fever is kept as clean as possible, if the skin is kept in good condition by hot or cold sponging as the case may require, if plenty of water is given to drink, and if the bowels are kept nicely opened, there will be very little call for the use of so-called antipyretics, and the non-use of such drugs will allow a more careful study of the temperature curve, and therefore a better understanding of the case. *Oliver T. Osborne.*

FIBRINOUS BRONCHITIS.—(Synonyms: Croupous, exudative, plastic, pseudo-membranous, bronchitis; Ger., *Bronchialcroup, croupöse Bronchitis;* Fr., *Bronchite pseudo-membraneuse.*)

DEFINITION.—An acute or chronic inflammatory affection of the bronchial mucous membrane characterized by the deposit of plastic matter which becomes detached and is expectorated in the form of moulds or casts of a more or less extensive portion of the bronchial tree.

CLASSIFICATION.—A distinction must be made between true fibrinous bronchitis, a comparatively rare disease, and those conditions in which the expectoration of similar moulds results from (1) an accumulation of clotted blood in the bronchi, as in hæmoptysis, (2) the extension of a plastic formation from the upper respiratory passages, as in diphtheria, or (3) the upward extension of the fibrinous exudate in acute pneumonia. The term bronchial polypus was applied to all these conditions, as well as to the disease under consideration, by many of the earlier writers from Galen[1] down to Laënnec[2] and Cheyne[3]; many indeed regarded the casts as pieces of flesh. Cheyne was one of the first to make a distinction between casts of hemorrhagic origin, mere coagula of blood "moulded into shape by the bronchial vessels," and those due to an inflammatory process.

Strümpell[4] classifies the disease into a true, essential form, or that which attacks persons who were previously healthy, and a secondary, symptomatic form, which occurs in those who have already suffered from some other disease, especially chronic pulmonary affections. An acute and a chronic form are recognized, but, although they differ very obviously, it is not always possible to assign a present case to one or the other class until its full clinical history has been revealed.

ETIOLOGY.—No specific etiological factor has been determined. It is quite probable that the exciting cause is not the same in all instances, so various are the conditions under which the disease occurs. It is encountered at all times of life from infancy to old age, but seldom before the tenth or after the fortieth year. Hayn[5] records a case with autopsy in a new-born child, and W. R. Brown[6] saw it in a man of seventy-four years, with recovery. The essential form is not frequent in childhood, many reported cases having been merely complications of diphtheria. Morrill[7] states that of seventy-six cases only eleven occurred in children of twelve years or under. It is about twice as frequent in men as in women, but attacks male and female alike in childhood. More cases have been observed in England, Germany, and Switzerland than in France, Italy, or the United States, and in the late springtime than at any other season (April and May—Beschorner; May and June—Eichhorst). More than one member of the same family has been attacked—Watson's two cases were in brothers,[8]—and Pichini[9] observed three simultaneous cases; but neither hereditary nor endemic influences have been demonstrated. Personal idiosyncrasy is probably a more important factor (Mason[10]). Robust individuals are sometimes attacked, but more frequently those who have been debilitated by some previous illness such as typhoid fever, pneumonia, measles, scarlatina, or other acute infection. The disease has occurred during pregnancy and in the course of typhoid fever, and the menstrual periods have apparently borne some etiological relation to it in some cases. The recurrences in Schnitzler's case of twenty-four years' duration occurred regularly for several years at the menstrual periods, but continued long after the menopause. Its association with such cutaneous affections as impetigo, herpes, and pemphigus has been repeatedly observed. Most of the subjects have been anæmic, and many have been the victims of syphilis, tuberculosis, rickets, or alcoholism. Six of Model's seven cases were tuberculous.[11] Its association with other diseases has no doubt been merely accidental in many instances. The disease is not contagious, and we have no direct evidence that it is infectious. The bacteriological investigations have been too few to aid us in the solution of this question. In some instances it has been attributed to the Klebs-Löffler bacillus, but Escherich[12] failed in his attempts to demonstrate this bacillus in the bronchial mucus or to inoculate animals successfully with the membrane. Pichini cultivated three varieties of bacteria, and reports that by the injection of pure cultures of them into the tracheas of animals he succeeded in producing a condition very similar to bronchial croup. Various micrococci found in the secretions by other investigators probably bore no relation to the disease, although Sokolowski[13] reported four acute cases which he considered due to the presence of the Staphylococcus albus and aureus.

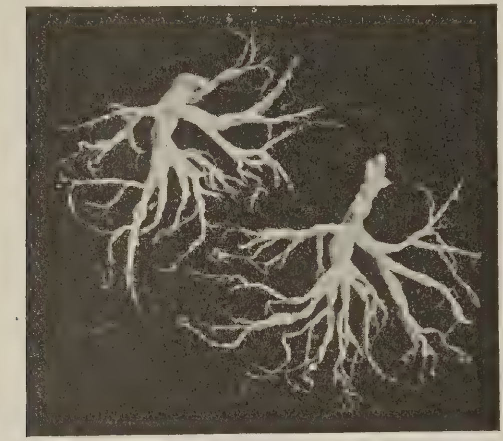

FIG. 2092.—Fibrinous Casts Photographed by the Author from Specimens Obtained from a Case Coming under his own Observation. (Three-fifths natural size.)

PATHOLOGY.—Hyperæmia and swelling of the bronchial mucous membrane have been found in most of the cases examined after death, but the autopsies have been few. In some instances the epithelium was intact, in others it had been lost. Casts when present were more or less firmly adherent to the bronchial walls or lay detached within their lumen. In acute cases there was often evidence of extensive inflammation reaching from the trachea to the terminal bronchioles, while in most chronic cases the disease had been confined to one or more isolated regions.

The casts (Fig. 2092), pure white or of a cream color, sometimes streaked with blood, are firm and very elastic in consistence. They correspond in size and contour to the lumen of the bronchial tree, branching dichotomously, and extending, as a rule, to the finest branches. They vary in length from 5 to 15 cm. The main stem is cylindrical, from 0.5 to 1.5 cm. in diameter, and corresponds to the second or third subdivision of the bronchus. It is either patulous or is filled with mucus. The smallest branches are generally compact, those of intermediate size contain air. From the presence of small masses or nodules at the extremities of the terminal branches or along their sides (Fig. 2093) it has been inferred that the plastic formation had extended into the infundibula. Transverse sections of the largest branches have to the naked eye a lamellated appearance, and the microscope reveals superimposed layers of a delicately fibrillated substance. In the meshes of this tissue various cellular elements are found—epithelium, leucocytes, oil globules, and sometimes red blood corpuscles. In the smaller branches Charcot-Leyden crystals and Curschmann's spirals are sometimes seen. Klebs[14] attributes the formation of casts to increased transudation into the alveoli arising from dilatation of blood and lymph vessels, and Eppinger[15] thinks that they are due to the escape of blood serum rich in fibrin into the bronchial tubes.

The chemical structure of the casts has not been definitely determined, although they have generally been regarded as composed of fibrin. Strümpell found that the Weigert fibrin stain had no effect upon them. Beschorner[16] reports two cases examined by Neelsen, in which they were composed chiefly of mucin; Grandy[17] found mucus alone, and Herzog[18] proved them to be definitely fibrinous by the characteristic fibrin stains and particularly by the peptic test. From these different results and limited personal investigation it seems probable that the casts are not always the same in chemical composition, or that they are composed of a substance closely related to both fibrin and mucin, but not identical with either of them.

SYMPTOMS.—The acute form may have a sudden, severe onset, with high fever, chill, dry cough, dyspnœa, and constriction of the chest, but in most cases it begins as a simple acute bronchitis, with cough, scant expectoration of clear mucus, and possibly a slight elevation of temperature. In children it is often preceded by malaise. Much difference is noted in the severity and abruptness of the initial symptoms in different cases. A chill may mark the transition from the simple to the fibrinous form. The pulse rate is accelerated, partly perhaps as a result of interference with the bronchial circulation. With the development of casts the cough becomes more harassing and paroxysmal, and the dyspnœa and substernal constriction become more pronounced. A more or less profuse hemorrhage sometimes accompanies or follows their expulsion. A most gratifying relief follows the removal of the obstruction, but it is transitory and the paroxysm may recur within a few hours. The casts are sometimes extensive. Niemeyer[19] records the case of a girl fifteen years old who for several years expectorated almost daily an entire cast of the left bronchial tree. In severe cases digestion becomes impaired, nutrition is interfered with, and great nervous irritability may be exhibited. Recovery takes place by a gradual subsidence of the symptoms; the casts no longer appear, the temperature, although high, rapidly declines, appetite and strength return. Fatal cases generally terminate in from three days to two weeks, sometimes suddenly by suffocation.

The chronic form generally follows a more or less protracted bronchial catarrh. Its course is one of exacerbations and remissions. Paroxysms of cough, dyspnœa, and constriction occur, to be followed by temporary relief when the casts are expelled. The paroxysms may be of short duration, but they recur at longer or shorter intervals for weeks, months, or years. Walshe[20] records a case of seven years' duration, Schnitzler[21] one of twenty-four years, and Kisch[22] one that lasted twenty-five years. Every grade of severity is seen in the recurrences, and months or years of perfect health may inter-

vene. Only a limited area of the bronchial system is involved in most cases, and the casts that are coughed up from day to day may be almost identical in size and form. The temperature rises, if at all, during the exacerbations and does not generally reach so high a degree as it does in the acute form.

The physical signs are exceedingly variable in both types of the disease and depend for the most part upon the presence or absence of casts in the bronchi at the time of examination. Retraction of the intercostal spaces and diminished respiratory excursions on the affected side have been noted. In acute cases we may find all the evidences of an acute bronchitis; in the intervals of quiescence there may be no adventitious signs. Percussion is usually negative; if, however, a considerable portion of the lung has undergone collapse as a result of the plugging of its bronchi, corresponding dulness will be elicited. A tympanitic tone has been more frequently noted, and is to be expected over the other parts of the lung in the presence of atelectasis. The results of auscultation are equally uncertain. Every variety of râles, from the sonorous and sibilant to the fine subcrepitant, may be heard, and blowing, rasping, rattling, and flapping sounds have been described. Over a collapsed area the normal vesicular murmur is replaced by bronchial breathing, and the vocal resonance is intensified. Flint[23] regarded the subcrepitant râle, confined to a limited area and not diffused as in capillary bronchitis, of value in the diagnosis. Escherich was able to see the fibrinous coating of the trachea surrounded by a hyperæmic and swollen area of mucous membrane in the laryngoscopic mirror, but as a rule the diagnosis rests solely upon the expectoration of the characteristic fibrinous moulds. To recognize these the sputum must be dropped into water where they unfold from the mass of mucus in which they are usually embedded. It is possible that the disease is sometimes overlooked from failure to make this test or when, as often happens with children, the sputum is swallowed.

Prognosis.—A guarded prognosis should always be made in acute cases. Strümpell places the mortality at twenty-five per cent. If, however, those cases are excluded in which the disease is merely a complication of another, perhaps more serious, disorder, neither the acute nor the chronic form can be regarded as in itself extremely dangerous. Recovery is the rule in chronic cases, but the duration of the immunity is uncertain. Much depends in either type upon the physical condition of the patient. The prognosis is, therefore, much more favorable in the primary form than in the secondary. High temperature is always to be regarded with suspicion if it persists through the intervals between the paroxysms, as it may indicate the development of pulmonary complications. There is at all times a possibility of accidents even in the most hopeful cases. The plastic membrane may quickly extend upward into the trachea, or a capillary bronchitis may develop. Oppolzer and Fagge each report the fatal termination of a case through plugging up of the glottis or trachea by a large cast after it had become detached. Death has occurred before casts had been expectorated. The danger is always greatest in the extremes of life. And there is no means of prognosticating the course of the chronic form, its recurrences and remissions, for each case has its own peculiarities.

Treatment.—No uniform method of treatment has been adopted. Many remedies have been tried with more or less benefit, but it is difficult to estimate the results, since so few cases have come under the care of any one observer. Potassium iodide has been employed more extensively than any other medicine with a view to hastening the detachment of the fibrinous deposits. It has been given in large or small doses, alone or with the alkaline carbonates, but its effect has not been uniformly satisfactory. Ammonium chloride, ipecacuanha, senega, benzoic acid, apomorphine, and other expectorants have been recommended for the same purpose. Emetics may be employed in robust individuals to assist in the expulsion of the casts after they have become detached. Apomorphine administered hypodermically in the dose of gr. $\frac{1}{10}$ has given the best results. Mercurial inunctions are recommended by Eichhorst[24] and Strümpell, but are condemned by others, except in syphilitic cases. N. S. Davis, Sr.,[25] obtained prompt benefit from sodium salicylate in a rheumatic subject. In the writer's case prompt recovery followed the administration of creosote carbonate in fifteen-drop doses.[26] Steam and various medicaments have been recommended for use by inhalation, but it does not seem probable that any remedy can be applied to the smaller tubules by this method in sufficient quantity to be of real benefit. Stewart and Gibson[27] find steam of undoubted utility. Lime water and solutions of the alkaline salts, lactic acid, carbolic acid, or trypsin have been employed by atomization. Schnitzler suggests the employment of papayotin in this manner, and Ewart recommends the intratracheal injection of oil.

Every effort should be made to improve the general condition of the patient by such measures as are advisable in cases of chronic bronchitis. In this way only is there a hope of preventing future attacks. Residence in a dry, bracing, atmosphere (Oliver[28]), proper clothing, good food, exercise especially directed to the development of the respiratory muscles, proper bathing, with the administration of the bitter tonics, arsenic, iron, and malt preparations, or cod-liver oil, are worthy of trial. In many cases the treatment of the underlying condition must to a great extent take precedence over that of the disease itself.

FIBROMA.—Definition; Synonyms; General Characteristics.—A fibroma is a tumor composed of fibrous connective tissue, *i.e.*, of cells, fibrillæ, and vessels. It is known also under the name of fibroid, desmoid, and, in certain positions, polypus. The term "fibroma" is applicable only to circumscribed new growths of connective tissue, and does not include the diffuse connective-tissue hyperplasia seen in elephantiasis, nor the connective-tissue stroma entering into the composition of other sorts of tumor. In this connection it is to be observed that the application of the term "fibroid" to the common tumor of the uterus is incorrect, since this tumor consists primarily of smooth muscle, and is therefore a myoma. The fibroma is a member of the connective-tissue or histoid group of tumors, and is co-ordinate with the lipoma, the chondroma, the myoma, etc. It is non-malignant, although not always sharply to be distinguished from certain forms of sarcoma. It is widely distributed, and may occur in any part of the body containing fibrous connective tissue.

General Morphology. Varieties.—Fibromata occur as rounded, sometimes lobulated, masses, often sharply circumscribed, and varying in size from a few millimetres to many centimetres in diameter. One variety of this form of tumor, the keloid, presents a more diffuse and less circumscribed character than is typical of the fibromata as a class. Fibromata originating in the subcutaneous and in the submucous tissues may present a papillary form and constitute certain sorts of so-called papillomata and polypi. According to their consistence and in a measure to their histological structure, fibromata present two general morphological types: (1) Hard; (2) soft.

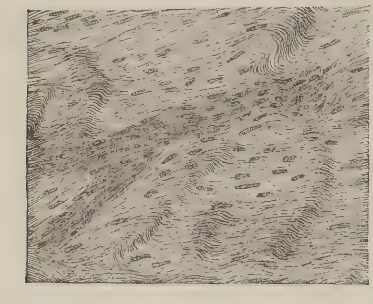

FIG. 2094.—Section of a Fibroma of the Ovary. (From Councilman.) The tumor is dense and compact; the cells are few in number; in several places on the section bands are seen in which the cells are more abundant. × 75.

I. HARD FIBROMA (F. durum.).—(*a*) *Anatomical Characteristics.*—This type occurs usually as a mass varying in size from that of a pin's head to that of a cannon ball, the smaller tumors rounded, the larger often lobulated; sometimes encapsulated; of white or pink color, and of very firm, tough consistence. Upon section the tumor creaks under the knife, and presents a dry, white or grayish-white, rather refractive surface, marked by striæ traversing it in various directions, sometimes forming concentric lamellæ or whorls. The surface of section in some cases presents a small amount of fluid resembling that found in synovial cavities, or is marked by red points corresponding to divided blood-vessels. The physical properties of the tumor may be uniform throughout its entire extent, or may vary in different localities.

(*b*) *Histological Characteristics.*—The constituents of this type of fibroma are analogous to those composing the dense fibrous connective tissue of the tendons, the fasciæ, and the periosteum. They consist essentially of connective-tissue cells, variable in number, but usually few, and fibrillæ closely compacted and running in various directions. The cells ("connective-tissue corpuscles") possess but little protoplasm and are recognizable chiefly by means of their nuclei, which are rather small, deeply stained, and spindle- or rod-shaped, sometimes curved; when cut transversely, the nuclei appear round. In a fibroma which is growing rapidly the cells are relatively numerous, large, and rich in protoplasm. The number of the cells is of no special significance, provided that they present the characteristics of the normal connective-tissue cell. The fibrillæ (intercellular substance) occur in compact, more or less wavy, refractive bundles between which may be seen the nuclei of the cells. In some instances the fibrillæ are indistinct and appear to be merged into homogeneous lamellæ. Besides the ordinary fibrillæ, the intercellular substance may include a variable amount of elastic fibre. In addition to these histological elements, the hard fibroma presents blood-vessels and a variable number of leucocytes and of lymphoid cells, the last named occurring usually in the form of perivascular groups which may be regarded as small lymph nodules (Ribbert). The blood-vessels vary both in number and in size; ordinarily they are few and poorly developed. In occasional instances the veins are of abnormally large size (F. telangiectaticum, F. cavernosum; angio-fibroma).

According to their situation, hard fibromata may embrace yet other constituents, and thereby present a more complex structure than that which is characteristic of simple fibroma, and one which in some instances warrants the classing of the tumor with other sorts of new growth. Thus fibromata arising from epithelial structures and from nerves, or occurring in their vicinity, by including such structures within them, may acquire special and distinctive characteristics (adeno-fibroma; neuro-fibroma; papilloma). Again, the development of fibromata from periosteum and from perichondrium may result in the presence, in such tumors, of bone or of cartilage (*vide infra*).

II. SOFT FIBROMA (F. molle; F. areolare).—(*a*) *Anatomical Characteristics.*—The soft fibromata occur as circumscribed, round, or lobulated masses, often of very large size, of a pale yellow color, and of soft, inelastic consistence. Upon section, they present a slightly transparent, grayish-white surface, showing a fine meshwork of fibres, sometimes large cystic spaces, filled with a variable amount of clear, watery fluid which flows freely from the cut surface, and allows the tumor to collapse. Occasionally the surface of section is traversed by broad, fibrous bands running in various directions.

(*b*) *Histological Characteristics.*—The structural elements of this form of fibroma correspond to those seen in the areolar type of fibrous connective tissue. They consist essentially of cells and fibrillar intercellular substance. The cells in general are of the type common to mature connective tissue. Together with these are larger, round, oval, or stellate cells. As in the hard fibroma, nodules of lymphoid cells are frequently present. The intercellular substance is relatively scanty, and the fibrillæ are delicate and arranged in small bundles. Elastic fibres occur frequently, and in some cases are so abundant as to form a large part of the tumor. The fluid content of the tumor upon microscopic examination presents but few cellular elements, and therein differs distinctly from the opaque, milky fluid, rich in cells, which may be expressed from malignant, highly cellular tumors.

The distinction between these two types of fibroma is not absolute; every gradation between the hard and the soft varieties occurs, and not infrequently both sorts are represented in the same tumor.

III. KELOID.—Included amongst the fibromata is a connective-tissue new growth of somewhat variable character and known by the name of keloid (cheloid). It differs from other fibromata in manifesting a less circumscribed mode of growth, in presenting a close resemblance to scar tissue, and in being devoid of elastic tissue (Aschoff). The keloid develops in the corium of the skin as a dense mass of connective tissue often of considerable size, situated usually just beneath the epidermis and smoothly covered by it. It may remain as a scar-like band, or by its weight become flattened and polypoid. The growth is not always sharply defined, and may not seem to possess the physical properties of a tumor. Histologically the keloid consists of dense fibrous connective tissue closely resembling scar tissue and containing thick, refractive bundles of fibrillæ. In its earlier stages of development, or when growing rapidly, the tumor is very cellular. It often is connected with underlying parts by fibrous prolongations, which render its complete extirpation difficult. Two types of keloid may be recognized, according to the origin of the tumor: (*a*) Cicatricial; (*b*) spontaneous.

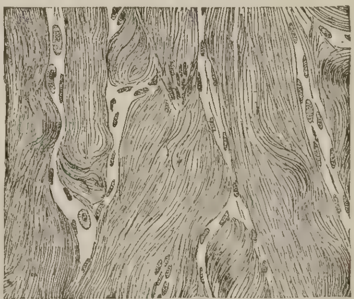

FIG. 2095.—Section of a Spontaneous Keloid from the Ear of a Young Negro. (From Councilman.) × 75.

(*a*) The *cicatricial keloid* occurs after injuries to the skin as an hypertrophy of the resulting scar, with more or less tendency to recurrence after removal. This form of keloid is more apt to develop in the scar following burns than in that consequent upon other sorts of injury. It is said to be more common in tuberculous and in syphilitic subjects than in others. Keloids developed from cicatricial tissue resulting from an infected wound of the skin may be transitory (Aschoff).

(*b*) The *spontaneous keloid* ("true keloid") occurs independently of trauma. It consists of dense connective tissue. Like the cicatricial keloid, and owing to the difficulty of complete extirpation, it possesses a marked tendency to recurrence. It appears most often in persons who live in tropical climates, and gives rise to intense itching in stormy weather.

MODE OF GROWTH.—Fibromata, from the fact of their dense consistence and relative paucity in cells, in the course of their development present no tendency to invade surrounding structures nor to produce metastases, and are thus essentially benign tumors. Increase in size is by central growth; surrounding structures either are pushed aside or undergo atrophy. In many instances the fibroma is enclosed by a capsule composed of dense tissue, which separates it sharply from surrounding structures. Others are less sharply defined, and bands of fibrous connective tissue pass from the tumor into adjoining parts; this may be true even of the pedunculated forms. The total extirpation of such a tumor is difficult and at times almost impossible. This fact probably accounts for the recurrence of fibromata in certain instances after operation. Leucke states it as a general rule that when operation for removal is complete there will be no recurrence. In other instances, supposed fibroma may have been a fibro-sarcoma. Virchow mentions a case, however, in which a large primary fibroma of the uterus was associated with metastatic secondary tumors in the mesentery and the omentum. There seems to be no tumor which under certain circumstances may not become malignant.

The course of development of the fibroma is slow but continuous, and the size to which it may attain indefinitely great. The direction of growth is always in that of least resistance, but in certain positions fibromata may exert considerable pressure and thereby injure surrounding parts. Fibromata developed in the skin and in the mucous membranes, if of sufficient size, may push upward, carrying the covering epithelium before them, and so give rise to warty or papillary tumors sometimes pedunculated and polypoid.

OCCURRENCE.—SPECIAL MORPHOLOGY.—The occurrence of fibromata is not associated with any special locality, but tumors of this class may originate in any part of the body which contains fibrous connective tissue. They develop most frequently from the skin, the subcutaneous tissue, the periosteum, the intermuscular septa, the submucosa of certain mucous membranes, and the nerve sheaths; also from the serous membranes, the retroperitoneal tissue, the perichondrium, and from the connective-tissue stroma of such organs as the breast, the kidney, the spleen, the ovary, and the uterus. The tumor presents distinctive morphological characteristics dependent upon its locus of occurrence.

1. *Skin.*—The skin is very commonly the seat of fibromata. They here may be of either variety, but are usually of the soft type; may originate either in the corium or in the subcutaneous tissue; and are often multiple. The multiple fibromata do not possess genetic unity, but may arise in various ways. The more common form of fibroma of the skin, and one frequently multiple, is that designated by Virchow as

(*a*) *Fibroma molluscum.* This develops from the subcutaneous areolar tissue of the face or of the back, sometimes of the entire body, as a rounded, dependent, often pedunculated outgrowth, at times no larger than a pea, often attaining an enormous size, and presenting a soft, almost fluctuant consistence. The tumor is sometimes broad, and when pendulous from its weight is attached to the body by a wide fold of skin. Such a tumor is known as *cutis pendula.* Histologically, this sort of fibroma is rich in cellular elements, many of which are spindle-shaped. Another mode of occurrence, in the skin, of multiple fibromata is seen in

(*b*) *Neuro-fibroma.* This form of tumor presents itself in the form of multiple, hard, spindle-shaped masses varying in size from that of a small pea to that of a walnut, and distributed along the course of a single nerve, or of all the nerves of an extremity or even the whole body. They originate from the connective tissue of the nerve sheaths, and usually contain within their substance a certain number of nerve fibres included by the tumor in the course of its development.

(*c*) *Multiple fibromata* of the skin of the hard type have been shown (von Recklinghausen) to originate also from the connective-tissue sheaths surrounding the sebaceous glands, the sweat glands, the hair follicles, and the vessels of the corium.

2. *Mucous Membranes.*—Fibromata of the mucous membranes develop from the submucous tissues, appear in the form of polypi, and are often multiple (Ribbert). In the nares they occur as soft, pedunculated, often œdematous masses, constituting one of the varieties of nasal polyp. In the larynx fibromata are common, and appear as polypi situated usually upon the vocal chords or in the fossa of Morgagni; the tumor may be of the hard type, originating from the perichondrium. Fibromata sometimes occur in the alimentary tract, especially in the large intestine.

3. *Periosteum.*—Periosteal fibromata are frequent; they contain not infrequently bone, which in amount may exceed that of the fibrous connective-tissue elements; and they present the appearance of firm, hard masses easily mistaken for either chrondroma or osteoma. An important example of periosteal fibroma is seen in one of the varieties of nasal polyp, viz., that occurring in the nasopharynx. The tumor here originates from the periosteum of the base of the skull, extends downward and laterally into the pharynx, and forward into the nares, and is remarkable for the destructive energy of its growth, which may suffice to force apart the bones of the face, giving rise to the characteristic "frog-face." It is usually lobulated. Histologically, it is characterized by a dense fibrous structure, although at times large vessels are present, and in other instances the cells are relatively numerous and indicate by their protoplasmic character rapidity of growth. The vascular character of certain of these tumors renders considerable the hemorrhage incidental to their removal. The naso-pharyngeal polypi contain as a rare constituent occasional islands of cartilage. Periosteal fibromata not infrequently occur as small masses upon the maxillæ of old people.

4. *Parenchymatous Organs.*—In the mammary gland the fibroma appears as a firm, circumscribed, encapsulated tumor, which may be multiple; and also as a more diffuse growth; the latter can with difficulty be differentiated from the fibrous induration consequent upon chronic inflammation. The fibroma of the breast frequently originates in the periglandular connective tissue; in this case there is usually associated hyperplasia of glands. Pressure exerted by the tumor upon the glands and their ducts may lead to cystic dilatation, and into the resulting spaces papillary projections of the tumor may extend, carrying upon their surface the glandular epithelium. Certain of these projections may grow for a considerable distance into the lumina of the glands and of their ducts, giving rise to variable and complicated histological appearances. Anatomically, such a tumor upon section presents clefts or irregular fissures, with occasional small cysts containing clear, viscid fluid. When the cyst formation is extensive, the major part of the tumor may project into the cavity, and upon section appear as a large, irregular polypus. This form of tumor belongs to the class of adeno-fibroma.

In the kidney a curious form of fibroma is met with. It appears as a pearly white, firm nodule, situated usually near the base of a pyramid, and histologically presents the characteristics of a circumscribed interstitial nephritis.

RETROGRADE METAMORPHOSES.—Retrograde changes of every variety occur in the fibroma, usually after prolonged duration of the tumor.

1. *Mucoid degeneration* is the more frequent, and is characterized by the formation of large cysts containing thick, viscid fluid. The process begins with an increase in the cellular constituents of the tumor, associated with a mucoid degeneration of the intercellular substance which thereby undergoes softening and is reduced to a fluid state. The cells in the degenerated area then disappear, the resulting space being occupied by the fluid. This degeneration may readily be confused with

2. *Œdematous infiltration*, a condition due to disturbances of circulation within the tumor; here the ground substance of the growth becomes soaked with fluid, the fibrillæ are pressed apart, and the tumor becomes soft and spongy, upon section presenting the appearances seen in gelatinous infiltration of the skin or in the umbilical cord.

3. *Fatty degeneration* occurs infrequently in the central part of the larger fibromata; the region involved becomes yellow, soft, and ultimately may be converted into a cavity filled with fatty detritus. Such an area of softening, if it extend to the surface of a fibroma situated near a free surface, may lead to ulceration.

4. *Calcification* is sometimes seen, at first in small and circumscribed areas, latterly in perhaps a large part of the tumor. The capsule of the tumor may be in great part calcified.

5. *Ossification* is common in fibromata developed from the periosteum, and occasional in those originating elsewhere.

COMBINATION WITH OTHER TUMORS.—The fibroma is frequently in combination with other members of the connective-tissue group of tumors. It is most often seen in association with *sarcoma* in the form of a tumor parts of which are made up exclusively of spindle cells and parts of fibrous connective tissue, with elsewhere intermediate gradations; such a tumor is known as a *fibrosarcoma*. Another combination often met with is the *myxo-fibroma*, which is a more common tumor than simple fibroma; here, in addition to fibrous connective tissue, the tumor contains myxomatous tissue consisting of branched and stellate cells embedded in a mucoid matrix. Association of fibroma with *hæmangioma* is seen in fibrous connective-tissue tumors containing large, intercommunicating venous sinuses; and with *lymphangioma* in such tumors of that class as show marked development of their connective-tissue elements. Combination with *myoma* is seen in the common tumor of the uterus; connective-tissue formation is here usually subsequent to the hyaline degeneration of portions of the primary constituents of the tumor. (For Neuro-fibroma, see *Neuroma*.)

ETIOLOGY.—Fibromata may develop at any time of life, and are sometimes congenital; they occur more frequently after the twentieth year than during childhood, but are not common in old age. The fibromata of the breast, like myomata of the uterus, occur most frequently between the thirtieth and the fortieth years; they are as common in nulliparous women as in those who have borne children.

As to the cause of this class of tumors there is little to be said. Irritation is often supposed to stand in causal relation with the origin of fibromata, but there are no better grounds for regarding mechanical injury as a factor in the development of this than of any other tumor. One of the forms of keloid, the cicatricial, is consequent upon injury to the skin, but that fact does not explain why the scar tissue in which it develops should become hyperplastic. It is possible that a predisposition to tumor formation may in this case exist in the skin, which becomes manifest as a weakening of the physiological resistance of the surrounding tissues toward the growing reparative tissue, or in a tendency on the part of the connective tissue to assume this special mode of growth. There is some evidence of a family predisposition to keloid formation (Aschoff).

DIAGNOSIS. — CLINICAL SIGNIFICANCE.—The clinical diagnosis of fibroma in a majority of instances presents little difficulty. The hard fibroma offers distinguishing characteristics in its circumscribed form and in its dense and homogeneous consistence. From the *sarcomata* as a class it may be differentiated by its relatively slow rate of growth. From *scirrhous carcinoma* it is usually distinguishable, save in those instances in which the fibroma is so situated as to cause pressure, by the absence of pain, by the mobility of the tumor, and by freedom from involvement of overlying skin. The differentiation of hard fibroma from *fibrous induration* of glands offers more difficulty, and is often attended with error. In such cases an important aid to diagnosis lies in the clinical history of a previous inflammatory process. The soft fibromata, or such of the hard type as have undergone degeneration with subsequent softening, may easily be mistaken for *lipomata* or for *cysts*.

Histological diagnosis offers little difficulty save when the tumor presents an appearance intermediate between fibroma and sarcoma, or when there is a question of fibroid induration, or of scirrhous carcinoma containing but few epithelial elements.

The clinical significance of the fibroma is comparatively slight. An essentially benign tumor, it is harmful only when its position is such as to result in pressure upon surrounding and possibly vital parts, or in the obstruction of important natural canals. Fibromata of the skin, from their exposed situation, are liable to trauma, and if injured may become the seat of ulceration.

George Burgess Magrath.

FIG.—FICUS. "The fleshy receptacle of *Ficus Carica* L. (fam. *Moraceæ*) bearing fruit upon its inner surface" (U. S. P.). This fruit can scarcely be regarded as a medicinal substance, though nutrient, and, like most sugary fruits, slightly laxative. It is retained in the Pharmacopœia merely because of its entering into the *Confectio Sennæ*, but it seems likely that both it and the latter little-used remedy will shortly be dropped. Figs are commonly combined with purgatives. One method is to turn them inside out and stuff them with senna leaves, the mass being then chewed and swallowed. Figs grow upon a large shrub or small tree, natives of the Orient, but cultivated in all warm countries, being hardy, with slight protection, as far north as Philadelphia. The dried fruit consists of nearly two-thirds its weight of sugar, some fat and gum, and small amounts of laxative salts. It is decidedly nutritious and has been known, in the fresh state, to constitute the chief food of armies for short periods. Besides the varieties distinguished by the names of the places from which they are exported, as Smyrna, Turkey, Greek, Marseilles, etc., figs are imported in two forms, known as "pulled" and natural. The former are rolled and kneaded until their structure is broken up and they have become soft and pliable; the solidly packed, layered, flattened figs are of this sort: the others are simply dried in the natural condition. These are oblong, rounded, and longitudinally wrinkled. *Henry H. Rusby.*

FIGWORT. See *Scrophulariaceæ.*

FILARIA MEDINENSIS; FILARIA SANGUINIS HOMINIS. See *Nematodes.*

FILMOGEN (Liquor adhæsivus) is a solution of soluble cellulose nitrate in acetone, with the addition of a little castor oil. It is transparent, adhesive, and impervious to water, and resembles flexible collodion in its appearance and uses. *W. A. Bastedo.*

FISSION.—(L. *fissio*, a cleaving, from *findere*, to split.) Fission is a process of multiplication in which the parent organism divides into two daughter organisms approximately equal in size and development; as distinguished from budding, in which the parent remains intact and the daughter organism is a new individual formed by a small outgrowth upon the parent. (See article *Budding.*)

Ordinary cell division is a process of fission, and, consequently, this is the usual method of reproduction among the unicellular organisms. The yeasts and some of the Protozoa, however, reproduce by a process more accurately described as budding. But the Bacteria, Protophyta, and nearly all of the Protozoa mutiply by fission and often with almost incredible rapidity. In the simpler forms there are no preparatory changes other than those ordinarily associated with cell division in these groups. But in the more highly differentiated Infusoria provided with permanent oral funnels, ciliated bands, etc., these structures may be duplicated in the two new individuals previous to their separation, a process analogous to what takes place in many multicellular organisms.

The multiplication of individuals by fission is unknown among plants above the very simple Schizophyta.

Among the Metazoa, on the other hand, this method of multiplication is common in some of the lower orders and may occur abnormally in so high a group as the vertebrates.

In a few cases fission occurs without any previous preparation. The adult animal tears its body apart by its own efforts. A wound is formed by the rupture of the tissues with a loss of the fluids of the body. This wound heals, and from its surface the missing parts of each of the new individuals are regenerated. The method has been observed in the genus Hydra, in two annelids, Lumbriculus and Ctenodrilus, and in certain star-fishes and ophiurans. In the latter the plane of fission passes through the disc dividing the mouth and the stomach, while to one part of the disc three arms remain attached, to the other, two; and each half regenerates the missing parts. But in one family of star-fishes, the Linckiidæ, the process is somewhat different. Here the five arms separate from the disc and then the disc regenerates five new arms, and each detached arm regenerates a disc and four new arms. Delage relates that he observed once the division of a sea anemone, *Anthea cereus*. The two parts of the body were extended as if trying to crawl in opposite directions. The intermediate portion became much constricted and finally ruptured. The whole operation occupied about two hours.

On the other hand, in most animals in which fission is a normal process of multiplication, it is preceded by preparatory changes which result in each of the new individuals being provided with a full complement of organs before separation takes place.

According to Parker, fission in the common sea anemone of the coast of New England, *Metridium marginatum*, is a slow process occupying many months. It begins with the division of the mouth and oral disc accompanied by the formation of new septa, and proceeds gradually toward the base. The final separation has not been observed, however.

In many worms fission takes place in what may be regarded as a larval stage, before the development of eggs and spermatozoa. This, according to Mensch, is the case with Autolytus, and it seems to be so with most of the worms in which fission occurs. In Antolotus and its allies an area of embryonic tissue appears at about the thirtieth segment, dividing the young worm into two parts. On the posterior part there is developed a new head. The tissues just in front of the head undergo degeneration, and by their own movements the two individuals are broken apart.

Among the jelly-fish of the group Scyphomedusæ fission is associated with the metamorphosis from the larval to the adult form. In Cassiopea, for example, the scyphistoma larva is a graceful little creature shaped like a wine glass and lives attached by its base to some solid body. When fully developed this larva becomes divided into two portions by a horizontal constriction. It is then called a strobila. The upper part of the strobila becomes transformed into a medusa, while new larval tentacles and the rudiment of a proboscis are developed on the lower part. Finally the narrow isthmus connecting these two parts undergoes degeneration and is at length ruptured by the violent swimming movements of the young medusa.

Fission may take place in an early embryonic stage of development. According to Kleinenberg this occurs normally in one of the earth worms, *Lumbricus trapezoides*, in which the embryo divides into two shortly after the gastrula stage and both develop into normal individuals. This has been observed to occur under abnormal conditions in the trout and the chick. If hen's eggs be incubated at a temperature slightly above normal a large proportion of the embryos will be found to show a tendency to the formation of double monsters and occasionally the area embryonalis will be found to contain two distinct embryos. A similar division of the embryo may occur in man. If incomplete, it will give rise to a double monster or to such cases as the Siamese twins and Millie-Christine. If the separation be complete the result will be a pair of twins of the same sex. In every case of fission all the individuals produced from a single ovum are of like sex.

In some of the lower forms of animal life fission may be normally incomplete, as in some corals, in which the individuals remain in organic union forming a colony, or cormus.

There are some animals in which a form of fission occurs in the fully mature adult, which does not serve to multiply the individual but for a more favorable dispersal of the sexual products. The formation of proglottides by the common tapeworm is an example. Another example is the palolo worm of Samoa, an annelid that burrows in the coral rock. When mature the posterior portion of the body, distended with eggs or spermatozoa, is separated off and swims on the surface of the water, where the sexual products are discharged. They occur at certain times in great abundance and are gathered by the natives, who relish them greatly as an article of food.

The relation between fission and budding is a very close one, so much so that Bock has argued that they are simply two forms of one fundamental process. In many sea anemones, for example, small fragments of the foot become detached and subsequently develop a mouth and tentacles and become complete individuals. Such cases make it difficult to draw a sharp line between fission and budding. In forms like Autolytus, mentioned above, the two processes are closely associated. For, after the original posterior part of the body is separated off, the embryonic area on the end of the anterior portion, or parent stock, may give rise to any number of new individuals by a continuous process of budding. Nevertheless in most cases the distinction between fission and budding is a clear one and is useful in practice.

FIXED OILS. See *Active Constituents of Plants.*

FLAG, BLUE.—IRIS. "The rhizome and roots of *Iris versicolor* L. (fam. *Iridaceæ*)" (U. S. P). This is a very common swamp plant of eastern North America, erect, about two or three feet high, with sword-shaped, equitant leaves and handsome blue flowers, marked in the centre with white and yellow stripes.

Rhizome of horizontal growth, branched, the branches 5 to 10 cm. (2 to 4 in.) long and 1 to 2 cm. (⅖ to ⅘ in.) thick, cylindrical in the lower half, thence becoming vertically flattened toward the crown, where it is terminated by a circular scar; dark brown, wrinkled, annulate with the leaf-bases; fracture short, purplish; roots long, slender, simple, crowded near the flattened end; odor peculiar; taste pungent, acrid, and nauseous.

This drug was in use by the aborigines, and has been employed to a moderate extent by physicians for many years. The uncertainty and harshness of its action have, however, prevented its becoming a favorite. An acrid resin, fixed oil, tannin, gum, starch, etc., are given as its constituents.

It belongs to the resinous class of cathartics. When quite fresh, it is an irritant-emetico-cathartic, easily acting as a poison in over-doses. Upon drying and keeping, these harsh actions are continuously ameliorated, and after a year or more it becomes a reliable purgative, not excessively harsh if given properly diluted and with the drug well distributed through the excipient. It then ranks with jalap, leptandra, and similar drugs.

Dose of the powder, from 0.5 to 1.5 gm. An extract (*Extractum Iridis*), dose gr. i. to iij., and a fluid extract (*Extractum Iridis Fluidum*), dose ♏ x. to xxx., are official. A precipitated extract, "Irisin" or "Iridin," is in rather common use. *Henry H. Rusby.*

FLAG, SWEET. See *Calamus.*

FLEABANE.—ERIGERON. Several species of the large genus *Erigeron* L. (fam. *Compositæ*) have been official and largely used in medicine. Because of their inferiority, they gradually disappeared from use, with the exception of one, known as *E. Canadense* L. Botanists now accord this generic distinction from the others. It is known as *Canada Fleabane, Colts-tail, Pride-weed, Bitter-weed,* Blood-staunch, etc., the leaves and flowering tops of *Leptilon Canadense* (L.) Britton. The plant is a very tall and robust annual weed, exceedingly common and abundant in the eastern United States and Canada, and widely distributed over the entire world, in tropical as well as temperate regions. The hairy stem is from two to eight feet high, erect, slender, simple up to the inflorescence and densely clothed with ascending or nearly erect lanceolate leaves, from three to six inches in length. Above this the tawny, fluffy paniculate inflorescence strongly suggests the appearance of a colt's tail and gives the name. The drug contains much tannin, about one per cent. of the volatile oil next considered, and an amaroid. It is not remarkable that this should be one of the most valuable of all household remedies for controlling severe attacks of serous diarrhœa, as its oil powerfully stimulates the sympathetic abdominal nerves, while its tannin astringes locally. It is at the same time a good aromatic bitter. The country practice of giving it in infusion, in doses of ʒ ss.–i., is improved upon by giving 2 to 4 c.c. (fl. ʒ ss.–i.) of the fluid extract.

Henry H. Rusby.

FLEABANE, OIL OF.—OIL OF ERIGERON. OLEUM ERIGERONTIS (U. S. P.). A volatile oil distilled from the last, of a pale-yellow or brownish color, a peculiar, pleasant odor, and a warm, pungent taste. It has a spec. grav. of about 0.850, increasing with age to about 0.890, and consists chiefly of dextrogyrate limonene. It is quite a different substance as distilled, even when fresh, from what it is in the plant, as there is a portion which is destroyed by even a moderate heat. This fact, together with the absence of the other constituents of the herb, indicates the error of substituting the latter by the oil. The oil is, however, active. It belongs to the astringent class of volatile oils, acting like oil of turpentine in this respect, but without its irritating properties. It is administered for the same purposes as fleabane, and for the control of hemorrhages of the bowels and uterus, and for gonorrhœa. The dose is 0.3 to 1 (♏v. to xv.).

Henry H. Rusby.

FLORIDA.—Twenty years or more ago Florida was perhaps the most popular winter resort in this country for the consumptive. He was sent there in all stages of the disease, especially in the more advanced ones. It was the final resource when all else failed, and, in the majority of cases, proved to be an illusive one.

At the present day it is rare that the phthisio-therapeutist directs his consumptive patient to this region, although possessing a winter climate unexcelled in many of its characteristics by any region east of the Rocky Mountains. Why is this? In a word, it is because we now have a truer conception of the limitations of climate, in its application to pulmonary tuberculosis. The hygienic-dietetic treatment is the authoritative one, established on the firm foundation of experience; and in the execution of this treatment climate is but one factor, and perhaps not the most essential one. Formerly climate was supposed to be the great determining element in the treatment and all else was merely accessory; and further, a warm climate was considered to possess peculiar advantages for the consumptive.

It is natural that such should have been the idea entertained with the knowledge of the pathology of the disease then obtaining, and before the results of Brehmer and other German pioneers in the sanatorium treatment had become known or had indeed been determined. What more natural than that a consumptive depressed in mind and body should look to a warm, sunny, equable climate, with its semi-tropical attractions, as the El Dorado from whence he should receive renewed hope and health? Although Florida will continue to be a great and a popular health resort for many functional and organic diseases, and for the valetudinarian in general, as will be more fully discussed later, it will still also, in the writer's opinion, offer certain locations which possess the essential climatic conditions for the successful accomplishment of the hygienic-dietetic treatment of tuberculosis. If situated on the more elevated portions in the central part of the peninsula, it would seem that sanatoria would justify their existence. Or even if they are situated upon the coast at one side or the other, they should serve a good purpose, for at these points there surely would be pure air, an abundance of sunshine, and an equable temperature, with a freedom from high winds. The objections are the enervating character of a warm climate of this nature,—a climate that increases the anæmia usually found in phthisical patients, as Solly has observed,—and also the possibility of malaria, which is present in some of the resorts at certain seasons of the year, and to the influences of which the consumptive with his depressed vitality is peculiarly susceptible.

Such places as Winter Park, Orlando, Altamonte in the interior, and Tampa, Los Pinellas, and the Lake Worth district on the coast, would seem to be favorable for the experiment of the genuine open-air treatment of consumption.

As with all tropical or semi-tropical countries, however, the summer climate of Florida would hardly admit of a continuous residence, which is, in many cases at least, important if the best results are to be obtained, although in Southern Florida the difference between the summer and winter temperatures is comparatively slight. The rainfall, however, in the summer months is considerably higher.

The State of Florida may be described as consisting of a continental portion, immediately contiguous to the States of Georgia and Alabama,—its southwestern portion washed by the Gulf of Mexico,—and a peninsula portion washed by the Atlantic Ocean and Gulf of Mexico. Keating (Transactions of the American Climatological Association, 1885) divides Florida geographically into a north and a south portion, the boundary line being the 29th degree of latitude, and topographically into the lowlands on the rivers and coasts, and the interior highlands, with an altitude of from 100 to 300 feet. Below the 29th parallel, the climate, both in summer and in winter, differs from that of the region north. The cold northwest winds are tempered by the warm waters of the Gulf of Mexico, which prevent the sudden changes of temperature that sometimes occur in the northern portion. In summer the sea breezes from both sides of the peninsula temper the heat and the nights are generally cool (Solly).

The land (except the interior highlands before mentioned) is for the most part low, and there are many lakes, streams, and salt-water channels. The principal river is the St. John's, running north, and navigable for large steamers a distance of 198 miles to Enterprise, and for smaller ones about 70 miles further up the river, to Salt Lake. The soil is "as a rule sandy, very porous in hilly or undulating sections, but finer and more compact on level reaches. The character of the subsoil hard-pan varies greatly in different localities, being sometimes clay and sometimes lime rock, at variable depths of from only a few to ten or more feet from the surface" (J. P. Wall, in the *Climatologist*, October 15th, 1891).

The varieties of land are the pine land in the highlands, high hummock, low hummock, savanna, and swamp. "The pine-land regions are those in which the sandy soil predominates, and, for the residence of invalids, places possessing such sandy soil appear to be the most healthful" (Richards).

The climate is a mild, moist, warm one, with a goodly number of sunny days. The principal season begins in January and lasts until April, and thousands of visitors who desire for any reason to avoid the inclemency of a Northern winter and lead an outdoor life, frequent the numerous resorts. Enormous palatial hotels and many boarding houses and villas exist in various portions of the peninsula, at St. Augustine, Palm Beach, Tampa, Palatka, Altamonte, Magnolia, Enterprise, Titusville, and at many other places. The attractive spots where one may pleasantly spend the winter are almost innumerable. The outdoor attractions in this fascinating country are varied and numerous,—fishing, hunting, bathing, golf, sailing, riding, and all the many excursions by water, chief of which is the famous journey up the Ocklawaha River, where one passes through cypress forests with the graceful hanging moss, or through clusters of palm and palmetto trees, and all the varied vegetation of a tropical region. Alligators are frequently seen, and "birds of the most curious forms and brilliant plumage are everywhere conspicuous" (Appleton's "General Guide to the Southern States," 1899).

The orange groves are always a delight; and the cultivation of the many fruits, flowers, and vegetables which grow so luxuriantly in this climate render outdoor life on the land a constant source of pleasure and interest. "The sun shines so brightly, the air is so balmy, the songs of the birds are so enlivening, and the orange trees in their bloom, or laden with their golden fruit, lend such a charm to the outlook from the windows that the most indolent or most cold-blooded invalid feels little inclined to stay indoors" (Lente).

The climatic characteristics will now be considered somewhat in detail, and for this purpose the following meteorological tables have been arranged from the observations of the United States Weather Bureau.

AVERAGE TEMPERATURE.

	December.	January.	February.	March.	July.	Year.
Jacksonville......	55.8	55.8	58.1	62.7	82.5	69.2
Jupiter	67.2	63.4	66.7	68.8	80.5	73.4
Tampa	62.2	58.6	63.1	66.4	81.5	71.6
Punta Rassa......	64.5	64.7	66.2	68.6	81.3	73.4
Key West	70.1	70.3	71.8	73.6	84.0	77.5

AVERAGE DAILY RANGE.

	December.	January.	February.	March.	July.	Year.

Key West	11.2	10.8	10.4	11.2	7.5	9.7

AVERAGE NUMBER OF CLEAR DAYS.

	December.	January.	February.	March.	July.	Year.
Jacksonville	10.2	9.0	9.7	12.7	10.2	123.2
Jupiter	9.8	13.0	11.0	17.4	12.5	131.4
Tampa	12.1	9.5	8.4	11.7	7.0	115.0
Punta Rassa	12.1	9.8	11.5	14.7	3.4	102.9
Key West	11.0	11.3	11.7	15.8	5.7	113.4

AVERAGE NUMBER OF FAIR DAYS.

Jacksonville	12.0	12.8	10.4	13.0	16.0	156.7
Jupiter	14.1	11.0	11.1	9.7	13.4	153.8
Tampa	12.3	16.4	14.3	14.4	20.0	188.2
Punta Rassa	12.8	15.0	11.4	11.8	10.4	186.1
Key West	15.5	14.7	12.6	12.5	19.8	192.5

AVERAGE NUMBER CLEAR AND FAIR DAYS.

Jacksonville	22.2	21.8	20.1	15.7	26.2	279.9
Jupiter	23.9	24.0	22.1	27.1	25.9	285.2
Tampa	24.4	25.9	22.7	26.1	27.0	303.2
Punta Rassa	24.9	24.8	22.9	26.5	23.8	289.0
Key West	26.5	26.0	24.3	28.3	25.5	305.9

Five points are taken in various portions of the State to illustrate the different climatic factors: Jacksonville, on the St. John's River, about thirty miles from the Atlantic; Jupiter, on the Atlantic Coast, seventeen miles north of Palm Beach; Tampa, about twenty-five miles from the Gulf Coast, and about half-way down the peninsula; Punta Rassa on the Gulf Coast, almost opposite Palm Beach; and Key West at the extreme south, an island about sixty miles from the mainland.

In observing these climatic features the distinguishing characteristics are mildness and uniformity. It will be seen that the diurnal range for the coast stations is small, while that of Jacksonville and Tampa, further inland, is considerably greater, and least of all, as we should expect from its insular position, is that of Key West.

From the table of maximum and minimum temperatures it will be observed that for the four months from December to March inclusive the maximum ranges from 78.1° to 88° F., and the minimum from 19° to 44.8° F.; Key West excepted. "There is a possibility then of frost, snow and ice, although these phenomena are rare: they are the infrequent 'chances,' and occasionally a cold wave sweeps over the whole State, damaging or killing the orange trees, demanding fires indoors and winter clothing out." The relative humidity is high, characteristic of a marine climate, as this is: it is quite uniform throughout the year. "Of course, as might naturally be expected of a climate with the temperature and humidity of that of Florida, heavy dews in clear still nights are always present; and during the winter and spring fogs in the night and early morning are not uncommon. Fogs are, however, somewhat worse on the Atlantic Coast and along the St. John's River than on the Gulf side of the peninsula" ("The Climate of Florida," Dr. J. P. Wall, the *Climatologist*, November 15th, 1891). The mean annual rainfall may perhaps be considered high for a health resort, although about half occurs in the summer. For comparison the mean annual rainfall of various resorts is here given:

	Inches.		Inches.
Jacksonville, Fla	54.6	Aiken, S. C	48.0
Jupiter, Fla	62.1	Thomasville, Ga	51.5
Tampa, Fla	53.0	Augusta, Ga	44.0
Punta Rassa, Fla	43.5	San Diego, Cal	10.0
Key West, Fla	40.8	Los Angeles, Cal	18.0
Redlands, Cal	15.0	Santa Barbara, Cal	18.0
Denver, Col	14.4	Cannes, France	25.0
Nice, France	32.0	Cairo, Egypt	15.0
New York, N. Y	42.5		

The prevailing winds are from the east, bringing the pure air from the Atlantic Ocean. The hourly velocity is between six and ten miles, considerably less than that at Cape May. "With the Atlantic on the east and the Gulf of Mexico on the south and west the temperature of Florida, and especially that of the peninsula, is very much ameliorated by the constant sea breezes, and the climate rendered remarkably equable and genial. The regular alternation of land and sea breezes prevents, especially during the hot season, the discomforts and suffering of excessive heat which is usually associated with the wind in the lower latitudes of the North Temperate Zone" (Wall, *loc. cit.*).

The number of clear and fair days is about the same for each of the resorts under consideration, and the yearly average is large, equal to that of San Diego or of Santa Barbara. Three out of four days during the winter months are fair or clear. The average number of rainy days for the year is considerably higher than at Cannes, Nice, or San Remo; but, as before mentioned, the greater part of the rain comes in the summer. It is to be regretted that there are no meteorological data, so far as known to the writer, for points situated upon the elevated ridge in the interior. Such data would probably approximate more nearly to those of Jacksonville and Tampa, which are situated some miles from the coast, and the mean average daily range of these two places, as we have already observed, is considerably greater than is the case with the coast towns.

Of Winter Park, situated 133 miles south of Jacksonville, 40 miles west of the Atlantic Ocean and 80 miles east of the Gulf of Mexico, with an altitude of over one hundred feet, we are told that "the air is fine and dry, the country around being made up of high pine lands, that there are no marshes or stagnant ponds, but instead a chain of beautiful, clear-water lakes. The temperature of the winter days averages from 60° to 65° F. during the twenty-four hours. Occasionally there is a frost, and once in a while freezing temperature occurs at night, but none during the days. It rains very seldom during the winter months, but there are heavy dews night and morning." (Report on Health Resorts, Transactions of the American Climatological Association, 1895.)

The climate of Key West is "essentially tropical, and typically insular." As will be seen in the tables, July shows a much greater amount of precipitation than the winter months, and such is the case with the other summer months; there is practically a dry (winter) and a rainy (summer) season. From this fact, however, it must not be supposed that it rains most of the time in summer, for July, for instance, shows 25.5 clear and fair days, and the other summer months about the same proportion.

It will be also noticed that the temperature is remarkably equable, the mean of the warmest being 91.3°, and of the coldest 66.5° F.; the diurnal range is also very small. The city of Key West, the largest in the State next to Jacksonville (about 25,000 inhabitants), is situated upon a coral island of the same name, seven miles long and from one to two miles broad. There are no springs on the island, and the water supply is derived from rain water or from distillation.

The foliage and fruits are luxuriant and more or less tropical. The streets of the town are broad, the residences are shaded with tropical trees, palms and brilliant flowers grow in profusion, all giving the town a very picturesque appearance.

Key West is not known as a health resort, as are the other well-known resorts in Florida; it is said, however, to be healthy, and it at least possesses an ideal semi-tropical insular climate. Its sanitary condition is unknown to the writer. It is the most southern city of the United States. "The fishing and boating are unsurpassed, and there are a number of charming drives on the island."

The warmth, abundant sunshine, equable temperature, marine atmosphere, and all the varied charms of land and water will always render Florida one of the great winter resorts of the United States. It is easily accessible from the Northern States by rail or by boat, and it possesses an unrivalled system of hotels. As Dr. Wall truly says:

"To the vast majority of the valetudinarian class from other causes than consumption, the winter's sojourn in the mild marine climate of Florida will always be found a powerful adjunct in re-establishing the impaired health."

Finally, to the person who wants a *change* from the exhausting routine of city social or business life and who, from such or other reasons, has become "stale," to speak in athletic parlance, Florida offers a veritable paradise, provided a simple outdoor life is pursued and business and society are abandoned. The writer can speak from personal experience of the keen delight one experiences in the trip up the St. John's or Ocklawaha River; fishing in the Gulf of Mexico or hunting for sea-beans on the shore. With such novel surroundings, mere existence is a pleasure, and the subtile influences of the balmy atmosphere bring renewed health and strength of mind and body.

Edward O. Otis.

FLUKES. See *Trematoda.*

FLUOROFORM WATER (Fluoroformol) is a saturated (2.8 per cent.) aqueous solution of gaseous fluoroform (CHF_3). It is odorless and almost tasteless, but produces a local reaction on the tissues which is evidenced in the mouth by a stinging sensation. Besides its internal use in tuberculosis and acute pneumonia, Stepp of Nuremburg uses it topically as spray or inhalation for respiratory diseases, as local application for lupus, and as injection for tuberculous joints and sinuses. Internally the dose for a one-year child is 4.0 gm. (ʒ i.), and for adult 15.0 gm. (ʒ iv.) several times a day. One hundred grams have been taken in twenty-four hours without inconvenience (Stepp).

W. A. Bastedo.

FŒTUS. See *Embryos.*

FOLLICULITIS DECALVANS.—This disease has been described under many names, such as alopécies cicatricielles innominées (Besnier), folliculite épilante (Quinquaud), acné decalvante (Lailler), ulerythema sycosiforme (Unna), and Brocq would include under it Kaposi's dermatitis papillaris capillitii.

Symptoms.—It may affect the scalp alone, or the bearded portion of the face from which it may extend to the scalp, while the hair of the pubes and axilla do not escape at times. Upon the scalp it takes one of two forms:

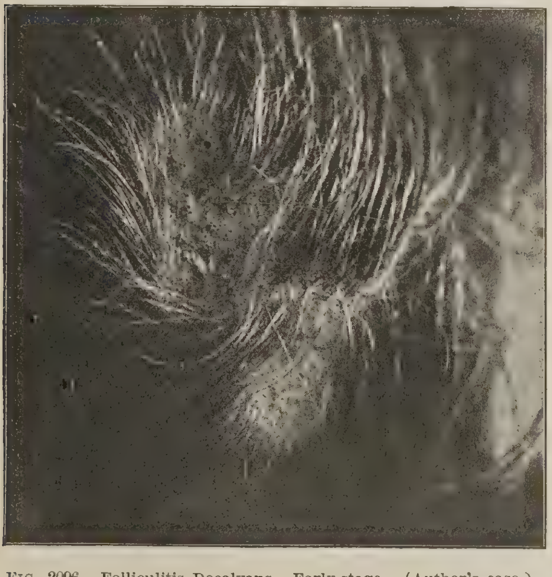

Fig. 2096.—Folliculitis Decalvans. Early stage. (Author's case.)

1. The *alopécie innominée* of Besnier. In this form we find one or more irregular, ill-defined bald patches about which are tufts of hair. Sometimes it will be noted that just beyond the circumscribing tufts of hair are other small bald patches showing the extension of the disease into neighboring parts. The scalp in the patches is cicatricial, thinned, slightly depressed, smooth or stippled over with follicular openings. Signs of active inflammation may be entirely wanting or confined to the mouths of the follicles. At other times there is a slight, diffused redness with furfuraceous desquamation; or there may be some very small and superficial pustules occupying the infundibula of the hair, which in a short time are transformed into depressions out of which the hair falls. As soon as the hair falls all signs of inflammation subside. The hair is permanently destroyed, and the scalp is gradually transformed into a mass of cicatricial tissue. New spots develop here and there in an erratic manner.

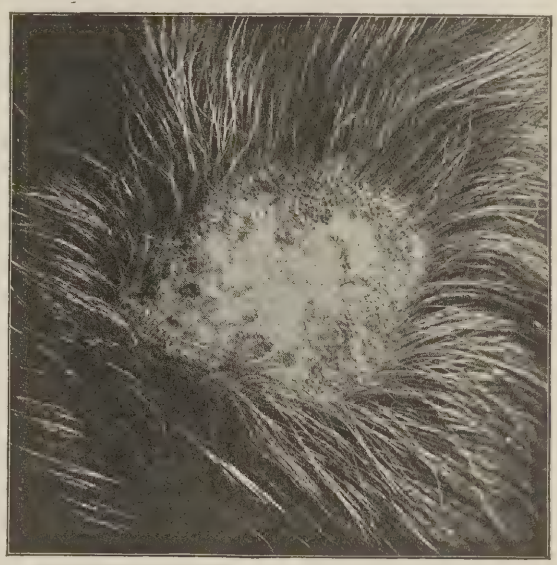

Fig. 2097.—Folliculitis Decalvans. A more advanced stage of the Disease. (Author's case.)

2. This is the *folliculite épilante* of Quinquaud. While the first form is confined to the scalp, the second may also affect the beard, pubes, and axilla. It differs from the first form in being accompanied by more marked inflammation. Like it it produces bald, smooth, irregularly shaped, cicatricial patches. These are scattered through the hair, and are of various sizes up to that of a silver quarter of a dollar. In them are some small red points, while about their edges and in their neighborhood are purulent points, miliary abscesses, and red papules, each with a hair in its centre. The folliculitis causes destruction of the hair which is permanent, giving rise to the cicatricial appearance. If there are a number of patches near each other they will be separated by tufts of sound hair. If the disease occurs on other parts than the scalp it will give rise to similar appearances.

Folliculitis decalvans is a chronic and progressive process, and it is impossible to say how great its ravages will be. It is usually slow in its progress.

Etiology.—Nothing positive is known of the cause of the disease. Some observers have found micro-organisms in relation with it, but we cannot as yet speak positively about these. Inasmuch as some of the cases yield to antisyphilitic treatment, it has been assumed that some of the cases are due to syphilis.

Diagnosis.—Occurring on the scalp it must be diagnosed from alopecia areata and the baldness due to favus. From alopecia areata it is distinguished readily by the fact that it is cicatricial in character, while in alopecia areata the skin is unaltered. Moreover, in the latter disease there are never signs of follicular inflammation. If there are favus crusts or evidences of folliculitis the diagnosis from favus is easy, as in folliculitis decalvans we do not have sulphur-yellow crusts, and in favus we do not have folliculitis. In inactive cases it is impossible to tell which disease we have, as both diseases produce baldness of the same general character. The history of the case will, however, enable us to decide.

TREATMENT.—Thus far, treatment has not been of much avail. Quinquaud recommends washing the patches with soap and water, and painting the scalp in their vicinity with tincture of iodine. Every morning the patches are to be bathed with hydrarg. biniodide, gr. i. (0.065); hydrarg. bichloride, gr. iv. (0.26); alcohol, ℥ ss. (16.); aquæ destillat. ad ℥ iv. (125). Of course the baldness is permanent, the scalp being converted into a cicatrix. *George T. Jackson.*

FOOD AND DRUG INSPECTION.—Modern Legislation Relative to Food and Drug Inspection.—The present article is chiefly devoted to the subject of legislation to provide protection against adulteration and to the amount of work accomplished under such laws.

Popular knowledge upon the subject of food adulteration is undoubtedly derived to a great extent from the occasional publications of the daily press, which are too often of a very sensational character, exaggerating not only the extent of adulteration, but also the comparative ratio of harmful adulteration to that which is merely fraudulent in its character. Fortunately these publications are not so common as they were a few years ago. It is but a few years since a public document, in commenting upon this subject, stated that "fraudulent adulteration is but little more common than injurious adulteration." An examination of the food supply of almost any community at the present day would undoubtedly show the incorrectness of this statement.

ENGLAND.—The history of food adulteration in England dates from a very early period. In the reign of King John, the price and size of the loaf of bread were regulated by law, and this law was afterward amended so as to provide penalties for adulteration, these consisting of fine, capital punishment, and the pillory. During the reign of Edward the Confessor punishment for brewing bad beer was publicly enforced, and in 1589 "this beverage could not be sold without the approval of official 'ale-tasters.'"

Addison says in the *Tatler* (1710): "These subtle philosophers are daily employed in the transmutation of liquors, and, by the power of magical drugs and incantations, raise under the streets of London the choicest products of the hills and valleys of France; they squeeze Bordeaux out of the sloe and draw champagne from an apple."

Modern agitation in England upon the subject of restricting food adulteration may be said to date from about the middle of the last century. From 1851 to 1854 the subject was often discussed in the columns of the *Lancet*, and a Parliamentary inquiry was finally ordered. After the report of the Committee of Investigation the first general English law was enacted, and was known as the Adulteration of Food Act of 1860. This act authorized the appointment of analysts by local boards, and made £5 the penalty for selling an adulterated article, the vendor knowing it to be such. For a second offence the offender's name and place of business could be published in addition to the fine. The Act was permissive as to the appointment of analysts, and was never satisfactorily enforced. In 1869, and again in 1871, bills were introduced in Parliament to improve the law, but failed to pass. In 1872, however, an act was passed which obliged the local boards to appoint analysts and provide for inspectors. The penalty for adulterating articles of food was fixed at £20 for a first offence, and for a second the name and residence of the delinquent could be published in a newspaper. The punishment for adulterating drugs was made £50 for a first offence, and for a second imprisonment not exceeding six months. Previous to 1874 there were various attempts to enforce this law, but without noticeable success, owing to the lack of recognized standards of purity, the disagreement of analysts, and the varying decisions of magistrates in regard to the meaning of the term adulteration. In 1874 a new Parliamentary investigation was ordered and more scientific examination made of the whole subject of adulteration than had been secured before. The report of the committee was reassuring, and was to the general effect that the public was more cheated than poisoned by the adulterations generally practised. In 1875 a carefully digested measure was passed by Parliament (38 and 39 Vic., c. 63), and this, with the amendments of 1878, 1879, and 1899, is now the law for Great Britain.

The principal provisions of the law are as follows:

First. No person shall mix, color, stain, or powder any article of food with any ingredient or material injurious to health, with intent that the same shall be sold in that state, and no person shall sell any such article under a penalty not to exceed £50 for the first offence, and every offence after a conviction shall be a misdemeanor, to be punished by imprisonment not to exceed six months.

Second. No person shall mix, color, stain, or powder any drug so as to affect injuriously the quality or potency of such drug, with the same penalties as provided in the case of food. Proprietary medicines and patented articles are excepted, as are also substances which are added merely to make the compound fit for carriage or consumption, and are not injurious to health.

Third. A person is not guilty, under the act, who proves that he did not know of the adulteration, and could not have obtained such knowledge with reasonable diligence.

Fourth. Mixtures containing articles not injurious to health, and not intended fraudulently to increase the bulk or weight, can be sold, if labels are affixed plainly stating that the substance is a mixture.

Fifth. Analysts are to be appointed, and any medical officer or private person can bring articles to be analyzed. The seller is to be informed that the article is purchased for analysis, and it is to be divided into three parts, one of which is to be kept by the seller if he desires, one given to the analyst, and one kept by the purchaser. A penalty of £10 is imposed for a refusal to sell.

Sixth. The seller cannot be convicted if the article sold is in the same state as when purchased by him, and he has a warranty from the manufacturer.

Seventh. A person forging a warranty is liable to two years' imprisonment. A false warranty makes the giver liable to a penalty of £20, and the same penalty is imposed for applying a warranty to a wrong article.

Eighth. A person upon whom a fine is imposed can recover the amount with costs from the person from whom he bought the adulterated article, if it was sold to him as of the quality for which he sold it to the last purchaser, and that he did not know it to be otherwise.

In addition to the general acts referred to, frequent statutes have been passed in regard to sophistications of special articles.

Adulterations of coffee were prohibited by acts passed in 1725, 1803, and 1822. Since the latter date there have been various Treasury regulations, the result of which was largely to permit the mixture of chicory and other ingredients with pure coffee, and in some cases an entire substitution of the imitations. Adulterations of tea were prohibited by an act passed in 1725, and other acts were passed in 1731, 1773, and 1824. Wines, liquors, ale, and beer have been the subject of frequent statutes from the earliest times. In the reign of Edward III., the Vintners Company was incorporated under the title of the "Wine Tonners," and power was given to examine wines and liquor offered for sale, and to confiscate any adulterated samples. They could also place the sellers in the pillory.

In the time of Queen Anne, the use of cocculus indicus was forbidden in brewing beer, and further legislation was passed in 1816, 1830, and 1863. The Licensing Act of 1872 is the present law on the subject, and the penalties imposed are £20 for the first offence, and £100 for the second. Tobacco and snuff adulterations are mentioned only in the more recent Parliamentary acts. The laws on the subject were passed in 1843, 1862, and 1868.

The adulteration of seeds used in agriculture has been found to be a serious injury to the farmers of Great Britain, and by the act of 1869, the killing * or dyeing of seeds is punished by a fine of £5 for the first offence, and £50 for the second, together with the publication of the offender's name at the discretion of the justice. The adulteration of drugs is prohibited and punished by the general acts of 1860, 1872, and 1875, but there have been a number of special acts relating to the subject. In the city of London, by laws passed in the reigns of Henry VIII. and Queen Mary, power was given to the College of Physicians to search for defective or corrupted drugs and medicines, and to punish the offenders by imprisonment and fines not to exceed £20. This power still belongs to the College of Physicians, but has not been recently exercised. The Pharmaceutical Society of Great Britain, founded in 1841, has been very active and influential in securing the passage of the recent laws relating to drugs and their enforcement.

The organization of the British Society of Public Analysts has proved to be a decided stimulus to the work of food inspection. This society was established in 1874 and its work as a society, together with its publications, has aided very greatly in carrying out the provisions of the Food Acts in establishing standards of purity and in formulating definitions of adulteration.

In 1896, after several years' experience under the Food and Drug Acts of 1875 and later years, it was deemed necessary to make certain changes in the statutes, and a new Parliamentary inquiry was ordered. The committee having charge of the inquiry reported certain recommendations to the Parliament, and after discussion an amended act was passed (62 and 63 Victoria, chap. 51). One of the chief objects of this act was to secure the agricultural interests of the country against the fraudulent sale of oleomargarine.

Section 1 of this act provides penalties of £20 to £100 if, (*a*) margarine or margarine cheese are imported into the United Kingdom, except in packages conspicuously marked as "margarine" or "margarine cheese" as the case may require.

(*b*) If adulterated or impoverished butter, or adulterated or impoverished milk or cream, is so imported, except in packages or cans conspicuously marked with a name or description indicating that the butter or milk or cream has been so treated.

(*c*) If condensed, separated, or skimmed milk, except in tins or other receptacles bearing the labels, "Machine skimmed milk" or "skimmed milk" as the case may require, in large and legible type, or

(*d*) Any adulterated or impoverished article of food to which the law may be applied, unless the same is imported in packages or receptacles conspicuously marked with a name, or description indicating that the article has been so treated.

Under this act an article is deemed to be adulterated or impoverished if any part of it has been abstracted, so as to affect injuriously its quality, substance, or nature. It is not to be deemed adulterated, by the addition of preservatives or coloring matter if these do not render it injurious to health. Prosecutions are to be undertaken by the Commissioners of Customs.

By Section 2, the officers of the Local Government Board and of the Board of Agriculture are empowered to procure samples for analysis. Section 3 makes it the duty of local authorities to appoint public analysts. If the local authorities neglect their duties in relation to the food acts, the Local Government Board is authorized to enforce the law and to charge the expenses to the defaulting local authorities.

Public analysts must satisfy the board of their competency.

By section 4, the Board of Agriculture can make regulations concerning the standard quality of milk products.

Sections 5–8 relate to the sale of margarine and imitation cheese.

Section 9. Name and address of vendor to be inscribed on his vehicle.

Section 10. Division of samples taken for analysis.

Section 11. Receptacles to be properly labelled.

Section 12. Labels to be legibly printed.

Section 16. Provides penalties for obstruction and bribery.

Section 19. Proceedings to be instituted within twenty-eight days after sale.

Section 23 and 24 apply the act to Scotland and Ireland. This act became effective January 1st, 1900.

The following statement from the Twenty-eighth Annual Report of the Local Government Board of England for 1898–99, shows the advantages of food and drug inspection in England and Wales since the beginning of Operations under the Food and Drug Acts in 1876.

The total number of analyses of food and drug samples made in 1898 was 49,555 * or about 1,600 more than those of the previous year. The increase in the annual amount of work performed has been quite constant for the past twenty-two years. In the five years 1877–81 the average number of samples examined per year was 16,688 or one to every 1,520 of the population; in 1882–86 it rose to 21,772, or one in 1,237; in 1887–91, it was 26,846, or one in 1,060, and in 1898 it was 49,555, or one in 585. In London one sample was examined for every 353 persons, and in the provinces one for every 659. But in some quite populous districts, the provisions of the acts were imperfectly carried out, and in commenting upon the neglect of the authorities in these districts the Board says: "The degree, however, in which the acts were utilized was by no means uniform in different districts. Within the jurisdiction of ten County Councils, extending over an aggregate population of 910,032, only 180 samples were analyzed, or one sample a year for every 5,056 persons; and in sixteen boroughs, with an aggregate population of 405,239, only 68 samples were analyzed, or one for every 5,959 persons." †

RESULTS OF EXAMINATIONS MADE IN ENGLAND AND WALES BY THE PUBLIC ANALYSTS, UNDER THE FOOD AND DRUG ACTS, 1877–1898.

Character of samples.	Number of samples examined in 1898.	Adulterated.	PERCENTAGE OF ADULTERATION.					
			1898.	1897.	Five-year Periods.			
					1892–1896.	1887–1891.	1882–1886.	1877–1881.

---

* This term "killing of seeds" is interpreted in the British Statutes (Chap. 112, 32 and 33 Victoria) as meaning "to destroy by artificial means the vitality or germinating power of such seeds."

* The Report of 1899-1900 (p. cxlv.) shows that 53,056 samples were examined in 1899, of which 9.4 per cent. were adulterated, and in 1900 62,858 samples were examined, of which 8.8 per cent. were adulterated.

† Report of Local Government Board, England, 1898–99.

In the foregoing table the five-year periods show a marked improvement if we compare the earlier with the later.

The comments of the Local Government Board show that the practice of milk adulteration in the cities of England differs but little from that which prevails in the large cities of the United States. The accounts of prosecutions which fill the pages of the *British Food Journal* confirm the same statement.

The whole number of samples of milk examined in England in 1898 was 20,315, or about two-fifths of all samples of food examined. Of these 2,011, or 9.9 per cent., proved to be adulterated. As might be expected, the samples obtained in cities were much more adulterated than those procured in the country districts.

In London the percentage of adulterated samples was 12.9. In Oldham, Huddersfield, Bradford, Cardiff, Salford, and Manchester, the rate of milk adulteration was only 2.1 per cent., while in six other cities, Liverpool, Birmingham, West Ham, Sunderland, Portsmouth, and Nottingham, it was as high as 20.3 per cent.

The Board says in regard to milk: "It is difficult to account for the great disparity between the rates of milk adulteration in these groups of towns, but part of it is probably due to differences in the methods of procedure adopted by the analysts. In certain towns every sample of milk submitted to the analyst is examined for the presence of boric acid, formalin, or other preservative, and the sample is condemned if only a small percentage of the preservative is discovered. In such cases the rate of milk adulteration appears to be relatively high, when compared with that of other districts in which the presence of preservatives is not regarded as of itself rendering the sample of milk liable to condemnation. Some analysts pass as genuine all samples, equal in quality to the poorest milk yielded by an individual cow, and some condemn only those respecting which there is a reasonable probability that legal proceedings, if instituted, will be successful. Others, again, hold it to be their duty to report unfavorably on every sample which fails to reach a somewhat high standard. We understand, also, that in certain districts it is the practice to test samples of milk with a lactometer or other similar instrument, and that only those that are suspected of adulteration are transmitted to the analyst for chemical analysis."

"Occasionally some instances of gross adulteration of milk are brought to light. One sample taken in Sheffield was reported by the analyst to contain as much as 85 per cent. of added water. In another case a man trading in several towns in the south of England under the name of the 'Farmers' Direct Milk Supply Company' admitted at his trial at Southampton, that for many months he had daily and systematically adulterated, by the addition of one-fifth of separated milk, the whole of the milk sent by him for retail sale to Southampton and Bournemouth."

"We have received a large number of representations as to the injurious effects upon infants likely to follow upon the consumption of condensed separated milk, which is almost entirely devoid of fat, and therefore contains but little (if any) nutriment.* It is stated that it is necessary to consume the contents of at least ten half-pound tins of condensed separated milk in order to obtain the nutriment yielded by a pint of good new milk. It is satisfactory to note that some local authorities have taken steps to make known throughout their districts that it is dangerous to use condensed separated milk for the feeding of infants."

Two-thirds of the samples of butter submitted by private purchasers and 55 per cent. of those submitted by agricultural societies were condemned. If we exclude the samples taken on behalf of these associations and by private purchasers, the rate of butter adulteration in London is found to be 14.2 per cent.; in the 32 great towns 12.9, and in the remainder of the country only 4.4 per cent.

Of the 1,879 samples of coffee examined 10 per cent. were condemned. As usual, many samples were reported to contain large quantities of chicory. In one case in Cheshire a sample was found to contain sugar. The analyst states that "this was probably due to the practice of roasting coffee with a certain proportion of sugar, which will increase the weight of the coffee from 5 to 10 per cent. This admixture is so skilfully done that each berry is coated with sugar, and any one buying his coffee in the berry would think he was obtaining it pure. Some may say this is an innocent adulteration, but it is at the same time a most profitable one, for the sugar, which is not much more than one penny a pound, is sold at the rate of a shilling or more."

Seventeen of the 584 samples of sugar were reported against, and 12 fines, amounting to £11 15s., were imposed.

Of 575 samples of mustard examined, 30 were condemned, and six small fines were inflicted.

Four hundred and eighty-eight samples of confectionery and jam were analyzed, and 14 were found to be adulterated, there being one conviction.

Thirteen samples of pepper out of 1,566 taken were reported against, and the vendors of three of them were fined.

Of the 1,421 samples of lard analyzed, all but 2 were found to be genuine. This is in striking contrast to the figures of 1888, when cotton-seed oil was extensively used to adulterate lard, and 299 samples out of 1,782 were condemned.

Eighty-four samples of wine were examined, and 2 were found to be adulterated.

Of 256 samples of beer, 1 was reported against on account of the presence of over 100 grains of salt per gallon. Apart from the presence in beer of salt in excess, it is difficult for analysts to pronounce beer to be adulterated, as under the present law beer may be manufactured by brewing any substitute for malt with any substitute for hops.

The percentage of adulteration of spirits is again higher than that of any other article specifically mentioned in the table.

There were 1,641 samples of drugs examined, of which 196, or nearly 12 per cent., were found to be adulterated. In only 93 of these cases were legal proceedings taken. There were 79 penalties, amounting in all to £53 0s. 6d. There were 39 samples of sweet spirits of nitre adulterated, out of 173 examined; of Gregory's powders 25 out of 75; of sulphur 15 out of 82; of rhubarb 15 out of 186; of lime water 13 out of 40; of magnesia 11 out of 44; and 8 out of 25 prescriptions were improperly or carelessly compounded. There were also 8 samples of wax condemned out of 30 analyzed; 9 out of 84 of cream of tartar; and 9 out of 43 samples of seidlitz powders.

Out of the 2,011 samples of milk reported as adulterated in 1898, 1,205 were the subjects of legal proceedings. In 986, fines were imposed amounting to £1,652 (about $8,250).

The use of poisonous pigments in England, as elsewhere, appears to have nearly or quite disappeared under the protection of the Food and Drug laws.

France.—In France, as early as the year 1396, there was an ordinance of the city of Paris forbidding the coloring of butter with herbs, flowers, or drugs, and there were laws, dating from about the same time, regulating the purity of bread, wine, and other food products. In 1802 the Conseil de Salubrité was established at Paris and this was followed by the organization of various health boards to whom the French are now mainly indebted for their present immunity from food adulteration.

In France, at the present time, there is a law establishing laboratories in the principal cities for the analysis of articles bought by private persons, or secured by duly appointed inspectors, who have power to punish offenders. The officials provided for the laboratory work and the inspection of the markets and stores are a director, inspectors, and chemists. In connection with the laboratories there are elaborate photographic apparatus provided, so that juries can judge by ocular demonstration of many forms of adulteration.

---

*The insertion of these words ("if any") is a manifest error. Skimmed milk has a decided food value, but not so great as that of whole milk. [Ed.]

Paris.—The work of examining the food supply of Paris has been conducted at the Municipal Laboratory, on the north bank of the Seine, during the past twenty years. Prof. C. Girard is the chief chemist in charge. Two printed reports of this laboratory have been published, dated 1882 and 1885. A monthly bulletin is also published detailing the work of the laboratory during each month.

By decision of the Municipal Council gratuitous qualitative analyses are made at this laboratory of such articles of food and drink as are deposited at the laboratory for this purpose. The greater part of the articles examined is collected by inspectors authorized to visit shops and markets where food is sold, for the purpose of making collection of such samples. These inspectors also have authority to destroy unsound food. Their collections are generally made from such kinds of food preparations as are suspected of adulteration or are especially liable to this species of fraud. Hence the monthly bulletins issued from the laboratory do not represent the actual condition of the markets, since many articles of food are not liable to adulteration. The number of articles examined in each year amounts at present to more than 25,000 annually. The scope of the analyses embraces several articles in common use besides food, such as children's toys, wall-paper, cooking utensils, preparations used in embalming, coloring matter, cosmetics, and illuminating oils.

The following condensed statement, compiled from the monthly bulletins for the year ending March 31st, 1900, will give a fair illustration of the work accomplished in Paris during that period: Number of visits made to markets and shops, 53,437.

Under the present classification articles are divided into three groups, good, passable, and bad.

The total number of articles collected for examination by the inspectors or collectors of samples was 26,583; of this number 48.2 per cent. were classed as good, 25.8 per cent. as passable, and 26 per cent. as bad.

There were also 969 samples for which a fee was paid for analysis, and 244 samples were deposited at the laboratory by citizens for gratuitous examination.

Classification of Work of Municipal Laboratory of Paris for the Year Ending March 31st, 1900.

Articles examined.	Good.	Passable.	Bad.
Wines	1,408	3,428	2,520
Vinegar	62	66	45
Beer	464	198	137
Cider	43	43	156
Spirits	402	970	249
Syrups	339	8	218
Water and ice	749	250	319
Milk	1,360	1,388	1,698
Butter and cheese	2,036	246	231
Lard	113	25	50
Oils used as food	107	12	75
Bread and cake	591	58	158
Flour	918	68	96
Sugar and confectionery	731	88	273
Preserves and honey	78	7	171
Chocolate and cocoa	240	33	133
Coffee and tea	972	60	29
Meat	715	37	237
Pepper and spices	873	4	96
Tinware and crockery	186	10	118
Toys and colors	68	3	21
Petroleum	301	10	20
Fireworks	....	....	37
Drugs	47	....	14
Embalming material	7	5	....
Miscellaneous	400	115	109

The principal adulterations found in the articles named in this list were the following:

Wines were either watered, fortified, sugared, plastered, or treated with salicylic and boric acids as preservatives. Beer was watered, or treated with glucose, sugar, and other materials. Cider was colored and treated with sugar or tartaric acid. Spirits were either watered or fortified by the addition of alcohol. Syrups contained glucose and artificial coloring matter. Water contained an excess of mineral and organic matter and in one sample lead was found. Milk was watered, skimmed, colored, or treated with preservatives, including formalin. Butter contained margarine, boric acid, and an excess of water. Lard was adulterated with cheaper fats and cotton-seed oil. Olive oil was adulterated with cheaper oils. Bread and flour were found to contain cheaper flour or meal than was called for. Sugar and confectionery contained glucose. Honey and preserves were adulterated with glucose and coloring matter. Meat was treated with salicylic and boric acids. Tin and earthenware contained lead. Pepper and spices contained starch, ground olive stones, nutshells and other foreign matter. Toys were colored with forbidden colors. Illuminating oil ignited at a lower temperature than 35° C. (95° F.). Drugs were found to be below the required standard.

In the recent years of work, bacteriological examinations were made in addition to chemical analysis of certain articles as follows. In the past year: Of wine, 380 samples, of milk 44 samples, of water and ice 1,849 samples, and of cider 8 samples. Of the water 828 samples were pronounced good, 651 passable, and 320 contained pathogenic germs and were condemned.

Germany.—In Germany there were enacted at a very early date laws inflicting severe penalties for selling adulterated bread, drugs, or wine. "In the fifteenth century, at Bieberich on the Rhine, a wine adulterator was forced to drink six quarts of his own stock and it is recorded with due gravity that the test resulted fatally" (Battershall, "Food Adulteration," p. 3). The statutes now in force were passed quite recently—one in 1872, regulating the sale of drugs, and another in 1879, relating to food. By the law of 1872, the German Pharmacopœia was made the standard of purity. In 1878, 231,478 samples of food, drink, drugs, etc., were examined, and there were 3,352 convictions for violations of the law. The penalties are fines or imprisonment, and it is not necessary to prove that the seller was aware of the adulteration. The following general laws relating to food inspection are in force.

By a law enacted in 1879 police officers are authorized to enter shops where food is offered for sale and to take samples.

Imitation or adulteration of food and stimulants with a view to deception, the sale of putrid, falsified, or adulterated food and stimulants, and offering them for sale under a description calculated to deceive the purchaser, are forbidden. The manufacture, sale, or traffic in food stimulants and other necessaries, whose consumption or use is injurious or may destroy health, is forbidden by heavy penalties (in some cases by imprisonment).

The application of these general principles is further facilitated by the following special enactments with reference to particular necessaries of life.

1. Petroleum, which parts with inflammable vapor at a lower temperature than 60° F. must be kept in vessels bearing the inscription "inflammable" in large indelible letters in a prominent position.

2. Eating, drinking, and cooking utensils must not be made of lead, or of any alloy containing more than ten per cent. of lead, they must not be coated internally with any metallic alloy containing more than one per cent. of lead. The latter regulation applies to all objects which come in direct contact with the mouth, or are used for preserving meat, fruit, spirits, etc. These precautions are for the prevention of lead poisoning.

3. No coloring agents can be used in the manufacture of food or stimulants, which contain any of the following substances: arsenic, antimony, barium, lead, cadmium, chromium, copper, mercury, uranium, zinc, tin, gamboge, coralline, or picric acid. Such colors cannot be used in the wrappings of provisions, in making soap, or other preparations for the skin or hair, in manufacturing toys, etc. In particular, the use of arsenical coloring is strictly forbidden in the manufacture of carpets, curtains,

wall-papers, paints, furniture, artificial flowers, clothes, type, etc., etc.

4. The sale of imitations of butter is forbidden, unless they are distinctly labelled and sold as margarine, etc.

5. By a law of February 1st, 1891, the use of machines for the manufacture of artificial coffee berries is forbidden.

6. By a law of April 29th, 1892, the addition of a number of specified harmful substances to wine is forbidden. Definite limits are also laid down relative to the use of other adulterations of wine.

Hamburg.—Drs. Dunbar and Farnsteiner report upon the inspection of food and drinks in Hamburg (*Rev. des Falsifications*, vol. xii., p. 111). Of medicinal wines, 22 out of 102 samples were condemned either for the addition of sugar, or salicylic acid, or other impurities; 11 out of 81 sweet wines were condemned for similar causes. Also 27 out of 212 German wines, 12 of which contained too little extractive matter, 3 out of 23 samples of beer were condemned; 2 out of 20 samples of vinegar; 21 out of 56 specimens of sausage and hashed meat were condemned on account of artificial color and excess of sulphurous acid.

Dresden.—Dr. Heinze, of Dresden, reports upon the examination of 1,781 samples of food made during 1898 (*Revue Internationale des Falsifications*, vol. xiii., April, 1900, p. 37). Of this number 590, or 33 per cent., were condemned. Of 170 specimens of butter, sold as such, only 4 proved to be margarine. Out of 69 samples of vinegar, 35 were of inferior strength. One hundred samples of sausage were examined and 58 were artificially colored. Three contained boric acid in small quantity. Of 269 samples of spices, 27 were condemned.

Three hundred and forty-one samples of milk were examined, and 267, or 77.7 per cent., were condemned as adulterated.

The high percentage of adulteration in some of the foregoing articles is accounted for by the fact that the police authorities charged with their collection were also instructed in the methods of making rough tests of purity, so that they were enabled to select for final examination an unusually large number of adulterated articles.

The chemist also reports upon 72 samples of children's toys, whistles, musical instruments, tin preserving cans, covers of beer mugs, etc., which were examined for lead, and of this number 49 were condemned.

Altona.—Dr. Reinsch, director of the Municipal Laboratory of Altona, reports upon the work of the year ended March 31st, 1899 (*Revue Internationale des Falsifications*, vol. xii., December, 1899, p. 179); 2,612 specimens were examined, of which 950 where articles of food and cooking utensils, 360 were samples of the public water supply, 965 were of the city gas supply.

One hundred and forty-three of the food samples, or 15 per cent., were condemned as adulterated or injurious to health.

Twenty-four out of 187 specimens of butter, or 12.8 per cent., contained more than 16 per cent. of water. Fines were imposed from 20 to 150 marks.

Of 348 samples of milk, 77 were adulterated either by skimming or watering.

Breslau.—The report of the official chemist of Breslau for 1898–99 embraced a wide field of objects. The principal articles examined were: butter, 326 samples, 28 adulterated; milk 341 samples, 12 adulterated; sausage, 93 samples, 2 adulterated. The general ratio of adulteration reported was very small.

One hundred samples of vinegar were examined, and the acetic acid varied from 1.4 to 5.8 per cent.

The samples of milk varied in their fat contents from a minimum of 2.40 to a maximum of 11.2 per cent. Thirteen samples contained over 6 per cent. of fat in each. The total solids in the lowest sample were 6.58 per cent., indicating an addition of 45 per cent. of water.

Three hundred examinations of illuminating gas were made on as many working days during the year.

Other examinations were also made of beer measures containing lead, lamp-shades containing arsenic, children's toys, etc.

HOLLAND.—Dr. Lam, commercial chemist at Rotterdam, reports upon the work of inspection for the year 1898 (*Revue des Falsifications*, vol. xii., p. 128).

The whole number of examinations was 5,438, of which 548, or 10.1 per cent., were condemned, the principal adulterations being as follows: Milk, 3,942 samples, 169 adulterated. Spices, 147 samples, 54 adulterated. Coffee and tea, 51 samples, all genuine. Cocoa, 43 samples, 32 adulterated. Vinegar, 500 samples, 143 adulterated.

AUSTRIA-HUNGARY.—Dr. M. Mansfeld, director of the Laboratory at Vienna, reports upon the food preparations collected during the year ending August 31st, 1899.

The whole number of samples examined was 1,028, of which 349, or 34 per cent., were condemned as adulterated, or injurious to health. Of 8 samples of beer, 2 were adulterated; of 42 samples of strong spirits, 13 were adulterated. Of butter, 23 out of 76 specimens were adulterated. Of cocoa, 15 out of 50 specimens were adulterated.

Several substances sold as preservatives were examined and found to contain salicylic and boric acids and formalin. An American sausage was found to contain boric acid; one specimen was colored with carmine. Of 39 samples of spices 21 were falsified. Pepper contained starch, ground olive stones, sago, and nutshells. Two samples of honey were adulterated with glue. Several coffee substitutes were examined and found to contain starch, chicory, barley, turnip, and figs. Five samples of lard out of 18 contained other fats and cotton-seed oil. Of wine, 62 specimens out of 175 were adulterated with glycerin, alcohol, sugar, plaster, and artificial coloring matter.[*]

SWITZERLAND.—In Switzerland the work of examining articles of food and drink is well organized by the appointment of a competent chemist in each canton, whose duties embrace the analysis of all articles in domestic use, where a chemical analysis may be required.

St. Gall.—Dr. Ambühl, canton chemist of St. Gall, reports upon 3,954 samples of food examined in 1898, of which 754 or 19.1 per cent. were condemned (*Revue Internationale des Falsifications*, vol. xii., 1899, p. 152).

Of 1,940 specimens of milk, 93 were condemned. Of 124 samples of butter, 40 were condemned. The addition of flour to sausages has nearly ceased. Out of 27 samples of American dried fruits, 15 contained zinc. Out of 775 samples of wine 254 were condemned, being either diluted, fraudulently marked, or otherwise adulterated. The use of lead in the manufacture of cooking utensils was prohibited in this canton as early as 1808.

Basel.—The chemist of canton Basel reported as follows for the year 1899[†]:

Whole number of examinations made, 5,469. Number adulterated, or of bad quality, 411. The list is as follows:

Articles examined.	Total.	Adulterated.
Beer	19	2
Bread	5	1
Butter	388	45
Cocoa and chocolate	13	6
Chemicals	350	....
Preservatives	1	....
Cosmetics	4	4
Vinegar	255	63
Colors	4	1
Meat and sausages	64	5
Fruits	3	3
Fodder for animals	4	1
Spices	162	4
Honey	62	7
Coffee	20	4
Meal	41	....
Milk	2,712	95
Petroleum	3	....
Lard and other fats	204	11
Soap	9	....
Oils	75	7

[†] "Verwaltungsbericht des Sanitäts-Departments über das Jahr 1899," Baselstadt, 1900.

Articles examined.	Total.	Adulterated.
Toys	1	....
Spirits	15	2
Water	285	....
Wine	493	111
Sugar	59	20
Examinations for poisons	28	....

Fines were imposed in 143 instances, chiefly for adulteration of milk, wine, sausages, vinegar, and butter.

Berne.—Dr. Schaffer, canton chemist of Berne, Switzerland, reported upon the following articles in 1900, from which it appears that the scope of the canton chemist's authority extends to other articles in domestic use as well as to food and drugs.

	1900.	
	Number examined.	Number found adulterated.
Beer	8	1
Brandy and spirits	128	45
Bread and cake	9	3
Butter	21	5
Vinegar	4	0
Meats	9	4
Cereals	15	4
Honey	3	1
Coffee and tea	19	10
Cocoa and chocolate	21	2
Cheese	4	1
Milk	204	79
Pepper	3	0
Saffron	3	0
Cloves	3	2
Water	520	68
Fats and oils	31	8
Wine	407	145
Preserved fruits	2	2
Sugar	6	1
Miscellaneous	27	6
Proprietary medicines	14	5
Examinations for poisons	27	12
Syrups	12	3
Articles of household use	160	36

In addition to the foregoing the chemist reports upon several proprietary articles, paints, metals, chemicals, clothing, wall-paper, coal and coal-oil soap, and washing-powders, compressed yeast, insect-powders, fire-extinguishers, ice machines, etc.*

UNITED STATES.

In this country most of the States have laws prohibiting adulteration in general, or special forms of it, and many of the larger cities have, in addition, municipal regulations to prevent the sale of harmful products. In the summary of food acts presented in the third volume of the REFERENCE HANDBOOK by Mr. Riley, in 1886, it was stated that there were four States in which no legislation had been enacted in regard to food. In a later summary presented by Dr. C. V. Chapin, in his work on "Municipal Hygiene" (1901), it appears that every State has enacted legislation upon the subject, although in several instances this legislation had reference to special articles of food and in some cases to such as were of comparatively little importance. In some of the States, public sentiment has not been aroused so as to secure a thorough enforcement of the laws, or else adequate appropriations have not been made for the proper performance of the preliminary work of analysis. As a result, the effects accomplished by legal methods have not been so satisfactory as could be desired. The condition of affairs is, however, steadily improving, the people are coming to see the great need for rigorous enforcement of the laws, and experience has shown in what directions the legislation already had, has proved defective.

Congress has passed no general law concerning adulteration of food and drugs, and such would not be greatly needed, except as regards the importation of adulterated articles, if all the separate States had adequate laws on the subject. A bill prepared under the auspices of the National Board of Trade was presented to Congress in 1880, but failed to be enacted. As early as 1848 Congress passed an act to prevent the importation of adulterated and inferior drugs and chemicals, and examiners were appointed. This law seems to have been much needed, for at New York alone, in nine years from 1848 to 1857, over 900,000 pounds of adulterated drugs were seized. For some time past the law does not seem to have been enforced, and the examiners have not made reports to the Treasury Department. No rules have been adopted to secure the systematic prosecution of the work.

Soon after the passage of the English Adulteration Act of 1875, a general interest in the subject was awakened in the United States, and legislation soon resulted. The way for this had largely been paved by the previous examination of adulterations of food by the State boards of health of some of the States, such as Massachusetts and Michigan. The lead in this agitation was taken by the *Sanitary Engineer*, a paper published in New York City, and through its efforts three prizes were offered for the best essays on the general subject of adulteration of food, accompanied by drafts of a law. This competition was established in 1879, and in October, 1880, a report was made by a committee consisting of Dr. John S. Billings, U. S. A.; ex-chancellor Williamson, of New Jersey; Prof. Charles F. Chandler, of New York, and A. H. Hardy, Esq., of Boston, awarding the first prize to George W. Wigner, of London, one of the English public analysts. The law framed by the committee was submitted to the legislatures in several of the States, and in its material parts became a law in New York and New Jersey in 1881, in Massachusetts in 1882, and still later in Ohio, Connecticut, California, District of Columbia, Illinois, Indiana, Kansas, Kentucky, Michigan, Mississippi, North Carolina, Oregon, Pennsylvania, Tennessee, and Wisconsin.

The committee, in making their report, stated that the investigation showed that the adulterations practised were not so injurious to health as had been claimed, and that legislation was needed more for commercial than sanitary reasons. At nearly every session since the 50th Congress, a bill for the prevention of food and drug adulteration has been favorably considered, but has not yet reached the stage of enactment. In 1892 Senator A. S. Paddock, of Nebraska, introduced a bill intended to prevent adulteration of food, but the bill was defeated, as would appear from the published debate upon it, by the vigorous efforts of certain Senators, who represented States in which the production of cotton-seed oil was largely conducted. A more recent bill known as the Brosius bill appears to have a fair prospect of becoming a law (June, 1900). This bill (H. R. 9677, 56th Congress, 1st session) provides:

Section 1. That the Secretary of Agriculture shall organize the Chemical Division of such Department into a bureau of chemistry, which is charged with the inspection of food and drug products and the analysis thereof. He is to publish the results of examinations and analyses. This Department is fully equipped, both in experienced men and in laboratory arrangements to carry out the work designed in this bill, more economically and thoroughly than any other branch of the Government.

Section 2. By this section adulteration or false handling of food and drugs is prohibited, and penalties are provided for violation of the law.

Section 3 provides for the examination of samples of food and drugs offered for sale in original packages in the District of Columbia, or in the Territories, or in any State other than that in which the same shall have been manufactured or produced.

Section 4 defines the duty of the district attorney.

Sections 5 and 6 contain the definitions which are practically the same as those which have existed for several years in New York, Massachusetts, New Jersey, and other States.

---

* "Bericht über die Thätigkeit des kantonalen chemischen Laboratoriums in Bern im Jahr 1900," Bern, 1901.

Section 7 provides for the establishment of a board of experts to fix standards of food products. The secretary of the Board of Agriculture being authorized to fix such standards, with the advice of experts.

Sections 8 and 9 refer to the method of taking samples.

By section 10, the bill is not to be construed to interfere with the police regulations of any State or Territory.

Section 11 provides for the disposal of confiscated articles.

This bill does not interfere with any legitimate trade or industry, or prohibit the use of any product so long as that product has not been deemed injurious to health by an impartial commission. It does forbid interstate traffic in articles injurious to health. It also forbids improper branding. Any imitation or compound or mixture may be sold so long as it is distinctly and properly marked so that the purchaser or consumer shall be protected in his rights.

MASSACHUSETTS.—As this was one of the first States to adopt a general food act, with annual appropriations for its execution, the law is herewith quoted in full, with the principal amendments. Similar statutes have since been enacted in several other States.

ACT RELATING TO INSPECTION OF FOOD AND DRUGS.

Acts of 1882, 263, § 1.

No person shall, within this Commonwealth, manufacture for sale, offer for sale, or sell any drug or article of food which is adulterated within the meaning of this act.

Acts of 1882, 263, § 2.
Acts of 1886, 171.

The term "drug" as used in this act shall include all medicines for internal or external use, antiseptics, disinfectants, and cosmetics. The term "food" as used herein shall include confectionery, condiments, and all articles used for food or drink by man.

Acts of 1882, 263, § 3.
Acts of 1884, 289, § 5.
Acts of 1884, 289, § 7.

An article shall be deemed to be adulterated within the meaning of this act—

(*a*) In the case of drugs—(1) If, when sold under or by a name recognized by the United States Pharmacopœia, it differs from the standard of strength, quality, or purity laid down therein, unless the order calls for an article inferior to such standard, or unless such difference is made known or so appears to the purchaser at the time of such sale; (2) If, when sold under or by a name not recognized in the United States Pharmacopœia but which is found in some other pharmacopœia, or other standard work on *materia medica,* it differs materially from the standard of strength, quality, or purity laid down in such work; (3) If its strength or purity falls below the professed standard under which it is sold.

(*b*) In the case of food: (1) If any substance or substances have been mixed with it so as to reduce, or lower, or injuriously affect its quality or strength; (2) If any inferior or cheaper substance or substances have been substituted wholly or in part for it; (3) If any valuable constituent has been wholly or in part abstracted from it; (4) If it is an imitation of, or is sold under the name of, another article; (5) If it consists wholly or in part of a diseased, decomposed, putrid or rotten animal or vegetable substance, whether manufactured or not, or, in the case of milk, if it is the produce of a diseased animal; (6) If it is colored, coated, polished, or powdered, whereby damage is concealed, or if it is made to appear better or of greater value than it really is; (7) If it contains any added poisonous ingredient or any ingredient which may render it injurious to the health of a person consuming it.

The provisions of this act shall not apply to mixtures or compounds recognized as ordinary articles of food or drinks, provided that the same are not injurious to health, and are distinctly labelled as mixtures or compounds. And no prosecutions shall at any time be maintained under said act concerning any drug the standard of strength or purity whereof has been raised since the issue of the last edition of the United States Pharmacopœia, unless and until such change of standard has been published throughout the Commonwealth.

Acts of 1882, 263, § 5.
Acts of 1886, 101, § 4.

The State board of health shall take cognizance of the interests of the public health relating to the sale of drugs and food and the adulteration of the same, and shall make all necessary investigations and inquiries in reference thereto, and for these purposes may appoint inspectors, analysts, and chemists, who shall be subject to its supervision and removal.

Within thirty days after the passage of this act the said board shall adopt such measures as it may deem necessary to facilitate the enforcement hereof, and shall prepare rules and regulations with regard to the proper methods of collecting and examining drugs and articles of food.

Acts of 1891, 319, § 1.

For the purpose of carrying out the provisions of chapter two hundred and sixty-three of the acts of the year eighteen hundred and eighty-two, relating to the adulteration of food and drugs, the State board of health may expend annually a sum not exceeding eleven thousand five hundred dollars: *provided, however,* that not less than three-fifths of said amount shall be annually expended for the enforcement of the laws against the adulteration of milk and milk products.

Acts of 1882, 263, § 6 (see also 1886, 318, § 1).

Every person offering or exposing for sale, or delivering to a purchaser, any drug or article of food included in the provisions of this act, shall furnish to any analyst or other officer or agent appointed hereunder, who shall apply to him for the purpose and shall tender to him the value of the same, a sample sufficient for the purpose of the analysis of any such drug or article of food which is in his possession.

Acts of 1882, 263, § 7.

Whoever hinders, obstructs, or in any way interferes with any inspector, analyst, or other officer appointed hereunder, in the performance of his duty, and whoever violates any of the provisions of this act, shall be punished by a fine not exceeding fifty dollars for the first offence, and not exceeding one hundred dollars for each subsequent offence.

Acts of 1884, 289, § 2.
Acts of 1886, 101, § 4.

The State board of health shall report annually to the legislature the number of prosecutions made under chapter two hundred and sixty-three of the acts of eighteen hundred and eighty-two, and an itemized account of all money expended in carrying out the provisions thereof.

Acts of 1884, 289, § 8.

Before commencing the analysis of any sample the person making the same shall reserve a portion which shall be sealed; and in case of a complaint against any person the reserved portion of the sample alleged to be adulterated shall upon application be delivered to the defendant or his attorney.

The principal amendment to the foregoing act was that of 1897, wherein the section relating to labels was amended as follows:

"The provisions of this act shall not apply to mixtures or compounds recognized as ordinary articles, or ingredients of articles of food, if every package sold, or offered for sale, is distinctly labelled as a mixture or compound, *with the name and per cent. of each ingredient therein,* and if such mixtures or compounds are not injurious to health."

Other and special statutes have since been enacted in Massachusetts relating to special articles of food, such as that of 1897 relative to canned goods, and to molasses and syrups, and the more recent statutes of 1901 relating to labels and to the use of preservative.

The following summary presents in a condensed form some of the results of the work of food and drug inspection in Massachusetts by the State board of health during the past eighteen years of its work in this direction:

Summary.	1883.	1884.	1885.	1898.	1899.	1900.	18 years, 1883–1900.
Number of samples of milk examined	218	1,123	2,219	6,247	6,186	6,232	63,616
Number of samples above standard	35	347	1,297	4,307	4,506	4,431	39,364
Number of samples below standard	183	776	922	1,940	1,680	1,801	24,252
Percentage of adulteration	83.9	69.1	41.7	31.1	27.2	28.9	38.1
Number of samples of other kinds of food (not milk)	477	839	1,552	3,738	3,069	3,132	42,725
Number of samples of good quality	328	432	883	3,238	3,615	2,670	34.744
Number of samples adulterated, as defined by the statutes	149	407	669	500	454	462	7,981
Percentage of adulteration	31.2	48.5	43.1	13.4	14.8	14.2	18.7
Number of samples of drugs examined	603	682	1,007	812	547	758	11,173
Number of samples of good quality	357	431	571	531	303	377	7,016
Number of samples adulterated, as defined by the statute	246	251	436	281	244	381	4,157
Percentage of adulteration	40.8	36.8	43.3	34.6	44.6	50.2	37.2
Total examinations of food and drugs	1,298	2,644	4,778	10,797	9,802	10,122	117,514
Total examinations of good quality	720	1,210	2.751	8,076	7,424	7,478	81,124
Total examinations not conforming to the statutes	578	1,434	2,027	2,721	2,378	2,644	36,390
Percentage of adulteration	44.5	54.2	43.7	25.2	24.3	26.1	31.0
Expense of collection, examination, and prosecution	$2,931.56	$5,529.60	$8,557.43	$11,062.68	$11,251.83	$11,108.73	$172,947.91
Expense of collection, examination, and prosecution, per sample	2.26	2.09	1.79	1.02	1.15	1.10	1.47

In the foregoing table the first three columns of figures present the general statistics of the first three years' work; the next three columns give the figures of the last three years, and the final column presents the summary of eighteen years.

As is customary under the operation of all new laws of similar character, the first few months of work are usually devoted to an examination of the different sorts of food, in order to determine the extent and the character of adulteration. This preliminary examination established the fact that many staple products are not subject to adulteration, except in rare and isolated instances. This applies, so far as Massachusetts is concerned, to sugar, flour, and the various other cereal products, so that it has not been deemed necessary to give much attention to these articles of food. Hence the figures in the foregoing table should not be understood as representing the actual amount of adulteration existing in the general food supply, nor even in articles liable to adulteration, since special pains are taken at times to obtain only such articles as are known to be adulterated. Experience often shows an inspector where to find adulterated articles of food. The difference in the percentages of the first three years (1883, 1884, and 1885) and the last three (1898, 1899, and 1900) in the foregoing table may be taken as representing quite fairly the improvement, not in the general food supply under the present inspection, but in those articles which are found to be liable to adulteration. Upon this point the board published the following general statement in its Annual Report of 1884:

"There can be no question as to the beneficial results of the law, as executed by the officers of the board, in improving the quality of the food and drug supply of the State, especially in regard to milk and butter—in the former case as relates to the quality of the supply, and in the latter as relating to the proper branding and marking of spurious goods. The extensive correspondence of the Health Department with wholesale houses outside of Massachusetts also confirms their appreciation of the value of the work done in this State, and also the necessity of furnishing articles of undoubted purity for this market. This is especially true of all classes of drugs sold at wholesale by parties outside the State.

"The actual economic results obtained by the enforcement of the statutes relative to food and drug inspection cannot be stated exactly. The law is comprehensive and its provisions cover a great variety of articles. Its restraining influence extends outside of the State to manufacturers sending goods to this market. It is specially provided by the statute that at least three-fifths of the amount appropriated shall be expended in the enforcement of the laws relating to the adulteration of milk and its products. This provision has been carefully observed."

It was found convenient, after a year's work, to adopt a code of regulations for the government of its analysts and inspectors in the performance of their duties under the Food and Drug Acts. The following is a copy of these regulations.

Rules and Regulations of the State Board of Health of Massachusetts Relative to the Inspection and Analysis of Food and Drugs.—1. The State board of health shall appoint analysts and inspectors, as provided in section 5 of chapter 263, Acts of 1882.

2. It shall be the duty of the inspectors to procure samples of drugs and articles of food at such times and places as the secretary shall direct, in the manner provided in section 6 of chapter 263 of the Acts of 1882, and in section 3 of chapter 289 of the Acts of 1884, and in all acts amendatory of said provisions.

3. Under the direction of the secretary, the inspectors shall, for the identification of samples, affix a number to each sample of food or drugs obtained by them, in such manner as may be prescribed. Under no circumstances shall an inspector convey any information to an analyst as to the source from which any sample was obtained.

4. The inspectors shall keep records of each sample, each record to include the following items: (*a*) The inspector's number; (*b*) the date of purchase or receipt of sample; (*c*) the character of the sample; (*d*) the name of the vendor; (*e*) the name of the city or town, and street and number where the sample is obtained, and, in the case of a licensed milk pedler, the number of his license; (*f*) as far as possible the names of manufacturers, producers, or wholesalers, with marks, brands, or labels stamped or printed upon goods.

5. It shall be the duty of the analysts so appointed to determine, under the direction of the secretary, by proper examination and analysis, whether articles of food and drugs, manufactured for sale, offered for sale, or sold within this Commonwealth, are adulterated within the meaning of chapter 263 of the Acts and Resolves passed by the General Court of Massachusetts in 1882, and all acts amendatory thereof, adulteration being defined as follows, viz.: (Here follows a statement of the statute as already given in a previous page.)

6. It shall also be the duty of the analysts to receive such specimens of food and drugs for analysis as may be delivered to them by the secretary, or by the inspectors,

and to examine the same. To avoid, as far as possible, all suggestion or danger of specimens having been tampered with, each analyst shall keep each specimen in his possession in a suitable and secure place, labelled in such a manner as to prevent any person from having access to the same without the knowledge and presence of the analyst.

Analyses of perishable articles should be made promptly after they are received.

7. An analyst shall give no information, under any circumstances, regarding the result of any analysis, to any person except to the secretary of the board, prior to any trial in court in reference to such analysis.

The analysts shall carefully avoid any error regarding the inspector's number attached to each sample, and shall report the results of their work in detail to the secretary.

In the case of all articles having a numerical standard provided by statute, the result of the analysis should show their relation to such standard.

8. Before beginning the analysis of any sample, the analyst shall reserve a portion, which shall be sealed, and in the event of finding the portion analyzed to be adulterated, he shall preserve the sealed portion, so that in case of a complaint against any person the last-named portion may, on application, be delivered by the secretary to the defendant or to his attorney.

9. Each analyst shall present to the secretary, on the Monday before the first Thursday of each month, a summary of the analyses made by him during the previous month.

Each analyst shall also present, on or before the first of January of each year, an annual report of the work done for the year ending on the 30th of September preceding.

10. The secretary shall have charge of the reports of analyses, and shall cause cases founded on such reports to be submitted to the courts for prosecution.

In each case of a retailer, and of every dealer not a manufacturer or producer, he may, if the party has not been previously complained of in court, issue a notice or warning of any violation of the law relative to the adulteration of food and drugs, and of the offender's liability to prosecution on a repetition of the sale.

11. Should the result obtained by any analyst be questioned in any given case, another analyst shall repeat the analysis, unless otherwise instructed by the board, provided a sufficient sum to meet the expense of the analysis be deposited with the secretary by any interested party feeling aggrieved, which sum will not be returned unless the second analysis fails to confirm the first in essential particulars.

12. Any appeal from the decision of an analyst shall be filed with the secretary, who shall report it, and any matter in controversy to the board, giving his judgment thereon, and the board shall supervise and control the action of its officers in executing the law.

13. Where standards of strength, quality, or purity are not fixed by the act, the analysts shall present to the secretary such standard as in their judgment should be fixed, and the secretary shall report the same to the board for its action. The standards set by the British Society of Public Analysts will be followed, as nearly as practicable, until otherwise ordered.

14. Whenever a drug or preparation, not prescribed in a national pharmacopœia or other standard work on materia medica, shall be manufactured, offered for sale, or used in this State, the standard of such drug, and the standard and proportion of the ingredients of such preparation, and the range of variability from such standard or standards, shall be ascertained by the analysts, who shall report the same through the secretary to the board.

15. The analysts shall occupy such time in the performance of their respective duties as a reasonable compliance with the terms of the statute shall require, and shall be present one hour of each day, at such time of the day and at such place as shall be designated by the board, to meet the convenience of interested parties and the public.

The following classified list embraces most of the examinations of articles of food examined in Massachusetts under the Food and Drug Acts up to October 1st, 1898:

Articles examined.	Total examined.	Number adulterated or below standard.	Per cent. of adulteration.
Milk	51,198	20,771	40.6
Condensed milk	247	21	8.5
Butter	3,563	413	11.6
Cheese	473	1	0.2
Vinegar	1,750	927	53.0
Lard	450	126	28.0
Olive oil	524	257	49.0
Spices and condiments	14,902	2,674	17.9
Coffee	1,088	245	22.6
Tea	976	31	3.2
Cocoa and chocolate	208	53	25.5
Wheat flour	167	5	3.0
Bread and cake	86	1	1.2
Cornmeal and other cereals	18	0	.0
Sago, tapioca, and corn starch	21	0	.0
Cream of tartar	4,486	465	10.4
Soda and saleratus	100	2	2.0
Molasses	2,394	305	12.7
Syrups	122	56	45.9
Maple syrup	483	135	28.0
Maple sugar	365	87	23.8
Sugar	156	9	5.7
Honey	716	209	29.2
Confectionery	784	65	8.3
Pickles	29	2	7.0
Lime juice and lemon juice	28	21	75.0
Horseradish	20	8	40.0
Arrowroot	21	4	19.0
Gelatin	34	3	9.0
Salt	21	1	4.8
Canned food *	523	244	46.6
Flavoring extracts	39	5	12.8
Sardines	5	4	80.0
Jellies and jams	112	47	42.0
Spirits, wine, ale, beer and cider †	192	121	63.0
Miscellaneous ‡	1,493	523	35.0
Drugs	9,898	3,532	35.7

* A considerable portion of these were French vegetables, which were examined for the presence of copper as a coloring agent.

† A large number of examinations of spirits and wines is included in the item of drugs.

‡ Under this head are included samples of sage, marjoram, macaroni, vermicelli, poultry dressing, desiccated cocoanut, citron, compressed yeast, meat extracts, cooking utensils, food wrappers, wall paper, clothing and textile fabrics, bottle stoppers, food preservatives, coloring matter, etc.

A broad view of the subject of food inspection would include the examination of water as one of the necessaries of life, since it is essential to the preparation of most articles of food, and also a convenient vehicle for the administration of very many of them. It is also absolutely necessary to the healthy growth of the human organism.

The important work of water analysis has been conducted by the Engineering Department of the State board of health since 1887, and this work has been extended to the examination of the waters of the ponds, streams, springs, reservoirs, and wells used as public supplies by about 160 cities and towns in the State. The total number of such examinations has been about 30,000. Full reports upon this subject may be found in the reports of the board for the years 1887 to 1900, and in the special document upon the examination of water supplies published in 1890.

In addition to the regular routine mode of food and drug inspection in Massachusetts, much has been accomplished by work in special directions during the eighteen years since the work was begun. These may be enumerated as follows:

Investigations relating to the *quality of milk* as produced by the cow.

Analysis of Injurious and other Empirical Preparations.—Hair dyes, cosmetics, bitters, and tonics; alleged cures for the opium and alcohol habits, catarrh and asthma cures containing cocaine, etc.

Coloring Matters in Food.—Milk, butter, oleomargarine, preserved vegetables, salts of tin in molasses, etc.

Food preservatives; the quality of *wines and liquors;* report upon *oleomargarine;* the uses of *glucose* in food; the presence of *trichinæ* in pork products; the standard of *vinegar;* the use of the word "*compound,*" etc.

The Standard of Milk.—For the purpose of determining the consistency of the existing standard of milk in Massachusetts, analyses were made in 1884 of the milk of six hundred cows, the samples being collected in different parts of the State, and from different herds of animals, of different ages, and in different seasons of the year. The average total solids of the entire number was found to be very nearly thirteen and one-third per cent. (the legal standard of Massachusetts is thirteen per cent. in winter, and twelve per cent. in summer). In later years these figures have been confirmed by further examinations upon the same point.

With reference to breeds of cows the results of analyses were as follows:

The average milk of 11 Jerseys had 14.02 total solids and 4.34 fat.
" " " " 92 native cows " 13.09 " " " 3.31 "
" " " " 30 Ayrshires " 12.97 " " " 3.35 "
" " " " 51 Durhams " 12.73 " " " 3.28 "
" " " " 47 Holsteins " 12.51 " " " 3.29 "

Artificial Coloring Matter in Food.—The practice of employing coloring matters in connection with different articles of food is very common. The following may be named as very common examples:

Certain condiments, such as mustard, ginger and other spices, sugar, confectionery, preserved and canned goods (especially peas, beans, and tomatoes), milk, butter, oleomargarine, pickles, cake, syrups, jellies, jams, preserves, fruit syrups, flavoring extracts, and various sorts of beverages.

The coloring matters employed in connection with these articles of food may be classified as follows:

1. *Harmless Colors.*—These are usually made from some comparatively harmless organic products, such as annatto, caramel, turmeric, and cochineal. Aniline dyes, the products of coal tar, are also quite largely used for the coloring of milk, jellies, jams, preserves, and other articles of food.

2. *Injurious Colors.*—These are usually some of the metallic compounds, such as lead, copper, and tin.

It cannot be urged in regard to any of these colors, whether harmless or otherwise, that they have any true value as articles of food, and the demand for their use comes mainly from the trader, and not from the actual consumer, excepting, so far as the latter has been erroneously educated by the former as to color standards in the matter of food. No good and useful end is attained by their use, so far as the question of nutriment is concerned, and not only may harm ensue, but also even fatal consequences.

The use of artificial food colors is usually a fraudulent one, and they are consequently employed mainly for the purpose of giving to an inferior article of food a fictitious value, and thus to imitate other articles of a similar character, but of better quality, at least so far as their actual cost is concerned. The difference in actual nutritive value as articles of food may, however, be but little or nothing.

When examinations of milk were made in Massachusetts soon after the enactment of the law of 1882, it was found that the addition of coloring matter to milk was a very common practice in the cities. From the fact that colored samples of milk were almost invariably found to be adulterated in other ways, it was inferred that artificial coloring was practised for the purpose of concealing fraud, and of giving to milk which had been skimmed and watered the appearance of milk of good standard quality. Hence a vigorous warfare was made against the practice until it disappeared.

The question of the sale of preserved vegetables colored bright green by sulphate of copper came to the attention of the board, and the safe ground was taken that the introduction of poisonous metallic colors in any amount whatever should have no legitimate place in the food-supply of the people. A general law forbidding the use of any sort of coloring matter in food would diminish the amount of food adulteration very decidedly.

Trichinæ in Pork.—Among the many questions relating to the food supply in Massachusetts the quality of the pork offered for sale has not been overlooked. Nearly thirteen thousand hogs have been examined under the direction of the board for the presence of trichinæ. Of this number 791, or 6.3 per cent., were found to be trichinous. Western hogs were found to contain less than Eastern, and of those raised in Massachusetts, those reared in public institutions and upon the refuse of cities were found to suffer the most. An examination was also made of sausages, and only one out of 365 was found to contain trichinæ.

Baking Powders.—No class of substances employed in the preparation of food has been the subject of so much discussion as these; and this is true notwithstanding the fact that, as elements in the matter of food economy, or as nutritive constituents of the necessary food of mankind, they have absolutely no value. Their use in the preparation of food was unknown until the early part of the present century, and for ages the human race thrived without them. Whenever bread was desired which should possess the properties of porosity and lightness of texture, in early times, some sort of leaven or yeast was employed for the purpose.

The use of baking powders at the present day is due, undoubtedly, to several causes, prominent among which is a demand for rapid and convenient methods of preparing bread and pastry for cooking; and, also, to the stimulus of trade produced by excessive advertising.

If the statements of rival manufacturers as to the poisonous qualities of all other baking powders except their own were to be credited, the use of these preparations would soon cease. Such false teaching does harm in misleading the community and creating a distrust. The fallacy lies partly in the want of discrimination between large and small doses of the ingredients of such powders. For example, common salt and mustard act as poisons in large doses and produce vomiting. In small doses, on the contrary, neither of them is harmful. Again the process of cooking changes the character of all baking powders.

It should be remembered that the introduction of these articles is of comparatively recent date; that they are compounded of several ingredients; that different manufacturers employ different ingredients to attain the same object or end, and, except in a few instances, standards of purity have not been adopted for this class of articles: hence the use of the terms *purity* and *impurity,* as applied to them, must be considered as arbitrary, or at least merely conventional. Experiments have been undertaken with the view of settling the question as to whether the ingredients of certain baking powders were injurious to health; and, while positively harmful results have in some instances been reached by the ingestion of considerable doses of such ingredients, when taken singly, still, the question of actual injury to the health of human beings on the one hand, or of freedom from harm on the other, from the use of baking powders in food, cannot be regarded as settled.

Intoxicating Liquors and Beverages.—The examinations of intoxicating liquors (including those of wines, ale, and beer), which have been made by the chemists of the board, have embraced samples which have been obtained both as drugs and as beverages, the former having been obtained exclusively from drug-stores, and the latter from places where such articles are retailed as beverages.

These examinations have shown that while adulteration of intoxicating liquors is a matter of very common occurrence, the presence of harmful adulterations, contrary to popular opinion, is rare. The following statement of the analyst in the report of 1886 is also confirmed by more recent examinations.

"For the sake of the public health, it is a cause for congratulation that the chief deviations from the requirements of the Pharmacopœia consist almost exclusively in the addition of alcohol, of water, and of harmless sweetening and flavoring substances. Not a single sample of adulterated spirits in the popular understanding of that term, that is, one containing a more injurious ingredient than alcohol itself, was met with, although very few were exactly what they purported to be" ("Supplementary Report of Health Department, Mass.," 1886, p. 184).

Mixtures or Compounds.—The work of inspection includes a careful examination of the methods in which food is offered for sale, especially with reference to the question of labelling and the agreement of the label with the actual contents of the package to which it is affixed, since the statute of Massachusetts provides that "mixtures or compounds" are not to be treated as adulterated in the eye of the law, "provided that the same are not injurious to health and are distinctly labelled as mixtures or compounds with the name and per cent. of each ingredient therein."

This provision of the law is frequently disregarded, especially in the case of spices; and while the term "compound" is to be found after prolonged search upon the label, it often occupies an obscure position, or is printed in extremely small type, so that the term "*distinctly* labelled" does not apply.

It is not always safe to infer that all parts or packages in a lot of spices or similar articles of food are pure, because a single sample or package proves to be pure. The following case is an illustration: Two packages of powdered cloves were obtained at a grocery. The packages were in unbroken tin boxes of one-quarter pound each, and were purchased at an interval of three weeks; each package was of the same size, and each had exactly the same brand or label. On inquiry of the retailer it was found that both of the packages came from the same lot. It appeared on examination that the first package was considerably adulterated and the second was pure. A notice of this fact was therefore sent as usual to the retailer, who transmitted the notice to the manufacturer, who lives outside the limits of the State; he denied the charge, and hence, as is customary in cases of disputed analysis, samples were sent to a second analyst, who confirmed the statements of the first; and finally, four analyses were made with the same result, neither chemist knowing anything of the source of the samples, nor did either know that a previous analysis had been made.

This circumstance shows that it is not always safe to judge of the character of any group or lot of articles from the examination of a single sample.

Gross Appearances.—It is evident that very little reliance can be placed upon the mere external inspection of articles of food, such as may be made by the employment of the senses of taste, touch, smell, and sight, since the principal object of the falsifier of food preparations is to deceive the senses of the consumer by every possible resource of his art. It is a common experience in this department of work to receive articles of food from various sources, which are believed by the persons presenting them for examination to be adulterated, but which the analyst finds to be pure. This experience is true in the case of many of the articles of food which are liable to adulteration, and also of some articles which are scarcely ever found to be adulterated. The same experience has been met by other authorities who have had charge of similar work ("Report of Commissioner of Internal Revenue," Washington, 1887, p. cxliii.). Among the various articles which have been thus submitted to the board for examination (under the impression of the person submitting them that they were adulterated) were the following: Flour, sugar, molasses, vinegar, cream of tartar, honey, milk, butter, cheese, lard, salt, and several kinds of spices or condiments.

The reasons for these false notions with reference to the quality of articles of food are mainly the following: 1. A liability to mistake the deterioration of an article, or an inferiority in grade or quality, for an actual falsification or substitution. 2. A lack of familiarity with the true physical characteristics of the article in question.

Notices to Retailers.—It has been the custom of the board to issue a warning notice to retailers selling articles found to be adulterated, in cases in which there was a reasonable probability that the retailer was not aware that such articles were adulterated.

In certain articles of food which have been specially liable to fraud, such as the various sorts of spices, condiments, cream of tartar, etc., adulteration has been greatly diminished, and is in many instances limited to parties whose business is conducted outside of the State, and cannot therefore be easily reached except through the customary notice sent to the retailer who buys of such outside parties.

These notices have proved to be a very efficient mode of diminishing adulteration. It is not the retailer who is seriously affected by the receipt of such a notice, but the wholesale dealer or manufacturer to whom it is speedily forwarded by the retailer, and who finds that he cannot afford to continue a wholesale imposition.

In the following table the ratio of adulteration found in articles of food and drugs examined in England and in Massachusetts during the period of inspection and enforcement of the laws is presented:

PERCENTAGE OF ADULTERATION AS GIVEN IN THE REPORTS OF EACH YEAR.

Year.	England and Wales.		Year.	Massachusetts.
	Ratio of adulteration. Per cent.	Average five years. Per cent.		Ratio of adulteration. Per cent.
1877	19.2	16.2		
1878	17.2			
1879	14.8			
1880	15.7			
1881	14.7			
1882	15.1	13.9		
1883	15.0		1883	44.5
1884	14.4		1884	54.2
1885	13.2		1885	42.4
1886	11.9		1886	38.7
1887	12.8	12.7	1887	34.3
1888	10.8		1888	30.3
1889	11.5		1889	31.9
1890	11.2		1890	31.5
1891	12.2		1891	32.8
1892	12.4		1892	33.7
1893	12.9		1893	31.2
1894	10.3		1894	31.9
1895	9.3	10.8	1895	38.5
1896	9.2		1896	26.6
1897	9.4		1897	24.8
1898	8.7		1898	25.2
			1899	24.3
			1900	26.1

As a comment upon the foregoing table and the diagram below the following observations may be made:

First. The gradual lessening of adulteration under the action of judicious legislation.

Second. The much greater ratio presented in the column headed Massachusetts than in that of England and Wales. The reason for this great difference may be found, *first*, in the fact that in conformity to the requirements of the statutes in Massachusetts more than half the samples examined were milk. The standard of milk in the State is unusually high as compared with that of other countries (thirteen per cent. of solids, in winter, and twelve per cent. in summer). Hence it is the custom to report all samples as adulterated which are found to be below the foregoing limits. Now, there are many animals, especially those of the Holstein breed, which habitually produce milk having less than thirteen per cent. of solids. Hence it has not been deemed prudent to enter complaints at court to the full extent of the legal requirements. In the case of milk, therefore, the ratio of adulteration as reported is for the most part an apparent and not an actual adulteration. *Secondly*, the samples selected under the Massachusetts law are mainly such as are known or suspected to be adulterated, while in England many samples of such staple articles as bread, flour, sugar, and tea are annually examined, which are practically free from adulteration.

A prominent feature in the execution of the Massachusetts law is that of expenditures. The sum appropriated for the work of the first year was $3,000; of the second year, $5,000; of the third year, $10,000, and for the past nine years, ended 1901, it has been $11,500 per year. About $35,000 has been collected since and including 1888 in fines for violation of the law, this amount being returned to the treasuries of cities, towns, and counties.

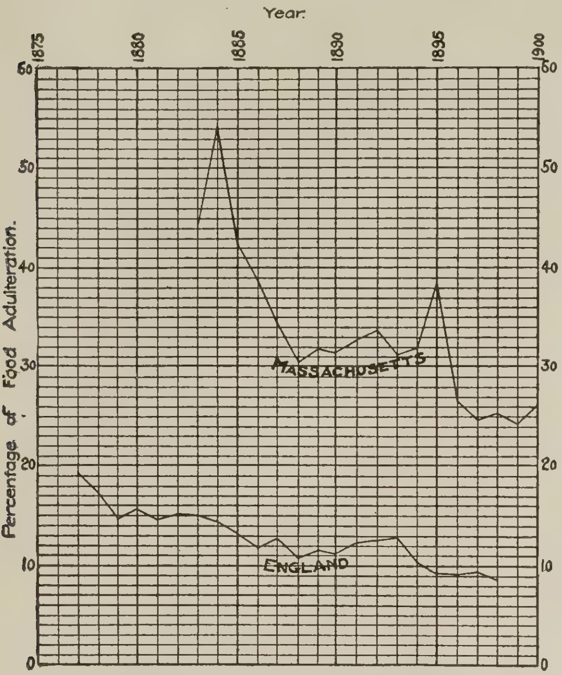

FIG. 2098.—Diagram showing the Ratio of Adulteration in England, 1877–1898, and in Massachusetts, 1883–1900.

Small amounts were expended annually at first for legal services, the entire amount for the first twelve years being $1,639.63, or less than $150 per year. But for the past six years, no expenses whatever have been incurred in the employment of counsel, the inspectors having become familiar with the methods of presentation of cases at court.

The annual ratio of samples of food collected for examination to the whole population in recent years has been as follows:

In England and Wales (1895–99)......	about	1	to each	700	inhabitants.
In Paris (1895–99).....................	"	1	"	100	"
In Massachusetts (1895–99)...........	"	1	"	250	"
In Ohio (1898) (612 samples).........	"	1	"	6,635	"
In Connecticut (1898) (1,265 samples).	"	1	"	665	"
In New Jersey (1899) (1,792 ").	"	1	"	1,026	"
In Minnesota* (1897-98) $\frac{1582}{2}$ = (791 samples)	"	1	"	1,062	"
In New York (1895) (2,391 ")	"	1	"	2,774	"

CONNECTICUT.—Acting under the provisions of a Law of 1895, the Connecticut Agricultural Experiment Station makes analyses of "food products on sale in Connecticut suspected of being adulterated," and is provided with an annual appropriation of $2,500 for this purpose. The station also examines food products submitted by the Dairy Commissioners.

During the year 1898, the number of samples thus examined, exclusive of cattle feeds, was 1,265. The principal articles examined were as follows:

Jellies.—Seventy samples, 43 adulterated, the chief adulterants consisted of gelatinous materials (starch, paste, gelatin, agar-agar, and apple jelly), sweetness (glucose, and saccharin). Saccharin costs $15 per pound, but is 500 times as sweet as sugar. It has no nutritive qualities. Coloring matter (mostly aniline dyes); fruit flavors, acids, and chemical preservatives. The report publishes the name of the brand and wholesale dealer and of the retailer in each case, also the place of sale, quantity, and price.

Of 51 samples of jams, preserves, and marmalades 45 were found to be adulterated, the principal adulterants were glucose, salicylic acid, and aniline or other artificial colors.

Tea.—Eighty-nine samples were examined and "none of the samples were found adulterated other than by facing."

Coffee.—Of 73 samples 11 were found adulterated, or 11 out of 45 to which the statutes would apply.

The percentage of adulteration of coffee in the past three years was as follows: 1896, 63.3 per cent.; 1897, 57.7, and in 1898, 24.4. This improvement the board attributes to the operation of the pure food law.

Ginger.—Ninety-one samples were examined, 24 adulterated.

Ale and Beer.—In 47 samples 12 were found to contain salicylic acid.

Sausage.—Of 19 samples 14 contained borax and 10 contained starch.

Honey.—Of 37 samples of honey the report says "five are probably pure, 22 may be genuine, though they seem to be made by bees fed somewhat with cane-sugar, or to have had invert sugar added to them; 2 unquestionably contain cane-sugar added as an adulterant, and 8 are adulterated with glucose syrup."

Examinations of milk, cream, maple syrup, mince meat, and canned vegetables failed to find any adulterations worthy of note.

Of 332 samples of spices in bulk and 242 samples in packages examined in the three years (1896–98) 41.5 per cent. of the former and 23.5 per cent. of the latter were adulterated.

The report recommends as the only safe course in buying spices, that they should be bought in "sealed packages, bearing the name of a reliable house whose goods have not been found adulterated."

Of 203 samples of molasses, 34 were found to be adulterated with glucose.

OHIO.—The Dairy and Food Commission of Ohio reports upon the examination of 612 samples of food examined in 1898, of which 292 or 47.7 per cent. were adulterated.

The principal articles examined were 31 samples of flour of which 4 were adulterated; 15 of maple syrup, 7 adulterated; 110 of milk, 31 adulterated; whiskey 54, of which 27 (or one-half) were adulterated; spices, 18, of which only one, a sample of cinnamon, was adulterated; wine 6, all pure; flavoring extracts, 17, of which 8 were adulterated; cream of tartar 6, of which 1 was adulterated; cheese 4, all genuine.

The number of prosecutions instituted was 68, of which 14 were for adulteration of milk, 33 for butter, and 5 for whiskey.

$2,064.40 was collected in fines and fees. About $8,000 was expended for legal services.

NEW JERSEY.—The Dairy Commission of New Jersey reports for the year 1899 that 1,792 samples of food were examined. Of these 712 were samples of milk, 959 butter and oleomargarine, 46 linseed oil, 46 condensed milk.

Six hundred and three of the milk samples were above the standard of 12 per cent. solids. Fifty of the samples purchased as butter proved to be oleomargarine; the remainder were pure butter.

Only five samples of milk contained formalin.

Five samples of linseed oil out of 46 were adulterated.

$3,050 were collected in fines.

MINNESOTA.—The Dairy and Food Commissioner of Minnesota, in his biennial report for the two years ended July 31st, 1898, presented the operations of his department under the dairy and food laws of the State. In addition to the general statutes relating to inspection of dairy products, other special laws have been enacted in

---

* Biennial Report.

Minnesota for the prevention of adulteration of honey, confections, jellies, spices, and condiments.

The whole number of samples of food examined in the two years was 1,582, of which 807, or 51 per cent., were adulterated. The principal articles examined were as follows:

Vinegar,	807	samples, of which	466	were adulterated.	
Baking powder,	175	" " "	131	" "	(alum).
Butter,	26	" " "	4	" "	
Cheese,	148	" " "	18	" "	
Cream of tartar,	2	" " "	2	" "	
Hominy,	32	" " "	8	" "	
Spices,	162	" " "	26	" "	
Jelly and jam,	28	" " "	15	" "	
Lard,	84	" " "	34	" "	

New York.—The State board of health of New York, in its fifteenth annual report (1895), presents the statistics of 2,391 samples examined during the year. Nearly all of these were drugs, which the chemist classified as follows:

Of good quality	1,307,	or 57.1	per cent.
" fair quality	284,	" 12.4	" "
" inferior quality	598,	" 26.1	" "
Not as called for	41,	" 1.8	" "
Excessive strength	59,	" 2.6	" "
Total drug samples	2,289		

The principal articles examined were 230 samples of ether, of which 114 were not of standard quality.

Compound spirits of ether, 109 samples examined, of which only 35 were of good quality.

Hydriodic acid, 127 samples, of which 111 were of good quality.

Dilute hydrochloric acid, 105 samples, of which 71 were of good quality.

Tincture of iodine, 205 samples, of which only 39 were of good quality.

Magnesia, 149 samples, of which 65 were of good quality.

Diluted phosphoric acid, 162 samples, 126 of good quality.

Aromatic sulphuric acid, 120 samples, only 9 of which were considered to be of good quality.

Precipitated sulphur, 104 samples, 38 of good quality.

Fifty-nine samples "contained large quantities of sulphate of lime."

The chemist also examined 102 samples of canned tomatoes, to determine whether they contained artificial coloring matter. Only 2 samples were found to be colored with eosin.

In the seventeenth report of the board, the director of the laboratory states: "Through lack of funds available for the purpose, the systematic collection and examination of food and drugs was suspended June 1st, 1895."

In Indiana the State board of health has been authorized "to prepare rules and ordinances, where and when necessary, regulating minimum standards for food and drugs, defining specific adulteration, and determining the proper methods of collecting and examining drugs and articles of food." Under this provision the board has published standards for the following articles of food:

Milk, butter, margarin, cheese, coffee, tea, candy, cider, flour, jellies and preserves, honey, lard, molasses and syrups, olive oil, spices, vinegar, baking powders, and spirituous liquors and wines. The use of preservatives is also regulated. Milk must contain no added coloring matter nor preservative. It must not be sold if taken within ten days after calving, or within twenty-one days before expected calving; nor must it be sold if taken from a cow fed with damaged food, or such as will impart a disagreeable flavor. It must not be taken from a sick or diseased cow, nor from one to which polluted water has been given, nor from one which has been "kept under conditions contrary to the rules of the State board of health governing dairies."

Classification of Work.—The work of a food analyst embraces a variety of branches. In a recent monograph by two French army surgeons, Polin and Labit, the following classification of such work is presented. Three principal groups, as follows: 1. Examination of articles in which the alterations in character are either of a chemical or of a mechanical kind. 2. Those which are biological. 3. Those which are parasitic.

The first group is subject to the following subdivision: (*a*) Additions have been made to the food products either of a commercial or a fraudulent nature, and of substances more or less harmful. (*b*) The vessel in which the food has been prepared or preserved renders the food poisonous. (*c*) The manipulation of food, or its surroundings, may expose it to harmful contamination. (*d*) It may be mixed accidentally with foreign substances.

The second group is subject to the following divisions: (*a*) An animal designed for food has been fed with food of a harmful or poisonous character; the poisons absorbed appear in the milk, or, not having had time to become eliminated, either the whole animal or some of its organs have become poisonous. (*b*) Recognizes the possibility of the formation of poisonous ptomaïns in meat, under certain conditions. (*c*) In consequence of certain unknown conditions wholesome vegetable food occasionally becomes harmful.

Third group: (*a*) Animal, vegetable, and mineral food products may be invaded by parasites of the larger kinds. (*b*) Food may become the prey of micro-organisms of a parasitic nature, involving the processes of (1) fermentation, (2) putrefaction, and (3) the development of infectious diseases, either of which may render the food harmful, either by infection, by ptomaïn poisoning, or by the combined action of both. (*c*) Food contaminated by its surroundings, or by infectious contact, becomes the carrier of pathogenic germs.

This list is sufficiently ample to show that the food analyst has a wide field of investigation.

Regulations.—The following special regulations regarding food inspection were published by Dr. Schumacher Kopp, canton chemist of Lucerne, and also a member of the International Jury of Award at the Paris Exposition of 1889.

The following extract is taken from his report:

Collection of Food.—In collecting food the greatest cleanliness should be observed. Clean bottles, and, if possible, new ones, should be used in collecting fluids. Bottles should be closed only with new corks.

In collecting drinks, the local experts must be present, and the beverages should be drawn from the regular source of supply.

In collecting milk, fill the bottle to the cork; seal every bottle at once after corking it. If milk is collected in a stable, the cows must be milked quite dry, by a disinterested person, and in the presence of the local magistrate or a policeman.

Strong glass, or porcelain, or crockery vessels should be used for the collection of butter.

For coffee, tea, and meal, boxes of clean wood or pasteboard should be used.

The use of paper bags for collecting samples is forbidden.

Bread and sausages should be wrapped in clean white paper; if possible, parchment paper.

The use of printed or colored paper for this purpose is forbidden.

Quantity of Food Necessary for Examination.—1. For the local health authority: Beer, 1 litre; bread, one whole loaf; brandy, 0.3 litre; butter, 50 gm.; vinegar, 0.2 litre; coffee, 30 gm.; meal, 200 gm.; milk, 0.5 litre; cider, 0.5 litre; tea, 10 gm.; drinking-water, 1 litre; wine, 0.5 litre; small sausages, one whole sausage; large sausages, 100 gm.; honey, 50 gm.

For the canton chemist the quantities are nearly the same as the foregoing, but in most instances two samples are taken. When two samples are taken, for example, of water, 2 litres in one bottle are not meant, but two bottles each containing 1 litre.

Sealing.—The samples collected must be sealed at once upon the spot, with an official seal. This seal must cover the whole head of the bottle, in order to keep the air out and to avoid leakage.

Marking.—The samples should be plainly marked in two different places immediately after collection, one on the neck of the bottle, and the other on the opposite side of the body of the bottle. Each marking must contain: (1) The number and name of the article collected; (2) name of the jurisdiction authorizing the collection, and of the collector.

Provision is made for the collection of two samples when necessary, so that, in case of a dispute, the second may be examined under the auspices of a superior authority. The samples sent to the canton chemist must contain no information as to their source. A report must also be sent to the health officer, stating the articles collected, the date of their collection, name of the dealer, his source of supply, and in every case his remarks upon the character of his goods. This report must be signed by the local expert and by the police assisting in the collection. All samples sent to the canton chemist must be so packed with sawdust, paper, or wadding, that they may be transmitted without injury. The name of the sender must accompany all packages, letters, etc., and they must be prepaid; otherwise they will not be received.

In sending milk to the canton chemist, observe especially: 1. That the milk is thoroughly cooled in cold water before it is forwarded. 2. (*a*) In the accompanying report mention must be made first of the number of cows from which a sample of mixed milk is taken; (*b*) how many cows, if any, are in the stable which have calved within fourteen days of collection of the milk; (*c*) how many cows, if any, are near the time of calving.

FOOD STANDARDS.—*Bread.*—The water in a freshly baked loaf of bread should not be more than thirty per cent. of its weight, and the ash, after deducting the common salt, should not be more than one per cent.

Butter.—This name should be associated only with the fat which is made from milk only. Artificial butter must be properly marked as such, being designated as margarine, and packed in separate parcels. Such names as "cheap butter," "tub butter," and "Alpine butter," are forbidden, except as applied to pure butter.

Vinegar must contain four per cent. of acetic acid. The addition of other acids, flavoring matter, and aniline colors, is forbidden.

Honey must be called honey only when it is free from adulteration. Such terms as "table honey," "Swiss honey," and "Appenzell honey," etc., are forbidden, except when applied to pure honey. Substitutes for honey, such as syrups, etc., and also mixtures of these with pure honey, must be plainly marked as such.

Coffee must not yield more than four per cent. of ash (Mocha, eight per cent.). Artificial coloring is to be regarded as adulteration. Mixtures of coffee with other substances are not to be called coffee.

Rye meal should not yield more than two per cent. of ash.

Wheat meal should not yield more than one and a half per cent. of ash. The water of rye and wheat meal should not be more than fifteen per cent. of its weight, and that of other meals eighteen per cent.

Milk.—Milk must be sold as drawn from the cow. Its specific gravity at a temperature of 15° C. (60° F.) before skimming should not be less than 1.029 nor more than 1.033, and when skimmed after twenty-four hours it should not be less than 1.033 nor more than 1.037. The chemical examination should show at least 11.5 per cent. of solid residue, and at least three per cent. of fat.* When taking milk at dairies for comparison, it is desirable to have examinations made within the shortest possible time, three days at the longest, and the cows should be milked dry by disinterested persons. "Centrifugal" milk should be marked as such, and when inspected at a temperature of 15° C. should have a specific gravity of from 1.034 to 1.037, and should have at least 8.4 per cent. of solids. The sale of the milk of sick cows is forbidden, as well as that of cows within eight days before and after the time of calving.

Cider, after fermentation, must not have less than three per cent. by weight, and 3.76 per cent. by volume of alcohol, and not less than 1.5 per cent. of solids, nor less than 0.15 of one per cent. of ash.

Tea must not have more than seven per cent. of ash.

Water for domestic use must have neither color nor sediment. Nor should it have smell or bad taste. Water containing infusoria and bacteria should be avoided.

Sausages should be made only of healthy, fresh meat, fat, and spices in general use. Any additions of starches are considered as adulterants.

PROPRIETY OF INTERNATIONAL LAWS ON THE SUBJECT OF FOOD INSPECTION.—Dr. Von Hamel Roos expressed his opinion at the International Congress of Hygiene at London, in 1891, that a *codex alimentarius* should be adopted for civilized nations, as agreed upon by a competent commission for general use. He commented upon the different standards of different countries, and as an example quoted the milk standard of Massachusetts (which is thirteen per cent. of solids in winter and twelve per cent. in summer), while milk having 11.5 per cent. solids is deemed to be pure in Holland.

At the International Congress of Agriculture at The Hague, in the following month (September, 1891), conclusions were formulated as to the need of uniform laws relative to food adulteration and the protection of food products. It was then voted "that each State should establish a commission of competent men, who should be charged with the duty of investigating the methods of analysis in use, and of determining the proper methods of such analysis, and that each state should publish an annual report of its proceedings and exchange reports with other states."

NEW FORMS OF ADULTERATION WHICH HAVE APPEARED RECENTLY.—*Arsenic in Food, in Drink, and in Drugs.*—In the preparation of many articles of food and drink, glucose enters as an ingredient, being a cheaper form of sugar than that which is prepared from the sugar-cane. In the manufacture of glucose it is necessary to use sulphuric acid, this acid being removed before the process is completed. The crude sulphuric acid often contains arsenic in consequence of the presence of arsenic in the iron pyrites from which a large part of the acid in the market is made.

Glucose is now used largely in the manufacture of beer, and as a consequence beer-drinkers in England have suffered seriously from arsenical poisoning. From the report of Dr. Buchanan to the local government board, dated February 7th, 1901, it appears that 3,652 cases of arsenical poisoning had occurred in Manchester, Liverpool, Chester, Salford, and neighboring places, and that many deaths had taken place among this number. Most of these persons were habitual beer-drinkers.*

A parliamentary committee was appointed in February, 1901, charged with the duty of investigating this subject and reporting upon it. This committee reported in July, substantially confirming the statement of the local government board. It was found, according to this report, that the glucose used came from one firm of manufacturers of brewing sugar, and upon analysis of several samples by different chemists quantities of arsenic were found, amounting in one instance to 9.17 grains per pound of glucose.

The conclusions of this commission, as summed up in this preliminary report of July 10th, 1901, are as follows:

"On consideration of all the circumstances connected with the recent epidemic, we think that some improvement in administrative measures is called for. It is evident that amendments have to be considered, not only with reference to the question of arsenic in beer, but also in relation to the broader question of the machinery available to public health authorities to obviate the risk of arsenic or other poisonous substances reaching articles of food and drink in general.

---

* The standard of whole milk in Paris is a minimum of 11.5 per cent. of solids and 2.7 fat. That of the British Society of Public Analysts is 11.5 total solids and 2.5 fat. That of the State of New York is 12 per cent. of solids and 3 per cent. fat. Of New Jersey 12 per cent. of solids. Of Massachusetts 13 per cent. of solids in winter and 12 per cent. in summer.

* Report to the Local Government Board on "Recent Arsenical Poisoning Attributed to Beer," by Dr. G. S. Buchanan, London, 1901.

"Upon this important general question we consider it essential to await further evidence before making final recommendations. But meanwhile, seeing that the epidemic of 1900 has been caused solely by beer, and that there exists in the case of breweries (although for another purpose) a system of close inspection by a government department—the board of inland revenue—we think that as a provisional measure the machinery under this system might effectively be turned to account to check the introduction of arsenic into beer by way of its ingredients.

"To this end we recommend that the board of inland revenue should possess and should exercise powers to specify in detail individual ingredients of beer which are liable from their origin or mode of preparation to be contaminated by arsenic, to prescribe for every such ingredient, and for the different materials used in their preparation, an adequate test which should insure their freedom from arsenic; and to prohibit, under penalty, the use in a brewery of any material which infringes the prescribed test.

"We are of opinion that by requiring the brewer to produce satisfactory evidence (whether in the form of a guarantee from the vendor, or as the result of analysis by the brewer's chemist, stated in such terms as the board of inland revenue may determine) that the prescribed tests have been applied to all the ingredients of beer at the brewery which have been specified as liable to contain arsenic, and that, by the examination of samples in the government laboratory, an immediate and effective safeguard to the public with regard to arsenic in beer can be secured." *

Among the adulterations which have increased very much in recent years are the various preparations of preserved fruits, jams, jellies, and marmalades, which, in the majority of instances of those which are sold at a low price, are adulterated with a multitude of substances other than those which they profess to be. They are also often highly colored with aniline dyes. Flavoring extracts are also adulterated seriously in many ways, and often contain none of the essential oil which is named upon the label. This form of adulteration has greatly increased in the past two years.

Artificial Coffee Berries.—An artificial coffee berry was made in New Jersey and advertised for sale. The berry was a very good imitation of the genuine in shape and color, but was entirely devoid of the taste of coffee. Its texture was easily distinguished by the microscope, and hence it proved to be a failure as a practicable adulteration. It was composed of burnt flour or starch.

False Nutmegs.—Dr. Vanderplanken† describes an artificial nutmeg having the following characteristics:

1. Absence of vegetable structure on section.
2. When treated for three minutes with boiling water, the nut is softened and breaks into a powder under the pressure of the fingers.
3. The ash amounts to more than eleven per cent., that of the genuine nut being from two to three per cent.
4. They are heavier than the genuine nuts.

A very good photograph of the true and false nuts is presented in the paper of Dr. Vanderplanken.

Coloring Matter.—The use of caramel and annatto is less frequently used for the false coloration of milk, and an aniline dye is now used, the quantity required being comparatively small.

Preservatives.—The use of boric and salicylic acids has increased recently for the preservation of meat, fish, milk, and other perishable articles of food, and still more recently formalin has come into use for the same purpose. The method employed for the detection of formalin is detailed in the report of the State board of health of Massachusetts for 1897.

Saccharin.—The question of the propriety of using saccharin as a sweetening agent in place of sugar is under discussion in France.*

The following list embraces most of the common articles of food which are liable to adulteration, together with the character of the adulteration.

ARTICLES LIABLE TO ADULTERATION, WITH THE CHARACTER OF ADULTERATION.

Name of article.	Harmful adulterants.	Fraudulent adulterations.
Arrowroot		Other and cheaper starches.
Alcoholic liquors.	Excess of fusel oil, harmful coloring matter.	Added water, sugar, alcohol, and coloring matter.
Bread	Alum, used as such; rare in United States.	Other and cheaper kinds of flour than those which are called for. The contained water should not be over forty-five per cent.
Butter		Other animal and vegetable fats, such as beef suet and cotton-seed oil, lard, coloring matter, and excess of water.
Beer	Salicylic acid and other preservatives; arsenic as an impurity in glucose; water polluted with sewage.	Burnt sugar, licorice, molasses, glucose, quassia, salt, etc.
Canned goods	Lead, tin, and zinc from interior of cans and from solder; copper as a coloring agent; harmful preservatives.	Contents of cans damaged by improper sealing and from other causes; use of coloring matter; use of old and damaged articles such as "soaked" peas.
Catsup	Salicylic acid and other preservatives.	
Cheese	Poisonous colors in the rind.	Lard, cotton-seed oil, and deficiency in fats.
Cider	Salicylic acid and other preservatives.	Water.
Cloves		Corn, wheat, allspice, nutshells, peas, ginger, pepper, charcoal, dirt, and clove stems.
Cocoa		Animal fats, starch, flour, sugar, and caramel.
Coffee	Harmful colors	Chicory, dandelion, beans, peas, rye, wheat, almond shells, and brown bread, imitation berries made of burnt starch, etc.
Confectionery	Harmful colors and flavors, terra alba, talc, baryta, fusel oil, and brandy.	The term "confectionery" has no standard and many substances enter into its composition. Glucose is largely used as well as cane-sugar, neither of which is harmful.
Cooking utensils.	Arsenic; antimony and lead in the glazing.	
Dried fruits	Occasional slight traces of zinc from the evaporating trays.	
Flavoring extracts.		Deficiency in essential oils and alcohol; excess of water; substitution of cheaper flavoring ingredients, addition of artificial colors.
Flour		Rarely adulterated in United States except with cornmeal.
Fruit syrups	Aniline colors and flavors.	Coloring agents generally; cheaper fruits and often no fruit whatever.
Ginger		Turmeric, Cayenne pepper, mustard, inferior and exhausted powder.
Gluten meal	Starch (injurious when the meal is employed as a diabetic food). Very few of the so-called gluten meal preparations found in the market consist of true gluten without starch.	
Honey		Glucose, sugar, molasses, syrups, and dead bees introduced for effect.

† Revue Internationale des Falsifications, vol. xii., 1899, p. 134.

ARTICLES LIABLE TO ADULTERATION, WITH THE CHARACTER OF ADULTERATION.—*Continued.*

Name of article.	Harmful adulterants.	Fraudulent adulterations.
Horseradish.		Turnips.
Ice cream	Poisonous dyes and flavors and as an accidental ingredient, poisonous ptomains.	
Jams and jellies.	Harmful dyes and flavors.	Glucose, gelatin, substitution of cheaper fruits, cores, parings, and seeds.
Lard		Other animal and vegetable fats and water.
Lime juice	Mineral acids and preservatives.	Tartaric and other organic acids.
Mace		Starches, and substitution of wild mace for true mace.
Maple sugar		Usually cane-sugar.
Maple syrup		Glucose and cheaper cane syrups.
Meat	The product of diseased animals; presence of parasites, and of ptomains.	Substitution of cheaper kinds.
Milk	Substitution of water and removal of cream. These are much more than mere commercial frauds, they rob the milk of its valuable nutritious constituents; use of preservatives.	Addition of coloring matters, caramel, annatto, aniline dyes.
Milk-sugar		Cane-sugar and glucose.
Molasses	Salts of tin	Glucose.
Pickles	Copper, alum, mineral acids.	
Preserves	Aniline dyes and preservatives.	Apples, pumpkins, turnips, glucose, and generally cheaper sorts of fruit, and fruit and vegetable seeds and other refuse products.
Sago		Cheaper starches.
Sausages		Colored with Bismarck brown and other colors. Made from meat of diseased animals.
Spices	Lead coloring matter in Cayenne pepper.	Starches generally, sawdust and other forms of wood, ground nut shells, olive and date stones, turmeric, charcoal, dirt, pepper and mustard hulls, cheaper kinds of spice, removal of essential oils; substitution of wild mace for mace.
Sugar	Salts of tin	Cane-sugar is rarely adulterated in United States except by use of ultramarine, which is employed to give a better color (bluish-white instead of yellowish-white) for same purpose as indigo is added to starch. So far as can be learned the ultramarine is harmless.
Tea	Lead, Prussian blue and other earths.	Leaves of other plants, spent tea, and substitution of cheaper kinds.
Vinegar	Mineral acids and aniline colors.	Glucose, apple pomace and jelly, water; cheaper vinegar for cider vinegar; caramel and other coloring matter.
Wines	Plaster of Paris, sulphur, harmful colors.	Alcohol (fortification), water (dilution), sugar; entire substitution of other articles as cider for champagne; fictitious imitations.

ADULTERATION OF DRUGS.

In nearly all countries in which efficient laws have been enacted for the purpose of preventing the adulteration of food, additional powers have also been provided for similar action in regard to drugs. Since, while it is important that the nutriment intended for the daily support of man should be of the best quality, it is also important that those articles which are used in the treatment of disease should be free from impurity.

In Great Britain and the continental countries of Europe generally, modern legislation for this purpose is very efficient, and the means provided for drug inspection are similar to those which are provided for food, the collections being made by the same set of officials, the examinations by the same analysts, and the work performed in the same laboratories.

ENGLAND.—In England the inspection of drugs is carried out under the provisions of the Sale of Food and Drug Act of 1875. The substance of this act is presented elsewhere in the section on Food Inspection. Dr. Hime says of this statute: "There are probably no statutes of the length of the Sale of Food and Drugs Act which have been the source of as much litigation and of as many appeals."* By the provisions of this act "the term 'drug' includes medicine for external or internal use."

It is also provided that "no person shall treat any drug so as to affect injuriously the quality or potency of the drug, with intent that the same may be sold in that state, under a penalty of not exceeding £50 for the first offence."

Under the operation of this law 235 public analysts have been appointed to carry out the work of inspection of such articles of food and drugs as are collected in the different districts of England.

The following figures present a condensed summary of the inspection of drugs since 1877:[1]

Percentage of adulteration found on examination: For the five-year period 1877–81, 22 per cent.; 1882–86, 13.6 per cent.; 1887–91, 13.1 per cent.; 1892–96, 12.3 per cent.

During the year 1896–97 the percentage of adulteration was 11.3 per cent. During 1897–98 it was 10.5 per cent.

The total number of samples of drugs examined in 1896–97 was 1,380, of which 156 were found to be adulterated. In 1897–98 the adulterated samples were 206 out of 1,964. The principal articles found to be adulterated in 1897–98 were sweet spirits of nitre, 39 samples out of 156; rhubarb, 35 out of 198; quinine, 10 out of 99; sulphur, 2 out of 90; glycerin, 23 out of 345; lime water, 13 out of 20. To these should be added in the former year: wine of ipecac, 10 samples out of 29; and beeswax, 10 samples out of 46.

The number of prosecutions conducted in 1897–98 against offenders of this class was 87, and 53 fines were imposed.

GERMANY.—The German code of laws relating to the sale of drugs is contained in a series of statutes which have been enacted and amended at different times during the past century. Special care is given in these statutes in relation to the sale of poisons, and lists of such poisons are published, allowing certain classes of poisons to be sold under restrictions (Law of 1890, January 27th).[2]

The law in regard to the sale of proprietary medicines is also quite explicit. By these statutes it is provided:

1. That unapproved panaceas cannot be sold.

2. In consequence of the unrestricted sale of patent medicines of a worthless character, a decree was published in 1867 that "all requests for the right to prepare and sell a secret remedy, although shown to be harmless, will be denied to private individuals, but concessions granted exceptionally in former years are to expire with the decease of the persons to whom they are granted, and cannot be transmitted to others."

3. Advertisements or private announcements of secret remedies are strictly forbidden.

In Berlin the police authorities cause patent medicines to be analyzed with reference to their composition. Attention is also paid to the price of such articles, and if necessary they can acquire information relative to the methods of manufacture. It is also allowable to publish the composition, the actual value as a remedy, and also any facts that may be revealed as to the character of the manufacture, and if necessary to warn the public against its use.

These regulations have had a salutary influence in Berlin, and have had the effect of driving the traffic in such articles into outlying provinces, where the manufacturers continue to plunder the public without hindrance (und daselbst das Publikum auszubeuten versuchen) (Ministerial Rescript of April 10th, 1886).

---

*"The Practical Guide to the Public Health Acts," by Thomas Whiteside Hime, B.A., M.D., London, 1901.

United States.—A statute existed in several States at an early date, providing that "whoever adulterates, for the purpose of sale, any drug or medicine, or sells any fraudulently adulterated medicine, knowing the same to be adulterated," shall be subject to a penalty.[*] Experience has shown, however, that laws of this character, requiring proof of guilty knowledge of the fact of adulteration in order to secure conviction, are of but little value in affording protection to the community. Hence it was that in subsequent legislation the *sale* of adulterated articles was deemed to be an offence subject to a penalty. Under the rigid enforcement, however, of such a law, much hardship might be inflicted upon retailers who purchase most of their stock at wholesale, and systems have therefore been devised by which retailers have been given the benefit of a warning notice to the effect that certain articles sold by them were adulterated, and that their sale should not be continued, or that they should be sold under some legal limitation, with the understanding on the part of the purchaser that they were goods of inferior quality. Such notices are usually forwarded direct to the wholesaler, and have a wholesome effect in correcting abuses.[3]

In a report made by C. L. Diehl to the national board of health in 1880[4] appears the following statement: "Previous to 1848 and for some years afterward, the condition of the drug market appears to have been in a very unsatisfactory state. This condition was largely attributed to the importation of inferior and adulterated drugs, which, in the absence of a law specifying a standard of quality, were freely admitted at our ports of entry. In 1848 Congress passed a law regulating the importation of drugs, which went into effect July 15th of that year, and during the first ten months Dr. M. I. Bailey, the special examiner at New York, had occasion to reject about 90,000 lbs. of drugs, such as rhubarb, senna, opium, jalap, gamboge, iodine, croton oil, sarsaparilla, etc.; and during the administration of his office, from 1848 to 1857, he found it necessary to reject over 900,000 lbs. of 'unsafe,' adulterated, and improper drugs and medicines. As a result of this action, the character of the drugs imported soon showed decided improvement."

The operation of this law does not appear to have been entirely satisfactory, if we may judge from the report of a committee of the American Pharmaceutical Association, which in 1855 "referred to the disregard that is paid to proper qualifications in the appointment of officers to carry out the requirements of the drug law." At a later date Mr. Diehl says: "Some attention is paid to the fitness and qualification of applicants, and the execution of the law is in the main satisfactory, though by no means incapable of being improved and rendered more efficient by wise revision."

After the establishment of State boards of health, investigations were begun in several States relative to the quality of the drugs found and offered for sale in these States, the result showing that legislation was necessary to prevent adulteration in the sale of drugs as well as in their importation. Laws have therefore been enacted, usually in conjunction with the food laws, for protection against this class of adulterations.

The term "drugs" in the Massachusetts Act of 1882 embraces "all medicines for internal and external use, antiseptics, disinfectants, and cosmetics." Hence the work of the State board of health, in this direction, has not been confined to the remedies defined in the United States Pharmacopœia, but has embraced many other articles, and especially empirical preparations of a more or less harmful character.[5]

The following section of the Massachusetts Act presents the requirements of the law relating to the standard of pure drugs, and has been enacted in practically the same form in the following States, according to Dr. Chapin:[6] California, Connecticut, District of Columbia, Illinois, Indiana, Kansas, Kentucky, Michigan, Mississippi, Nebraska, New Jersey, New York, North Carolina, Ohio, Oregon, Pennsylvania, South Dakota, Tennessee, and Wisconsin.

Acts of 1882, 263, § 3, Mass., as amended by later statutes.

An article shall be deemed to be adulterated within the meaning of this act—

(*a*) In the case of drugs: (1) If, when sold under or by a name recognized by the United States Pharmacopœia, it differs from the standard of strength, quality, or purity laid down therein, unless the order calls for an article inferior to such standard, or unless such difference is made known or so appears to the purchaser at the time of such sale; (2) if, when sold under or by a name not recognized in the United States Pharmacopœia but which is found in some other pharmacopœia or other standard work on *materia medica*, it differs materially from the standard of strength, quality, or purity laid down in such work; (3) if its strength or purity falls below the professed standard under which it is sold.

Of the drugs found to be of a specially inferior quality during the earlier investigations of the analysts in 1883 and 1884 were the following:

Tincture of opium (U. S. P., 1.20 to 1.60 parts per 100 of morphine), 144 samples out of 197 fell below the required limit of 1.2, and some had as little as 0.01, 0.14, 0.17, or a mere fraction only of the minimum requirement. Citrate of iron and quinine (legal requirement twelve per cent. of quinine), eighty-five per cent. of the samples had less than the required amount, and several had as little as 3 and 3.5 per cent., or but little more than a quarter of the requirement. Of powdered jalap only one sample out of twelve conformed to the pharmacopœial standard. Of 192 samples of powdered drugs, 39 were found to be adulterated in various forms. Of 19 samples of compound spirits of ether, 2 only contained the required amount of the ethereal oil required by the statutes. Of 23 samples of spirit of nitrous ether, scarcely any had the required amount of ethyl nitrite.

Twenty-two samples or lots of the quinine pills made by different manufacturers were examined. These were examined in two groups, at an interval of several months, during which time the manufacturers had become aware of the work of the board in this direction. The analysis of the second group showed in nearly every instance an improvement. The following figures indicate the percentages of the required weight of the pills made by nine manufacturers, in the two series of analyses:

	First series.	Second series.
1.........	93.5	97.9
2.........	86.6	97.3
3.........	93.3	99.6
4.........	93.8	100.7
5.........	107.6	76.5
6.........	84.7	89.5
7.........	93.8	101.1
8.........	104.4	100.5
9.........	97.0	97.1

The foregoing list shows an improvement in each case except two. Of 106 samples of pharmacopœial spirits and wines, only 10, or 9.4 per cent., conformed to the legal requirements.

In proof of the improvement under the action of the statutes, very marked changes for the better have been found to have taken place in many of the foregoing articles.

Among the non-pharmacopœial preparations examined in 1885 were 11 hair dyes, all of which contained lead in large amounts; also 20 different fraudulent nostrums advertised for the cure of the opium habit, most of which were solutions of morphine. One of them was the so-called "Keeley gold cure," which was found to contain no gold whatever. In 1887 about fifty proprietary articles, sold as tonics and bitters (some of which were advocated as temperance drinks), were examined chiefly for their alcoholic contents. All were found to contain alcohol in the proportion of six to forty-eight per cent. by volume. One of these, which was advertised as a remedy for inebriety and the opium habit, was the celebrated "Scotch oats essence," containing alcohol and morphine, the latter in varying proportions. This nostrum very soon disappeared after its analysis had been published. Cocaine as a common ingredient in the composition of remedies for asthma, hay fever, and catarrh has also been the subject of examination.

---

[*] Law of 1853, Mass., P. S. 208, § 5.

Cosmetics for the complexion, termed face bleaches, freckle lotions, skin tonics, have been examined and found to consist of strong solutions of corrosive sublimate. Of this class were Ruppert's complexion bleach, and Yale's complexion bleach, Perry's freckle lotion (39 grains corrosive sublimate in an eight-ounce bottle), and Mrs. McCorrison's diamond lotion.

Skin Success Ointment contained red oxide of mercury. Cocaine as an active ingredient was found in Dr. Birney's catarrh remedy, Instant cold relief, Dr. Tucker's asthma cure, Azmasyde, and Coca-kola.

It was required that such articles, if sold at all, should be labelled as poisons, and sold only under careful restrictions. Seventeen complaints were made against parties selling the most poisonous of these articles in violation of the statutes.

The powerful influence of the proprietary medicine interest, however, prevailed, and that section of the statutes which required that poisonous patent medicines should be labelled as poisons was repealed, so that the people are now deprived of that protection which was once afforded by law.

As an evidence of the character of the most poisonous of these preparations (cosmetics), it may be said that the cost of a bottle of face bleach which sells at $2 is about five cents, bottle included, and the package is often marked "harmless."

In later years the following were some of the more important adulterations found upon analysis:

In 1897, of 18 samples of chlorinated lime, all proved to be below the required standard. Eight of these were very deficient in available chlorine. All the samples obtained in 1898 and 1899 were also deficient.

Of distilled water, only 19 samples out of 69 obtained in 1897, 1898, and 1899 were free from solid residue. The highest amount of solid residue in any sample was 23.7 per 100,000. A comparison of the water collected from drug stores in certain localities with that collected from the public water supplies of the same cities and towns, made it apparent that it was quite a common custom for druggists to fill orders for distilled water from the faucet supplying the city water.

Of 61 samples of powdered opium collected in the same years and in 1900, 20 were deficient in morphine strength. (This result shows a decided improvement over the samples collected in 1883-84.) Of 172 samples of tincture of opium, 133 were deficient, but many of them were quite near the minimum limit of 1.3 per cent. of morphine.

Of 30 samples of compound spirits of ether, 18 were deficient in ethereal oil.

Of 113 samples of tincture of iodine, 95 were deficient in iodine.

Of 156 samples of olive oil, 47 were either wholly or in part cotton-seed oil.

Of 37 samples of lime juice, all except 1 contained salicylic acid; and one sample marked "Santiago, W. I., triple refined," consisted of a dilute solution of hydrochloric acid flavored with oil of lemon and preserved with salicylic acid. It contained no lime juice whatever.

Thirteen samples of so-called diabetic flour were examined for starch, and only 3 were free from it; 7 of these contained as much as 60 per cent. of starch in each sample.

In 1900 and in 1901 special attention has been given to the analysis of drugs for arsenic, with the result of finding it in appreciable amounts in glycerin and in phosphate of soda.

Of 11 samples of grape juice collected in 1900 5 were found to contain either boracic or salicylic acid.

The pharmacopœial wines and liquors were found to be quite generally falsified by the addition either of alcohol, water, or sugar, and only very rarely with substances of a more injurious character than the alcohol.

New York.—The State board of health of New York for several years maintained a system of drug inspection under the direction of a competent chemist, which was practically discontinued in 1895 by withdrawal of the necessary appropriation.[7]

In its report for the year 1893, it appears that 2,637 samples of drugs were collected and 2,434 were examined, making a total of 7,035 samples collected and 6,832 examined since 1891. These were all officinal articles having a definite standard, and of these 1,018, or 41.9 per cent., were of "good" quality; 446, or 18.4 per cent., were classed as "fair"; 699, or 28.7 per cent., as "injurious"; 131, or 5.3 per cent., were "not as called for"; and 140, or 5.7 per cent., were of "excessive strength."

The principal articles were as follows:

Dilute acetic acid, 231 samples examined, 61 good, 52 fair, 78 inferior, 34 excessive strength, 6 not as called for.

Water of Ammonia, 297 samples, 77 good, 66 fair, 94 inferior, 54 excessive strength, 6 not as called for.

Capsicum, 17 samples, 13 good, 1 fair, 3 inferior.

Creosote, 222 samples, 119 good, the remainder consisted chiefly of carbolic acid.

Compound Spirits of Ether, 206 samples, 54 good, 22 fair, 129 inferior.

Stronger Ether, 144 samples, 91 good, 7 fair, 46 inferior.

Ginger, 15 samples, all good.

Dilute Hydrochloric Acid, 232 samples, 151 good, 45 fair, 32 inferior, 4 excessive strength.

Compound Solution of Iodine, 100 samples, 68 good, 23 fair, 7 inferior, 1 excessive strength, 10 not as called for.

Tincture of Iodine, 237 samples, 57 good, 96 fair, 81 inferior, 3 excessive strength.

Ipecac, 15 samples, all good except one.

Tincture of Iron, 21 samples, 19 good, 2 fair.

Magnesia, 111 samples, 52 good, 3 fair, 50 inferior, 6 not as called for.

Aromatic Sulphuric Acid, 289 samples examined, 29 good, 93 fair, 167 inferior.

Dilute Sulphuric Acid, 259 samples, 171 good, 33 fair, 11 inferior, 44 excessive strength. *Samuel W. Abbott.*

FOOD: METHODS OF INSPECTION AND ANALYSIS.

FOOD: METHODS OF INSPECTION AND ANALYSIS.—There is no field of chemical analysis more unique in itself than that covered by the food analyst, who necessarily employs methods of a much more varied character than almost any other chemical specialist. Processes of food analysis are not exclusively chemical. Physical methods are frequently employed, especially those along optical lines involving the use of the microscope, the polariscope, the spectroscope, and the refractometer. Besides these instruments, the food analyst should be provided with a water bath, a delicate balance, a Babcock centrifuge, the usual laboratory glassware and reagents, and, if possible, with a number of platinum dishes.

It is desirable in the examination of foods to employ quick processes for separating the pure from the impure, afterward applying special methods to the impure samples to ascertain the nature and extent of the adulteration.

No attempt is made in what follows to deal with the processes of analyzing foods for their nutritive values, but simply briefly to outline methods of detecting, and in some instances estimating adulterants in such classes of food products as experience has shown to be most liable to fraudulent adulteration. Wherever possible, methods are selected involving the simplest possible apparatus. The usual laboratory reagents are used, mainly solutions of simple salts, and for their preparation the reader is referred to any text book in qualitative analysis.

Baking Powder.—The adulterants of cream of tartar are, of course, to be looked for in baking powder, and are tested for as indicated under "Cream of Tartar."

Alum is tested for by burning a small quantity of the sample to an ash, which is then treated with boiling water and filtered. If, on the addition of ammonium chloride to the filtrate, a flocculent precipitate is formed, this will indicate the presence of alum in the sample. The test is applicable in presence of phosphates.

Butter.—If accustomed to the odor and taste of oleomargarine, one can usually distinguish by these senses alone between it and pure butter. The odor of the melted fat is very distinctive, the melted oleomargarine lacking the butyric odor so characteristic of the butter and possessing a distinct "meaty" smell that generally betrays its nature. Certain quick physical tests are sometimes employed to distinguish pure from adulterated butter.

The Spoon Test.—If about a gram of the sample be placed on a spoon, held over the free gas flame and brought to the boiling point, the mass will assume a "foamy" appearance if the butter is pure. If the sample is oleomargarine or "process butter" (old butter reworked), the mass will bump and spatter like hot grease containing water, but does not foam.

The Milk Test.—Five to 10 c.c. of the sample are added to 50 c.c. of sweet milk heated nearly to boiling. The contents are stirred with a rod till the fat is melted, after which the container is placed in cold water and the stirring is continued till the fat congeals. If oleomargarine, the fat can readily be collected into one lump with the stirring rod, and if butter, it cannot be gathered together, but granulates.

Under the microscope pure butter should theoretically show no crystalline structure when viewed by polarized light, being uniformly bright throughout and, if the selenite plate be used, showing an evenly colored field entirely devoid of fat crystals. With process butter or oleomargarine, both of which have been melted and subsequently cooled, the crystalline structure should be marked, showing with polarized light a mottled appearance, and a play of colors with the selenite. These conditions are, however, not sufficiently sharp to be reliable in unskilled hands.

The Zeiss Butyro-Refractometer furnishes a ready means of distinguishing between butter and oleomargarine. This instrument is so constructed that the degree of refraction of a beam of light reflected from a mirror obliquely through a thin film of the melted fat is read on an arbitrary scale of sufficient extent to cover the widest limits of deviation possible for butter fat and oleomargarine under ordinary temperatures. The butter fat is kept at a constant temperature above the melting point by a circulation of heated water maintained through a jacket that encloses it, the temperature being read on a thermometer. Each fat has fixed limits of reading at a given temperature, the scale reading of oleomargarine being from six to twelve degrees higher than that of butter.

The Volatile Fat Acids.—The presence of a considerable percentage of volatile fatty acids in genuine butter and the lack of them in oleomargarine furnishes the most ready chemical means of distinguishing between the two. The result is usually expressed by the number of cubic centimetres of decinormal alkali necessary to neutralize the volatile fatty acids in 5 gm. of the fat, being known as the "Reichert number." The method of obtaining this is fully described in Bulletin 46, United States Department of Agriculture, Division of Chemistry.

Cheese.—*The Fat Content* of cheese is the most important factor in determining whether whole or skimmed milk has been used in its manufacture, and the Babcock milk tester is used with advantage in estimating the fat.

Weigh 5 gm. of the finely divided sample into a tared Babcock milk testing bottle. About 15 c.c. of hot water are then added, and the mixture is shaken until an emulsion is formed. A few drops of ammonia aids in softening the cheese. The mixture is kept warm by immersing the test bottle in hot water. When a complete emulsion is formed, the bottle is cooled, 17.5 c.c. of concentrated sulphuric acid are added and the test is completed in the usual manner for carrying out the Babcock test (see Milk Fat). The reading of the fat in the bottle is multiplied by 18 and this result divided by the number of grams of the sample taken gives the percentage of fat in the cheese, which in case of a whole-milk cheese should be at least thirty per cent.

Detection of Foreign Fat.—The presence of foreign fat in cheese is best detected by submitting the separated cheese fat to the same examination as is given to butter fat (*q. v.*), the fat for chemical examination being best removed by extraction of the cheese with ether.

Cocoa.—The purity of cocoa is best determined by means of the microscope. See "Spices" for brief directions as to mounting, etc. Samples of known purity should be studied for comparison with doubtful specimens. Under the microscope pure cocoa shows a loose mass of yellowish-brown matter, with small starch granules and oil globules.

Coffee.—This, like cocoa, is best examined microscopically, being first ground to a fine powder in a mortar. Figs. 6, 7, 8, Plate XXVI., show the characteristic appearance under the microscope of both pure and adulterated samples. Pure coffee appears as a mesh-work of irregular hexagonal thick-walled cells enclosing oil droplets and amorphous material.

Condensed Milk.—Forty grams of the thoroughly mixed sample are weighed out and made up to 100 c.c. with water.

Total Solids.—An aliquot part of the above solution is further diluted with an equal amount of water, and 5 c.c. of the diluted mixture is evaporated over the live steam of a boiling water bath for three hours in a platinum dish and the residue weighed.

Ash.—The residue from the total solids is burnt to a white ash and weighed.

Fat.—This is the most important factor in determining

EXPLANATION OF
PLATE XXVI.

EXPLANATION OF PLATE XXVI.

Fig. 1.—Pure Cayenne. Patches of the inner and outer skin appear most prominent, with scattered bits of cellular tissue.

Fig. 2.—Cayenne Adulterated with Wheat. The mass to the left of the centre is cayenne. The circular granules are of wheat starch.

Fig. 3.—Allspice Adulterated with Cayenne. The large mass is cayenne skin. The small stone cell and mass of gum below are of allspice.

Fig. 4.—Pepper Adulterated with Buckwheat. Large masses of buckwheat starch granules are above the centre, and a small mass of finer pepper-starch grains below and to the left.

Fig. 5.—Olive Stones in Alleged Pepper. Elongated, thick-walled stone cells of the ground fruit stones are grouped together in the centre.

Fig. 6.—Pure Coffee. A meshwork of cells tending to hexagonal in shape, enclosing amorphous material and droplets of oil.

Fig. 7.—Coffee Adulterated with Peas and Pea Hulls. Masses of pea-starch granules are most prominent. The rectangular billets, like bunches of matches around the lower edge, constitute the pea hulls.

Fig. 8.—Chicory in an Adulterated Coffee. Chicory shows as a mass of cellular tissue, traversed by broad bands (juice ducts) having striking transverse markings.

FOODS AND ADULTERANTS

OF THE
UNIVERSITY of ILLINOIS

the purity of the sample. Twenty-five cubic centimetres of the forty-per-cent. solution are measured into an ordinary Babcock test bottle, which is then filled nearly to the neck with water. The contents are shaken and 4 c.c. of a seven-per-cent. solution of copper sulphate are added. The bottle is then well shaken and whirled in the centrifuge until the precipitate has settled out. The clear supernatant liquid is drawn off by means of a pipette, a small wisp of absorbent cotton being lightly twisted about the lower end to serve as a filter. After the liquid is drawn up into the pipette, the cotton is removed by rubbing against the inside of the bottle, and the pipette is withdrawn. The precipitate is washed twice as above by decantation, and after the final washing, sufficient water is added to amount to about the quantity of milk measured for the Babcock test (17.6 c.c.). From this point on the usual Babcock centrifuge method is followed, adding the regular 17.5 c.c. of strong sulphuric acid (see Milk Fat). Multiplying the final reading by 1.8, we get the percentage of fat.

The above process is to be used for the ordinary condensed milk containing added cane-sugar. The fat in "evaporated cream," which is really condensed milk without the cane-sugar, is best determined by the ordinary Babcock method as in the case of milk, using 17.6 c.c. of a uniform mixture of equal volumes of the sample, and water.

CREAM is treated similarly to milk (*q. v.*) for total solids, color, and preservatives.

Fat.—A weighed portion of the sample is introduced into the specially constructed cream bottle furnished for the Babcock test. The test is then conducted as in the case of milk fat (*q. v.*), the final reading being multiplied by 18 and the result divided by the number of grams of the sample taken to give the exact percentage of fat.

Gelatin, sometimes used to thicken cream, is best detected by mixing 10 c.c. of the cream with an equal volume of a dilute solution of acid nitrate of mercury. After diluting and shaking, the mixture is allowed to stand a few minutes and filtered. To a portion of the filtrate an equal quantity of a saturated solution of picric acid is added. A yellow precipitate indicates gelatin.

CREAM OF TARTAR.—The purity of this substance is usually established if the sample is found to be readily soluble in hot water; since most adulterants other than alum are insoluble. It is best to weigh out 0.1881 gm. of the cream of tartar and dissolve in hot water, titrating the solution with one-tenth normal sodium hydroxide, and using phenolphthalein as an indicator. If the sample is pure, it should require just 10 c.c. of the alkali to neutralize.

If *alum* is the adulterant, the alum would be precipitated by the sodium hydroxide, the precipitate being soluble in an excess of the alkali.

Starch is detected by adding a drop of iodine reagent to the solution of the sample, a blue color being produced if starch is present. The starches are most readily identified under the microscope.

Calcium (present as sulphate or phosphate) is best shown by burning the sample to an ash, dissolving in water acidified with hydrochloric acid, filtering, and treating a part of the filtrate with ammonia and ammonium oxalate. A precipitate shows calcium.

A Sulphate is indicated, if, on treatment of a part of the acid filtrate above obtained with barium chloride reagent, a precipitate is formed.

A Phosphate is detected by boiling a little of the sample with nitric acid and adding ammonium molybdate reagent. A yellow precipitate indicates phosphate.

HONEY.—*Commercial Glucose* and *Cane-Sugar* are best estimated by means of a Schmidt and Haensch polariscope. 26.048 gm. of the sample are weighed out in a flask graduated to hold 100 c.c., 5 c.c. of alumina cream* are added to clarify, and the solution is made up to 100 c.c. with water. It is well shaken and filtered, the filtrate being polarized in a 200 mm. tube and the reading taken. If the scale reading is to the left of the zero point, the honey may usually be considered pure; if it is to the right, the honey is probably adulterated with cane-sugar or commercial glucose or both. Fifty cubic centimetres of the filtrate are taken, 5 c.c. of strong hydrochloric acid are added, after which the solution is made up to 100 c.c. with water and heated in the flask to 68° C., cooled and filtered. This process is termed inversion. The filtrate is then polarized in the 200 mm. tube, and the result multiplied by two gives the invert reading. The amount of cane-sugar is obtained by the following formula (Clerget's):

$$R = \frac{100\ S}{144 - \frac{1}{2}t}$$

wherein R is the per cent. of cane-sugar, S the difference of the two polarizations before and after inversion, and *t* the temperature at which the readings are taken. If commercial glucose is suspected, the portion of the sample subjected to inversion is heated and polarized at 87° C. in a 200 mm. jacketed tube, the reading being multiplied by two. This result, divided by 175, gives the approximate per cent. of commercial glucose in the sample.

The presence of commercial glucose may usually be qualitatively detected by submitting the sample to a test for dextrin, one of the chief ingredients of glucose. A solution of the honey is treated with an excess of strong alcohol. A precipitate indicates dextrin. Pure honey should give no precipitate.

LARD.—The color, smell, and consistency of the sample of adulterated lard often serve to betray its character to a careful observer, and, as in the case of butter, the odor of the fat when melted is much more distinctive than when in its natural condition. The adulterants commonly to be looked for are cotton-seed oil and beef tallow.

Reaction with Strong Acid (sulphuric or nitric).—A small amount of melted fat is poured into a test tube, an equal quantity of acid is added and the contents are well shaken. Genuine lard and beef stearin usually give but slight coloration, while mixtures containing cotton-seed oil invariably give a red-brown color, more or less intense in proportion to the amount of cotton-seed oil present.

The Zeiss Refractometer, described under "Butter," is useful in the examination of lard as well as other fats and oils. The refracting degree of cotton-seed oil on this instrument is about 8.9 in excess of that of lard, while that of beef tallow is about 3.8 less. If the scale reading of the sample is unusually low, the presence of beef stearin is to be suspected; if unusually high, cotton-seed oil should be looked for. A mixture of the two adulterants either with or without pure lard may be such as to give refractometric readings within the limits of pure lard. In such a case the positive detection of the cotton-seed oil by the Halphen test (given below) will indirectly show the presence of the tallow, which should be confirmed by crystallization and microscopic examination.

Halphen's Test for Cotton-Seed Oil.—A mixture is made of equal volumes of amyl alcohol and carbon bisulphide containing one per cent. of sulphur. From 3 to 5 c.c. of melted fat is mixed with an equal volume of the above reagent in a test tube and heated in a bath of boiling water for fifteen minutes. If cotton-seed oil is present, a deep red or orange color is produced. If the lard is pure, little or no color is developed.

Microscopical Examination of the Crystallized Fat.—From 2 to 5 gm. of the fat are dissolved in 10 to 20 c.c. of a mixture of equal parts of ether and alcohol in a test tube, and the solution is allowed to stand a few hours, the tube being loosely stoppered with cotton. The crystals obtained vary somewhat with the condition of heat, rate of crystallization, etc. A careful study of these crystals and comparison with samples of known purity, crystallized under similar conditions, should be made.

Theoretically, pure lard crystallizes under the best conditions in thin, flat, rhomboidal plates, while beef-stearin crystals are more in the form of cylindrical rods or needles, often bent or curved. Both forms are often found in fan-shaped clusters, which, however, differ from each other in certain important particulars, best distinguished by a careful study of their appearance.

---

* Prepared by adding ammonia water in excess to a saturated solution of alum and washing free from ammonia. The aluminum hydrate held in water is shaken so as to form a thin, emulsion-like paste to clarify.

MAPLE SUGAR AND SYRUP.—Commercial glucose is determined in maple syrup precisely as in the case of molasses (*q. v.*) excepting that as a rule no clarifier need be used for maple syrup. A normal solution of pure maple syrup should polarize at from 60° to 64° on the cane-sugar scale. Cane-sugar other than maple is best detected both in syrup and sugar by the sense of taste.

MILK.—There are various simple appliances for roughly testing the quality of milk, but most of them are of little value. The lactometer test is perhaps the best of these, if used with judgment.

The Lactometer is simply a hydrometer covering the widest variations in specific gravity of milk. A thermometer is also necessary and for this reason a Quevenne lactometer, combining in one instrument both the hydrometer and thermometer is convenient. Milk of good quality should have a specific gravity between the limits of 1.027 and 1.033. A watered milk would run below the former, and a skimmed milk above the latter figure, though a milk unusually rich in fat would also run low. It should easily be apparent from the taste and appearance of the milk whether a low specific gravity is due to watering or to unusual richness in cream.

Feser's Lactoscope gives an approximation of the amount of fat in the milk, and its use, especially in connection with the lactometer, is of some value. This instrument consists of a glass cylinder with graduations indicating the per cent. of fat. A measured amount of milk being introduced by means of a pipette, sufficient water is added with thorough mixing to allow certain black lines on a spindle within the cylinder to become apparent through the translucent fluid. The height of the level of milk and water in the cylinder is then read off, indicating roughly the per cent. of fat in the milk.

Total Solids.—Five grams of the thoroughly mixed milk are weighed from a pipette into a tared shallow platinum dish on the pan of a delicate balance, and the dish is transferred to a boiling water bath, where it is kept for at least two hours in direct contact with the live steam. It is afterward cooled and weighed, the residue being the total solids and the loss in weight being reckoned as water.

Ash.—The residue from the total solids is burnt to a white ash and weighed.

Fat.—The fat is most readily determined by the Babcock process. There are various forms of Babcock centrifuge from the simple hand machine to the steam or electrically driven variety, all carrying the same form of graduated bottle. Into this bottle 17.6 c.c. of the thoroughly mixed milk to be examined is introduced by a pipette, the same amount of concentrated sulphuric acid is added and well mixed with the milk to dissolve the albuminoids and set free the fat, after which, by whirling and by the addition of hot water, the fat is driven into the graduated neck of the bottle, where the exact percentage is directly read off.

Calculation of the Total Solids.—The total solids may readily be calculated with considerable approach to accuracy, if the specific gravity and the fat are known, from the formula of Babcock:

$$\text{Total solids} = 0.25\,G + 1.2\,F.$$

G being the lactometer reading and F the fat. This method of obtaining the total solids by calculation is convenient, when, as is often the case, dairymen and others are provided with the inexpensive and easily operated Babcock apparatus and lactometer, but do not have the more involved and costly appliances necessary for the direct determination of the solids.

Distinguishing Watered from Skimmed Milk.—The proportion of solids not fat to fat determines whether a sample below the standard is skimmed or watered. If both these factors are abnormally low, and the proportion of fat to solids not fat is about the same as, or higher than in a normal milk, the sample may as a rule be assumed to be watered; if both total solids and fat are considerably below the standard, and the solids not fat nearly normal, the milk has undoubtedly been skimmed; if total solids and solids not fat are proportionally low, while the ratio of fat to solids not fat is abnormally small, the milk has probably been both skimmed and watered. From legal standards fixed in various States the total solids in pure milk should run from 11.5 to 13.0 per cent., the fat from 3 to 4 per cent., and the solids not fat from 8.5 to 9.3 per cent.

Foreign Coloring Matter.—This may be determined as follows: about a gill of the milk is curdled by heat and acetic acid, the curd being separated and gathered by a stirring rod into one mass. It is then squeezed free from whey and shaken with ether in a corked flask, where it is allowed to macerate for an hour or more. The ether extract containing the fat and annatto, if present, is evaporated and the residue made alkaline with sodium hydroxide and filtered through a wet filter. If annatto is present, it will permeate the filter paper, coloring it a more or less deep orange more apparent when the fat is washed off and the filter is dried. Stannous chloride solution will turn the orange stain pink, if the color is annatto. After pouring off the ether, if the curd is left white, neither caramel nor aniline orange is present. If the aniline dye has been used, the curd will show a more or less brilliant orange color; if caramel, the curd will be brown.

Shake a small portion of the fat-free curd in a test tube with strong hydrochloric acid. The caramel-colored curd will, like an uncolored curd, gradually produce a deep blue color in the strong acid solution. The aniline orange if present in the curd will *immediately* produce with the hydrochloric acid a deep pink color.

Preservatives.—(*a*) *Formaldehyde* is best tested for by heating about 10 c.c. of the milk with an equal quantity of concentrated hydrochloric acid and a drop of ferric chloride solution. A violet coloration is produced if formaldehyde be present, delicate to 1 part formaldehyde in 300,000.

(*b*) *Boracic Acid* is tested for by soaking turmeric paper in a solution of the milk ash, acidified slightly with hydrochloric acid. On drying the turmeric paper, a cherry red color indicates the presence of boracic acid, which is confirmed by applying to the reddened paper a drop of a dilute solution of sodium hydroxide. This reagent turns the paper a dark olive if boracic acid was present.

(*c*) *Carbonate of Soda* is indicated by an effervescence on treating the milk ash with acid, and may further be tested for by mixing 10 c.c. of milk with an equal volume of alcohol and a few drops of a one-per-cent. solution of rosolic acid. A rose red coloration indicates carbonate.

MOLASSES.—*Determination of Commercial Glucose.* Direct and invert polariscopic readings are obtained as directed under "Honey," except that instead of clarifying with alumina cream as in the case of honey, from 5 to 25 c.c. of United States Pharmacopœia subacetate of lead solution are used, depending on the color of the sample, the darker the molasses the more clarifier being necessary. The polarizations should be made in a 100 mm. tube, if the sample is high in glucose, and the proper correction made. If molasses is of average color, its normal solution should polarize less than 60° in the 200 mm. tube on the cane-sugar scale. A dark sample should, if pure, polarize under 50°. Determine the cane-sugar by Clerget's formula (see *Honey*). The cane-sugar deducted from the direct polariscopic reading gives the reading due to glucose. This result, divided by 175, gives the per cent. of commercial glucose.

OLIVE OIL.—As in the case of lard, the presence of cotton-seed oil, which is the most common adulterant, may often be roughly shown by the reaction with strong nitric acid. When shaken in a test tube with an equal volume of the acid, pure olive oil should show a green coloration, while if cotton-seed oil is present, a red color is quickly developed.

The Zeiss Refractometer, though primarily intended for

FOODS AND ADULTERANTS

[illegible]
UNIV[illegible] ILLINOIS

use with butter and lard, is of great service in examining olive oil. The refracting degree of cotton-seed oil on the scale of this instrument is about 4.8° higher than that of pure olive oil at a given temperature. Peanut oil, which has been used as an adulterant of olive, has nearly the same degree of refraction as cotton-seed oil, while corn oil, found by the author in alleged olive oil, is at least 13° higher on the Zeiss scale than pure olive oil.

The presence of cotton-seed oil is best confirmed by the Halphen test described under Lard.

Spices.—Adulterants of spices are best detected by submitting them to microscopical examination. The finely ground sample is mounted by placing a small portion on a glass slide by means of a knife blade, treating with a drop of distilled water, and rubbing out under the cover glass between the thumb and finger. The specimen is best examined with a one-sixth-inch objective and a medium ocular, giving a magnification of from 240 to 330 diameters.

It is extremely difficult to describe the actual microscopical appearance of such composite substances as the spices. Each has its own particular characteristics, and the analyst should provide himself with a complete set of powdered pure spices, and of starches, ground olive and date stones, nut shells, bark, pea hulls, sawdust and other adulterants of known purity, and familiarize himself with their microscopical appearance, making his own standards for comparison. Plates XXVI. and XXVII. illustrate both pure and typically adulterated samples of some of the spices as they appear under the microscope. A few of the most striking features to be looked for in the common spices are as follows:

Allspice.—Small circular starch granules, often arranged in clusters; very striking amber-colored lumps of gum; a considerable quantity of stone cells, mostly colorless.

Cassia.—Small starch granules, intermingled with patches of yellow skin and bundles of brown and yellow wood fibres; stone cells, often of a brown color.

Cayenne.—No starch; yellow droplets of oil; patches of skin with striking markings not unlike the convolutions of the intestines.

Cloves.—No starch; occasional, though very few colorless stone cells; colorless oil drops; masses of spongy, brown cellular tissue of indefinite structure, but unmistakable; spiral ducts.

Ginger.—Large starch granules, egg-shaped with small protuberances at one end; colorless cellular tissue; masses of wood fibre.

Mace.—No starch; colorless oil drops; characteristic cellular tissue.

Mustard.—No starch; colorless oil drops; spongy, colorless cellular tissue with both yellow and colorless patches of hull, filled with brown spots.

Nutmeg.—Small, circular starch granules with central hila; colorless, indefinite cellular tissue.

Pepper.—Very minute starch granules; arranged in large masses; rectangular stone cells.

Tea.—The percentage of ash is a ready means of ascertaining whether or not any considerable amount of dirt or mineral matter has been added. Five grams of the sample are carefully burnt in a tared platinum dish to a white ash over a free flame at a low red heat, and the residue is cooled and weighed. The ash of a pure tea should not exceed seven and one-half per cent. If the ash is abnormally low, the presence of spent or exhausted leaves is indicated. Tea stems and fragments as well as foreign leaves are best recognized by soaking the leaves in boiling water, which opens them out so that their nature is readily apparent.

Vinegar.—Although the percentage of solids and acidity in cider vinegar are important factors in determining its purity and strength, standards being fixed for these in many localities, it by no means follows that a sample of cider vinegar high in both solids and acidity is pure.

Total Solids.—Five grams are weighed from a pipette into a tared platinum dish, which is then transferred to a boiling water bath and kept in contact with live steam for at least an hour and a half. It is then cooled and weighed, the residue representing the vinegar solids. If the solids have been reinforced by apple pomace, this is rendered apparent by burning the residue to an ash in the platinum dish and determining the weight of the ash. If the ash is less than six per cent. of the entire solids, there is no doubt that unfermented sugar-containing material has been added. The normal percentage of ash in total solids of pure cider vinegar should be at least eight and one-half.

Acidity.—This is commonly determined by titrating 6 c.c. of the vinegar with decinormal sodium hydroxide, using phenolphthalein as an indicator. The per cent. of acetic acid is exactly one-tenth of the number of cubic centimetres of the alkali required for neutralization.

It is possible to use lime water as a reagent in determining approximately the acidity of vinegar. A saturated solution of air-slaked lime has a nearly constant alkalinity. If 2.75 c.c. of vinegar are titrated against saturated lime water, the number of cubic centimetres of the latter required to neutralize, divided by ten, gives directly the per cent. of acetic acid very closely.

Reaction with Lead Acetate.—The *absence* of a precipitate with this reagent shows positively that the vinegar is not genuine, but a precipitate does not necessarily prove the vinegar to be pure.

The Polariscope Test.—A genuine cider vinegar should always polarize to the left of the zero point, a right-handed polarization being absolute evidence of adulteration, the adulterant often being in this case apple jelly containing glucose.

The vinegar sample may usually be sufficiently clarified for polarization in a 100 mm. tube by simply passing through a double filter.

Sulphuric Acid or Sulphates are indicated, if on the addition of barium chloride reagent to the sample, a precipitate is formed. *Albert E. Leach.*

FOOD POISONS.—From the earliest times poisoning from diverse foods has attracted the attention of the laity and of medical men. Numerous explanations, many of these decidedly absurd as viewed from the standpoint of our present knowledge, have been put forth, and it is only within comparatively recent years that vague hypotheses have given way to exact chemical and bacteriological studies. As a result, a flood of light has been thrown upon the causation of food poisonings, and the observations thus made have in turn served their purpose of indicating the relatively simple means by which many of these intoxications may be avoided.

Individual susceptibility plays a most important part in all poisonings. It is very well known that a given poison may affect two individuals in a wholly different manner. Moreover, observations are not wanting which show that a substance which we may have good reason to consider as wholly innocuous is nevertheless very deleterious to some. The fortunately very rare instances of fatal results following the injection of antitoxic sera may be taken as an example of such idiosyncrasy. In like manner one may meet with individuals to whom a given article of food invariably plays the part of a poison, and justifies the oft-quoted adage that "what is meat to one is poison to another." The use of veal by some, and of eggs by others, is often followed by distressing symptoms. The cleavage products of such foods, whether due to defective metabolism or to a peculiar bacterial flora in the intestines, are in the main responsible for the ill effects experienced.

While idiosyncrasy has to do with a single individual, there are on the other hand hundreds of instances of "food epidemics" where an extraneous cause must be sought for. In the latter cases the food or article consumed has acquired in some way marked poisonous properties, and in so far as the origin of this poison is concerned it may be spoken of as *endogenous* or *exogenous*.

Those articles in which the poison is of endogenous origin can hardly be designated as foods, although it may be very convenient to speak of them as auto-poisonous. The poisonous mushroom, for example, is often mistaken for an edible form. The two kinds are wholly distinct, and the former is injurious because it normally produces a highly poisonous alkaloid, muscarine. In like manner the blood of eels is toxic, because of the presence of preformed physiological products. Some animals, especially molluscs and fish, are popularly believed to acquire poisonous properties at certain phases of sexual life. However, it is very certain that there are fish which when perfectly fresh are highly poisonous. Just as the poisonous mushroom is capable of elaborating its specific poison, so certain fish are similarly endowed and give rise to normal physiological but toxic products. The nature of the products elaborated in the tissues of such poisonous fish is not known. They are believed by some to be leucomains or basic alkaloidal substances formed by the peculiar cell metabolism. Intoxications which are due to fish which are poisonous in and of themselves are of common occurrence, especially in the West Indies and in Japan. It is to this class of poisonings that Blanchard has applied the term *siguatera*, to distinguish it from the more ordinary food poisonings of exogenous origin.

The exogenous origin of food poisons is by far the most common occurrence. Under this head are to be placed all those articles of food or consumption which are ordinarily perfectly wholesome and which only occasionally, and then through what may be designated as an accident, acquire injurious or poisonous properties. The poison or injurious element in such cases is of foreign origin, and it is because of the introduction and presence of such poison in a food that the unexpected manifestations of intoxication are observed.

The food poisons of exogenous origin may be discussed under three heads: (1) Poisonous metals; (2) animal parasites; (3) vegetable organisms, including bacteria and fungi.

With reference to the first head, that of poisonous metals, it may be said that they play as a rule only a very secondary rôle in outbreaks or epidemics of food poisoning. The metals which are supposed or have been shown to be the active cause of poisonings are arsenic, antimony, tin, lead, zinc, and copper.

An interesting instance in which arsenic and antimony were the cause of fatal poisoning in animals was noted several years ago by Vaughan. In a Western mining region where hydraulic mining was practised, the disintegrated ore deposit was washed down into a river, the water of which as a result became highly charged with soluble and suspended arsenic and antimony compounds. A much more notable instance, however, of poisoning of this kind is that recently (November, 1900) observed in Manchester, where a widespread epidemic of peripheral neuritis followed the use of beer which on analysis was shown to contain appreciable amounts of arsenic. The arsenic in this case was derived from the sulphur ores which were used in the manufacture of sulphuric acid. The latter, in turn, with its unknown arsenic contents, was employed in the preparation of the glucose, and it was through the glucose that the metal found its way into the beer.

Lead poisoning which follows the use of water which is conveyed through lead pipes is a well-known fact. An unusual instance of intoxication was reported in 1887 by Stewart. A Philadelphia baker ignorantly used lead chromate as a substitute for eggs to color his dough. The buns prepared with this material are known to have caused 64 poisonings, 8 of which proved fatal. A somewhat similar mistake is that reported many years ago by Ungefug, who found that a large quantity of zinc sulphate had been used in place of the preservative saltpetre.

In articles of food which have been kept for some time in tin cans, or in zinc or copper vessels, traces of these metals can be invariably expected, and while unquestionably these metals in large doses are poisonous, it is nevertheless true that they have little or nothing to do with the acute poisonings so often observed. The bare possibility of canned foods being poisonous as a result of the presence of these metals may be conceded, but the occurrence of such is very doubtful indeed. In such cases it can be shown that bacterial decomposition has taken place, and while it is possible for the organic acids produced by such decomposition to dissolve the metals, still true bacterial poisons may be present and should be looked for. This can be done only by studying the effects produced by pure cultures of the organisms present in such food.

Food poisoning as the result of the presence of animal parasites has been a recognized fact ever since the discovery of trichinæ in the flesh of hogs. It is very important in suspected poisonings when pork or pork sausage has been eaten, to make a careful search for trichinæ. This should be done before a chemical and bacteriological examination is undertaken. Like trichinæ, other animal parasites, notably those of the intestines, may be introduced with the food, but these occurrences are rarely considered under the head of food poisons, and for that reason need no extended consideration in this connection.

Vegetable organisms constitute by far the most common cause of food poisoning. It will be presently shown that certain moulds or fungi thriving especially on plant food may render these injurious. Apart from these isolated and in this country largely unknown intoxications, it may be said that bacteria are the only type of vegetable life which are concerned in the vast majority of food infections. Dead animal or vegetable matter is prone to invasion by bacteria, and putrefaction or fermentation, as the case may be, is soon established. To use an axiom of Claude Bernard's, "death is life," and the life thus established in dead matter under favorable conditions is seen in the myriads of the tiny workers, whose duty it is to break up and transform the complex organic substances present in plants and animals and return their elements to the inorganic world. The bacterial invasion of wounds finds its analogue in the bacterial invasion of foods, and just as cleanliness and asepsis obviate the former, so proper storage and thorough cooking will prevent the latter. Of the large number of different kinds of bacteria which may find lodgment in a wound only a few perhaps are capable of producing poisonous products. This fact is likewise true of those bacteria which invade dead plant and animal matter. The mere fact that a food, solid or liquid, contains enormous numbers of bacteria does not indicate that it is poisonous. The vast majority of bacteria are harmless organisms which elaborate simply non-poisonous products. On the other hand, a relatively small number of bacteria are capable of making poisonous products, and to these organisms the term *toxicogenic* may be applied.

Inasmuch as bacteria, when injurious, produce their ill effects by means of the poisons which they elaborate, it is desirable briefly to touch upon these products. The term *ptomaïn* was introduced a quarter of a century ago by the Italian chemist Selmi to designate basic alkaloidal products formed in putrefaction. Bearing in mind the fact that strychnine and muscarine are intensely poisonous vegetable alkaloids, it was quite natural to explain the profound intoxication met with in infectious diseases and in the poisoning from foods by assuming that bacteria elaborated similar toxic alkaloidal products. It is largely through the labors of Brieger that our knowledge concerning ptomaïns was gained. A considerable number of these basic alkaloidal products were isolated. The mytilotoxin found in poisonous mussels is of this class and is by far the most poisonous of the known ptomaïns. As a rule these substances are but feebly poisonous or not at all, and it follows that in such instances some other poison non-basic in character must be present. The term "ptomaïn poisoning" has been popularized to such an extent that it is used synonymously with food poisoning. The fact is that in only very exceptional instances are ptomains to be credited with being the cause of such poisoning.

The study of snake venom showed that the active poison in that secretion was an albuminous substance. Like investigations made with the seeds of jequirity and with the castor bean showed the presence of other poisonous proteid bodies. Brieger and Fraenkel in 1889 examined highly poisonous diphtheria cultures, and from these they obtained very poisonous precipitates which being proteid in composition were designated as *toxalbumins.* The same method of examination soon revealed the presence of toxalbumins in cultures of other disease-producing bacteria. In a very short time, however, it was shown that the so-called toxalbumin was not a definite chemical substance but rather a mixture of an inert proteid and an active poison non-proteid and non-basic in character. To distinguish the real poison from ptomaïns and from the so-called toxalbumins it has been designated as the *toxin.* After all, this is merely a term for an as yet unknown or rather but as yet imperfectly known substance. The toxins of diphtheria and of tetanus have been studied the most, but beyond a general knowledge of their reactions and behavior nothing is known as to their structure or composition. One thing is certain, that in the toxin many bacteria possess a most deadly weapon. Brieger and Cohn, after purifying the tetanus toxin, for example, as much as possible, found that the extremely minute amount of 0.00000005 gm. killed mice. A similar and almost equally destructive toxin has been separated from cultures of the Bacillus botulinus obtained from some poisonous ham. This product will be presently discussed at some length.

Recognizing the fact that bacteria are the cause of the majority of food poisonings and that they induce their poisonous effects by means of the toxins which they elaborate, it is of interest to inquire into the formation of these products. While many toxicogenic bacteria, especially including the disease germs, are capable of growing at the temperature of the body, there are those which cannot do so. The latter are therefore incapable of growing in the body. The poisons which such organisms elaborate must of necessity arise in the food, while this is kept at the ordinary room temperature. The effects which follow the eating of such food will necessarily vary directly with the quantity of the food taken, since the active poison is made wholly outside of the body. Ballard's Iron Bridge cases are instances of this kind of poison production, for in these the specific germ would not grow above 86° and its cultures at 60° were markedly poisonous. The same is true, as will be presently shown, in poisoning with food which contains the B. botulinus. The organisms at work in such cases, although toxicogenic, are nevertheless practically obligative saprophytes. Poison production then may take place (1) wholly outside of the body. On the other hand, (2) given an organism which is capable of growing at the body temperature as well as at the room temperature—in other words a facultative parasite,—it follows that such an organism, having begun the production of poison outside of the body, in the food, may continue to elaborate like poisons in the intestines after such food is taken. While in the first instance the effects are those of a plain intoxication following the introduction of a ready-made poison, in this case intoxication and infection are combined. A third type of poison production is shown when the organism present in the body is truly pathogenic. It may be present in but very small numbers in the food and the poisonous products made therein may be practically nil yet disease may follow. In other words, a true infection results from the presence in the food of disease-producing organisms. Contamination of drinking-water or milk with cholera or typhoid bacteria would fall under this head. More directly, however, this group will include bacterial diseases of animals which may be transferred to man through the flesh of animals so diseased. This type of food poisoning, it will be seen, is analogous to that with animal parasites. A number of well-defined instances of this kind will be presently given.

From what has been said it is evident that the greater part of food poisonings are instances of food infection. Such food either was at first perfectly wholesome and through improper handling became contaminated with poison-producing bacteria; or, derived from diseased animals, it already contains the specific harmful germ. In view of the undoubted fact that the germs producing these poisons are very rarely the same in two distinct outbreaks, it follows that the poisons are different and as a consequence the symptoms observed will vary within very wide limits. It is not reasonable or in accordance with known facts to believe that in poisonous cheese, for example, only one and the same organism is always present and that the chemical poison is the same in all intoxications from such food. A considerable number of organisms undoubtedly, if the opportunity is given for their development in cheese, are capable of rendering it poisonous. In like manner, poisonous meats, sausage, and fish do not owe their toxicity to any one specific organism. Already a number of toxicogenic bacteria have been isolated during the past ten or twelve years from different outbreaks of meat poisoning. This number will of necessity be increased as more careful methods come to be employed in the study of these accidental poisonings.

POISONOUS MEAT.—Every kind of meat which man is accustomed to use as food is liable to become poisonous. Raw or improperly cooked meat is usually responsible for the occurrence of such results. The frequent occurrence of sausage poisoning in Germany led to its designation as botulismus or alantiasis. These terms, however, may be used so as to embrace any meat poisoning, but it is preferable to retain the original meaning of botulismus and following the nomenclature of Vaughan to designate meat poisonings, regardless of form or origin, as *Kreotoxismus.*

Bacillus Botulinus.—By far the best studied instance of meat poisoning is that recorded by Van Ermengem. The outbreak occurred in the Belgian village of Ellezelles and at first affected thirty-four persons who were all members of a musical society. A few days later a number of other persons became sick with the same symptoms. Three of the persons afflicted died within a week. The investigation which took place showed that the sick people had all partaken of a certain ham. The hog from which the meat was prepared was perfectly healthy and at the time of slaughtering a portion of the meat was eaten raw without any effect following. After salting, both hams and other portions of the animal were packed away. The brine used was clearly deficient in salt and insufficient in quantity, since only the bottom ham was immersed in the liquid. The upper portions of meat were consumed without any ill effect and it was only the immersed ham which caused the poisoning. This exclusion of air as well as the deficiency of salt allowed the development of an anaërobic bacillus to which Van Ermengem applied the name B. botulinus. It may be remarked in passing that Kempner obtained the same organism from the fæces of a hog.

The symptoms observed in this outbreak were shown to be due to a toxin elaborated by the bacillus in the ham. The lateness in the onset of the symptoms and the absence of fever were rather remarkable for a true intoxication. As a rule no effects were observed during the first twenty-four hours after the meal and in some cases the onset was delayed for thirty-six hours. Gastric pains with repeated vomiting were first observed. With the exception of two cases all had an obstinate constipation. The gastro-intestinal symptoms were not so marked as in most instances of food poisoning, but the nervous symptoms were especially pronounced. All showed characteristic disturbances of vision. The eyes became fogged and in a short time recognition of people failed. Diplopia set in. Marked dilatation of the pupils with total loss of reaction as well as ptosis of both eyelids followed. Added to this was the sensation of a burning thirst and a constriction of the throat. The latter at times was so marked as to render the swallowing of even liquids difficult. The mucous membranes were strongly reddened, and in some the abundant secretion of viscid mucus led to violent attacks of coughing and even of suffocation. At times complete aphonia and anuria were observed. Extreme muscular weakness was general. In spite of these severe symptoms the pulse remained below 90, the respiration and temperature were normal. In fatal cases coma or mild delirium occurred. The recovery was very slow and extended through several weeks and even months.

Feeding of the ham or of macerations made with it proved fatal to mice, white rats, young cats, guinea-pigs, and monkeys. Subcutaneous injections of 0.001 c.c. of the maceration (1 to 5) killed mice. In larger doses it was fatal to rats, doves, and cats. Rabbits were extremely susceptible, while frogs, dogs, and chickens were refractory. The fact that the maceration after being filtered through porcelain was as active as when unfiltered showed that a soluble toxin existed in the ham. The further fact that the bacillus was not present in the organs of the animals that died after inoculation showed that it was a true saprophyte, although markedly toxicogenic.

The toxin of B. botulinus in its activity resembles that of tetanus or diphtheria. It is promptly destroyed by boiling but not by putrefaction. Marinesco found that the lesions produced by this toxin are largely confined to the cells of the gray matter of the cord. With very small doses the lesions consist of a rarefaction of the chromatophil elements. Under the influence of larger amounts of poison the granules of Nissl undergo more or less marked disintegration or chromatolysis. When fatal doses are administered some of these cells will be found to be completely destroyed. Kempner has successfully immunized a goat against the action of the toxin and obtained an antitoxic serum of marked potency.

Non-febrile intoxications with pronounced nervous symptoms accompanied by obstinate constipation have been repeatedly observed in the past in connection with sausage poisoning, and it is quite possible that a similar, if not identical, toxin to that just described was the cause. A noteworthy instance of this kind was furnished by the observation of von Faber, who reported in 1821 an outbreak which caused the death of five out of sixteen people who had eaten fresh unsmoked pork sausage. There were constriction of the throat, difficulty in swallowing, retching, vomiting, colic-like pains, vertigo, hoarseness, dimness of vision, and headache. Later on, in the severe cases, there was complete exhaustion, and finally paralysis. The eyeballs were retracted, the pupils were sometimes dilated, then contracted, and did not respond to light. The upper lids were paralyzed. The tonsils were swollen, but not as in tonsillitis. Liquids which were not irritating could be carried as far as the œsophagus, when they were ejected from the mouth and nose with coughing. Solid foods could not be swallowed. On the back of the tongue and in the pharynx there was observed a puriform exudate. Obstinate constipation existed in all, while the sphincter ani was paralyzed. Breathing was easy, but all had a croupous cough. The skin was dry and there was no incontinence of urine. There was no delirium and the mind remained clear to the last.

As a rule, however, intoxications resulting from sausage and other foods are characterized by a febrile gastro-enteritis. Thus, in the Wellbeck cases reported by Ballard the temperature at times rose to 103° and 104° F. and the diarrhœa was quite unrestrainable. Muscular weakness was an early and marked symptom and the debility of convalescence was in nearly all cases protracted to several weeks. Intense and distressing thirst with nausea and vomiting was quite general. Ballard has described several additional outbreaks of food poisoning which it is scarcely necessary to dilate upon.

Bacillus Enteritidis.—This name was applied by Gärtner to the organism which he isolated in 1888 from meat which had poisoned a large number of persons. The same organism was also isolated from the spleen of a man who died from the effects of the meat poisoning. The meat was unquestionably infected from the beginning, inasmuch as the cow which furnished it had a severe diarrhœa for some days before she was killed. Of the fifty-eight people who were rendered sick one died. The effects observed were those of a pronounced gastro-enteritis with subsequent desquamation. These symptoms occurred in persons who had eaten the cooked meat as well as in those who had taken it raw. On feeding animals with sterilized cultures of this bacillus Gärtner was able to show that such cultures were highly poisonous. Guinea-pigs thus fed died in anywhere from a few hours to five days. Mice similarly fed died in a few days. It is noteworthy that unlike Van Ermengem's toxin, which is readily destroyed by heat, the cultures of Gärtner's bacillus maintain their toxicity even after boiling for several hours. The poison then is very resistant to heat and resembles in this respect the intracellular toxins of the colon bacillus which have recently been studied by Vaughan. Morphologically the Bacillus enteritidis is closely allied to the colon bacillus, from which, however, it differs in not producing indol and in its pronounced infectiousness even when fed to animals.

The same organism, or at all events one closely allied to it, was isolated in 1891 by Lubarsch from the lungs and spleen of a child who died of what was diagnosed as Winckel's disease. Karlinski has also succeeded in isolating this bacillus from a case of food poisoning which came under his observation. Fischer likewise met with what he believed to be Bacillus enteritidis in an outbreak of food poisoning which affected nineteen persons. The vomiting and violent purging observed were traced to the meat of a sick cow which had recently calved.

In a case of food poisoning studied by Johne the B. enteritidis was also found. The same organism has also been met with in all probability by Poels and Dhont, Holst, and Günther and it would therefore appear that this bacillus is widely distributed in nature. The food poisoning reported by Günther in 1897 affected some twenty-six or twenty-seven families and was due to the eating of pork, as well as to the sausage and blood derived from the same. Abdominal pains, vomiting, diarrhœa, and extreme weakness were the symptoms observed. Only one person died, and from the internal organs of this individual Günther isolated the B. enteritidis. It was assumed that this organism was present in the poisonous food, but all efforts to isolate it from the latter failed.

Another instance in which presumably the B. enteritidis was involved is that observed by Silberschmidt in 1896. A small outbreak resulted from the use of the smoked meat of a suckling pig which was diseased when killed. The symptoms were essentially the same as those just given, and one death resulted. Those who had eaten cooked meat were also affected, although boiled extracts of the meat had no effect on animals.

Bacillus Morbificans Bovis.—The organism thus designated by Basenau was obtained from the meat of a cow which was slaughtered while suffering from puerperal fever. Subsequently he isolated the same organism from the meat of animals sick with perforative peritonitis, puerperal paralysis, and chronic pyæmia. The germ proved to be very infectious to the ordinary experimental animals. On the other hand it is by no means certain that the organism is toxicogenic with respect to man. It is more than probable that it is nothing more than a variety of the colon bacillus.

Bacillus Breslaviensis was found under conditions similar to the preceding in several distinct outbreaks. According to Van Ermengem food poisonings in Morseele and in Ghent in 1892 and in 1895 yielded this bacillus. In the Morseele outbreak the cause was found in the flesh of two calves that died of an undoubted infection. Of the eighty people rendered sick four died. The symptoms were those of pronounced gastro-enteritis accompanied by a high fever. In severe cases ecchymoses of the skin and disturbances of vision, while in children convulsions were observed. The outbreak in Breslau was studied by Kaensche in Flügge's laboratory. In this case also the meat was derived from a diseased cow which was killed while suffering from a high fever and a severe diarrhœa. No deaths occurred, although some eighty people were affected. Taken as a whole, the descriptions of the organisms met with in these cases agree very closely, and it is quite probable that the same germ was present in each. It is to be noted that the cultural and morphological properties of this germ are essentially those of the colon bacillus. Unlike the latter, however, it does not make indol or coagulate milk. An important feature is the fact that the poison is not destroyed by heat, and in this respect it agrees with Gärtner's B. enteritidis. Boiled or unboiled cultures or infected meat, when fed to or injected into mice and rabbits, caused death, while dogs and cats were wholly unaffected.

Bacillus Friedebergensis.—Kruse has thus designated the bacillus which Gaffky and Paak described in 1890. The source was some sausage made from the flesh and livers of several horses. The sausage was prepared in a most careless manner and as a result showed putrid decomposition. More than thirty persons were poisoned by eating this sausage and one of these died. The onset of the symptoms occurred in a few within half an hour, as a rule within six hours, although some were not affected for twelve to twenty-four hours. A marked chill, headache, abdominal pains, loss of appetite, nausea, vomiting and diarrhœa were present. As in other instances of food poisoning muscular weakness was pronounced and many were therefore unable to resume work for many days. Dizziness, thirst, and fever were also observed, but apparently no disturbances of vision. The injection subcutaneously of macerations of the sausage proved fatal to rabbits, guinea-pigs, and mice, and from these animals a short bacillus was recovered. A single feeding of sausage to mice caused the death of one in eight days and in it the same bacillus was found. Gaffky and Paak considered this organism to be responsible for the effects observed in man. The pure cultures, when given by the mouth or injected subcutaneously or intravenously, proved fatal to animals. Unlike those of B. enteritidis the cultures when boiled lost their toxicity. Like the preceding organism this one does not give rise to indol nor does it coagulate milk. Otherwise it resembles very closely the colon bacillus and may be considered to be a variety of the same.

From cooked meat which caused an outbreak of diarrhœa in Utrecht in 1896, Hamburger isolated a non-motile bacillus to which he gave the name *B. cellulæformans.* The organism did not liquefy gelatin and when grown in bouillon it produced a heavy scum but little or no cloudiness of the liquid. The infected meat when fed to mice proved fatal.

In 1897 Pouchet reported a case in which forty-nine people were poisoned by eating spoiled pork. Headache, dizziness, vomiting, diarrhœa, and fever with a general erythema were observed in those affected. Pouchet isolated an organism which he considered to be the same as the hog cholera bacillus of Metschnikoff. Inasmuch as the germ studied by the latter was really that of swine plague and not of hog cholera, it is probable that the swine-plague germ was responsible for this poisoning. It is interesting to note in this connection that Lubowski (1901) has succeeded in isolating the bacillus of hog erysipelas from the intestines of an icteric child, and it is not unlikely that in this instance infection took place through the food. There are undoubted instances in which anthrax has been conveyed to man in this way.

Ballard has reported a number of outbreaks of meat poisoning. Beef, canned pig's tongue, jellied pig's head, pork, ham, veal pie, pork pie, and canned sardines were the respective causes in these several outbreaks. It is interesting to note that the "Middlesborough pneumonia epidemic" which caused four hundred and ninety deaths, is attributed by Ballard to poisoning with imported bacon. He believed that the disease developed in a person who had eaten of the infected food and was transmissible from the sick to those who had not partaken of the infected food. In the lungs Klein found a short, thick bacillus which he called Bacillus pneumoniæ. This germ was different from the bacillus of Friedlaender and from the diplococcus of Fraenkel. Fourteen out of the twenty samples of bacon when fed to rodents produced death with lesions similar to those observed in man. During the progress of the investigation an epidemic of pneumonia broke out among the animals and in these the same organism was found. The poisonous bacon when kept for three months lost its toxicity and no growth of the bacillus could be obtained.

In 1894 Vaughan and Perkins examined some dried beef which had quite seriously poisoned a family of four. There was nothing in the appearance or odor of the beef to cause any suspicion. In fact it seemed to be of exceptionally good quality. Anaërobic cultures from the interior of the meat gave a colon-like bacillus which was pathogenic to white rats, rabbits, and guinea-pigs. The sterilized cultures were also poisonous. In an outbreak which occurred in Sturgis, Michigan, in the same year, a large number of men were rendered ill after partaking of pressed chicken. All were taken, within two to four hours after eating the chicken, with nausea, violent griping and purging, many fainted while attempting to rise from bed. From the food Vaughan and Perkins isolated a slender bacillus and a streptococcus. The former proved to be very fatal to experimental animals. Anaërobic cultures were much more powerful than aërobic ones.

During the past few years a number of food poisonings have been investigated in which the causative organism has been shown to be in all probability the *Proteus vulgaris* or its related species. Thus Levy, in 1894, investigated a case of this kind. The keeper of a restaurant and some of his guests suffered from a most violent purging, which in the case of the host terminated fatally. Proteus vulgaris was isolated from the vomited matter, from the stools, and from the ice-box where the food was kept. Levy sought to demonstrate that the poison in this case was identical with the sepsin of Schmiedeberg. Wesenberg in 1897 studied a food epidemic which affected sixty-three persons. The suspected meat came from a cow that was slaughtered when sick. Violent headache, intense abdominal pains, dizziness, extreme muscular weakness, and diarrhœa were the symptoms noted. The greenish or brownish discharges were very putrid. The more or less decayed meat yielded a bacillus which Wesenberg believed to be identical with Proteus vulgaris. It remains a question, however, whether this germ was the actual cause of the intoxications.

Silberschmidt reported similar results from an epidemic which occurred in a Swiss canton in 1899. In this instance forty-five persons were affected and one death resulted. The symptoms came on within twenty-four hours after eating "Landjäger" sausage, made out of beef and pork fat. The animals were apparently perfectly healthy. The taste and appearance of the sausage were faultless. Cultures made from the sausage gave B. coli and Proteus vulgaris. The etiological relation of the latter organism to the poisonings was by no means clearly demonstrated.

A somewhat similar outbreak was investigated in 1900 by A. Pfuhl. A "beef sausage" made by chopping up finely and potting the entrails, hearts, lungs, and spleens of three cattle was the cause of an acute gastro-enteritis in eighty-one soldiers. The material fed to rats and mice induced diarrhœa, and gradual paralysis of the limbs, but the animals recovered. One of the mice was killed and from it Pfuhl isolated a bacillus which he identified with

Proteus mirabilis. Pure cultures of the germ fed to mice caused death whereas rats recovered. The organism when inoculated into fish formed capsules but not otherwise. The toxin was destroyed on heating to 60° C. The dead bacilli were shown to be as toxic as the living, indicating that the poison was largely intracellular.

In the above instances the demonstration that the poisoning was due to the Proteus group is far from perfect. There is no question but that these organisms are toxin producers, but that fact and the detection of such organisms in a food does not prove that they are the cause of the poisonings observed. Nevertheless, it may be well to indicate that at times proteus infections have been met with in man and that several observers have ascribed epidemics among fish to this same group. These will be presently touched upon.

Poisonous Fish.—In those countries where fish is the chief form of animal food it not infrequently gives rise to severe outbreaks of acute poisoning. Just as sausage poisoning is of relatively frequent occurrence in Germany so fish poisoning in Russia is equally common. In this country poisoning from canned fish has been repeatedly observed. As in the case of meat, fish may become poisonous as a result of being diseased; or, improperly preserved, the otherwise wholesome fish may become infected with saprophytic toxicogenic bacteria. In the one case the organisms are present during life and in the other they are introduced after death. On the other hand it is well to remember that some fish are always poisonous either as the result of the presence of poisonous glands or as a result of eating certain kinds of food, while others may become poisonous during the spawning season. In such instances the toxic condition is normal and physiological. It is this form of poisoning which is designated by the Spanish physicians of the West Indies as *siguatera*, to distinguish it from the bacterial poisoning or botulismus. It is preferable, following the classification of Vaughan, to designate fish poisoning as *ichthyotoxismus*.

Epidemic diseases among fish have been observed by a number of investigators. Thus Charrin, in 1893, isolated several organisms which were pathogenic to fish. Emmerich and Weibel in the following year described the Bacillus salmonicida as the cause of an epidemic among trout. Sieber, in 1895, found that the fish in an aquarium, from which some had been taken to supply a table and had proven poisonous, were sick and that as many as thirty died within the next two days. From the dead and sick fish she isolated a highly toxicogenic germ to which she has given the name Bacillus piscicidus agilis. From cultures of this bacillus she isolated cadaverin and other known ptomaïns, besides which at least two undetermined bases were present. Sieber found the same germ in the dejections of two cholera patients. In 1898 Wyss reported the results of his study of an epidemic which prevailed among the fish in Lake Zurich. From the diseased fish he isolated an organism which he believed to be identical with Proteus vulgaris, although there were slight differences, such as the non-coagulation of milk, and non-decomposition of urea. Moreover, Wyss believes that the above-mentioned Sieber's bacillus is identical with that isolated by him and hence is also a Proteus vulgaris. That fish infected with this germ, if eaten in a partially cooked state, may cause poisoning in man is seen in Sieber's observation, and in the fact that proteus infections of meat have been described by Levy, Wesenberg, Pfuhl, and Silberschmidt.

Arustamoff, in 1891, observed eleven cases of fish poisoning, five of which proved fatal. The imperfectly salted fish contained enormous numbers of bacteria which formed typhoid-like colonies. The symptoms were general weakness, dull pain in the abdomen, dyspnœa, mydriasis, vertigo, and dryness of the mouth. It is probable that diseased fish were packed away with wholesome ones and, as a result, the entire mass became eventually infected. Cooking destroyed the toxicity of the fish.

According to Schmidt the fish poison is an animal alkaloid, a ptomaïn, produced most probably by bacteria that cause an infectious disease in the fish. Anrep partially isolated two active ptomaïns from poisonous fish. One of these was extracted from alkaline solution with ether, chloroform, and benzin. It was fatal to rabbits in doses of 0.5 mgm. A somewhat similar ptomaïn was isolated by Kakolew. From our present knowledge of bacterial poisons it is quite certain that the real toxic principle in poisonous fish, like that of Bacillus botulinus, of tetanus or of diphtheria, is not a basic product but is rather a non-proteid toxin.

Ballard reported fatal poisoning following the use of canned salmon. The can was "blown" and the contents were partially decomposed. The one who ate the most was attacked about ten hours after eating and died in three days. One who ate less became ill in about twelve hours and died in five days, while three others recovered. Klein found in both fatal cases necrosis of the mucous membrane of the stomach, fatty degeneration of the liver, and inflammation of the kidneys. Mice fed upon the salmon died, but no germs could be found in their blood. Evidently, as in Van Ermengem's case, a powerful toxin was produced by a mere saprophytic organism.

Another instance of poisoning from canned salmon is that reported by Vaughan. In this case the patient suffered from nausea, vomiting, and a griping pain in the abdomen; six hours later he vomited at frequent intervals small quantities of bile-colored mucus. Constipation was present and a scarlatinous rash appeared, covering the body from head to foot. The pulse was 140 and the temperature 102° F. Although the rash disappeared next day, a slight fever persisted for some time and the patient was confined to his house for a week. From the salmon Vaughan isolated a micrococcus which proved highly toxic when grown under anaërobic conditions.

Poisonous Milk.—Milk is unquestionably a most prolific source of intoxication and especially of real infection. This is readily understood when it is remembered that raw milk, the form in which it is most often consumed, contains enormous numbers of bacteria. Under most exceptional conditions a disease of the animal may be transferred through the milk which it secretes. As a rule, however, large numbers of bacteria from all imaginable sources enter the milk after it leaves the animal. More or less fermentation, even if no change is recognizable by the eye or taste, exists necessarily in such a product. The diarrhœas of infancy only too often stand in the same relation to milk as do the forms of gastro-enteritis resulting from the use of infected meats. Again, the transmission of typhoid fever through milk is known to have occurred. Thus Davies, in 1897, reported an outbreak of 197 cases of typhoid fever, all of which were directly traceable to one milk supply. Wilckens, in 1898, reported upon a similar epidemic which developed in Hamburg. Of the 82 cases unquestionably resulting from milk infection 65 were in women and children and only 17 were in men. However, by milk poisoning, or galactotoxismus, usually is meant acute intoxications analogous to those noted in connection with meat and fish.

The *tyrotoxicon*, discovered by Vaughan in 1885, first in cheese and later in milk, has been repeatedly found in milk and other milk products since then. Newton and Wallace in 1886 reported an outbreak of milk poisoning of this kind which affected a large number of people at Long Branch. In the same year Schearer found tyrotoxicon in milk used by, and in the vomited matter of, persons made sick at a hotel in Corning, Iowa. In 1887 Firth, an English army surgeon stationed in India, reported an outbreak of milk poisoning among the soldiers of his garrison, and from the milk he isolated tyrotoxicon. In the same year Vaughan reported an instance of milk poisoning, due to tyrotoxicon, in which three of the patients died. In 1898, Wesener and Rossmann reported the isolation of tyrotoxicon in crystalline form from poisonous cheese.

In view of the large number of different species of bacteria which may be present in milk it is evident that diverse organisms may take the causative rôle and hence different toxins may be elaborated in milk. Gaffky, for example, reports an instance in which three laboratory men became infected through milk, and suggests that the epidemic which prevailed in Christiania in 1888, in which six thousand people sickened within three weeks, was probably due to milk infection. From the former instance Gaffky isolated a small, highly virulent form of the colon bacillus.

Poisonings from various products of milk such as ice-cream, cream-puffs, and frozen custards have been frequently met with. In such cases undoubtedly the injurious organism is derived from the milk and with favorable conditions is enabled to multiply and give rise to its peculiar toxin. Here again no one organism is at work in all poisonings of this kind and consequently diverse poisons are to be expected. Coloring matter and especially flavoring extracts, such as vanillin, are often credited with causing these poisonings, but it can be readily shown that large quantities of such extracts can be taken without the least injury. While it is possible for deleterious substances or poisonous metals to find their way into milk, ice-cream, and other products, yet such instances have not been demonstrated. On the contrary a careful examination of such poisonous matter will invariably demonstrate the presence of toxic bacteria and their products.

In poisonous ice-cream, Vaughan and Novy repeatedly found tyrotoxicon, and this toxic bacterial product has been likewise detected in similar material by Schearer, Allaben, and Welford. In 1896, Vaughan and Perkins reported upon an outbreak of ice-cream poisoning which affected many people. Nausea, vomiting, and diarrhœa were as a rule present and the most alarming feature was the feebleness in the heart's action. In some persons the entire body became cool and clammy and the radial pulse was not detectable. In some delirium and stupor were also present. The germ isolated from the ice-cream showed a marked resemblance to the colon bacillus.

Cheese poisoning, or tyrotoxismus, like sausage poisoning is of relatively frequent occurrence and for that reason both attracted the attention of scientists at an early date. It is unnecessary to recapitulate the various theories that have been propounded from time to time to account for this toxicity of cheese. The phenomenon is readily explained along the lines heretofore laid down. Various toxicogenic bacteria may accidentally develop during the ripening or storage of the cheese and consequently impart to it poisonous properties. To Vaughan is due the credit of being the first to discover and isolate the chemical poison tyrotoxicon, in several outbreaks of cheese poisoning. Wallace, Wolff, and others have also isolated the same poison from cheese. Dokkum, employing a modification of the method used by Vaughan, isolated a somewhat different substance to which he gave the name tyrotoxin. From poisonous cheese Le Pierre obtained a basic body, $C_{16}H_{23}N_2O_4$. Insufficient attention has been given in the past to the study of the bacteria present in toxic cheese, and it is to be hoped that in the future special attention will be directed to this work. The studies of Vaughan and McClymonds have shown that toxicogenic germs are present in nearly all cheese. Cultures obtained from forty-nine samples of American green cheese killed white rats, guinea-pigs, and rabbits. The colon group is usually thus represented, and it is therefore a matter of little surprise if under favoring conditions some of these organisms develop sufficiently to render a given sample poisonous.

POISONOUS MOLLUSCS.—Mussel poisoning, or mytilotoxismus, is characterized by a greater variety of symptoms and a relatively greater fatality than is observed in other food infections. There can be no question as to the main fact that poisonous mussel owe their toxicity to the presence of bacteria and more especially to the products elaborated by these organisms.

In general three types of symptoms have been noted. A gastro-enteritis, characterized by nausea, vomiting, and diarrhœa, shows no difference from many of the common instances of meat poisoning. The exanthemic type has been most frequently observed. This begins with a sensation of heat which spreads from the face to all parts of the body and is followed by a papular or vesicular eruption. Itching is a marked feature and dyspnœa may be pronounced. The third type is very similar to that observed by Van Ermengem in connection with the Bacillus botulinus which he isolated from ham. The symptoms on the part of the nervous system predominate. Headache, dizziness, constriction of the throat, difficulty in speech, extreme muscular weakness, and numbness and coldness of the limbs are marked symptoms. The pupils are dilated and reactionless, but the pulse is relatively low and there is no elevation of temperature.

In recent years the best studied outbreak of mussel poisoning was that of Wilhelmshaven. In this case the cooked mussels produced symptoms within an hour or more and death resulted in two, three, and five hours after eating. From these mussels Brieger obtained the highly poisonous ptomaïn *mytilotoxin*. The fact that the poisonous mussel were obtained from brackish water and that they became non-poisonous when removed to fresh sea-water would indicate that the mussel were either diseased or their vitality was lowered to such an extent that they allowed the free development of toxicogenic bacteria.

Instances of poisoning with oysters are frequent enough. This is especially true when the oysters come from a bed polluted with sewage. Just as polluted milk or water may be the carrier of typhoid fever, so likewise oysters when gathered from polluted banks can, and have been known to, cause epidemics of this disease as well as less dangerous diarrhœas. At times the symptoms of acute intoxication following the use of oysters are as pronounced and as fatal as those noted in connection with mussel poisoning. Brosch, for example, reported a case in 1896 in which an officer died in twelve hours after eating some oysters which at the time were noted to have a bad taste. The symptoms were of the paralytic type: dimness of vision, salivation with inability to swallow or expectorate, anuria, difficult and indistinct speech, with paralysis of the right side of the face, including dilatation of the pupil and ptosis of the right eyelid, great muscular weakness, cyanosis and death.

POISONOUS VEGETABLE FOODS.—Although animal foods are most often the cause of food poisoning, yet they are by no means alone in this respect. Canned vegetable foods, tomatoes for example, have been known to give rise to serious illness. The presence of toxicogenic bacteria or of their products is responsible for these effects rather than are the traces of tin or lead which may be present. Instances of slimy bread which, as is well known, are due to the presence of slime-producing bacteria of the potato bacillus group, have been shown by Vogel to cause at times marked symptoms of gastro-enteritis.

Under the designation *sitotoxismus* Vaughan includes all forms of poisonings with vegetable foods, infected with moulds and bacteria. Mould infections especially play a most important part in vegetable foods, whereas they are practically unknown in connection with food of animal origin. The best-known example of this kind is ergotismus, veritable epidemics of which have prevailed in different parts of Europe during past centuries. At present, examples of this form of intoxication are relatively rare and are practically unknown in this country. The cause is the fungus, Claviceps purpurea, which develops on rye and other grain. At least three poisons, ergotinic acid, sphacelinic acid, and cornutin, are known to be present in ergot.

The disease known as pellagra, which prevails to an unfortunate extent in Northern Italy and in Spain, is due to a similar cause. The food in this case is corn which has been altered presumably by the action of moulds. Some investigators have credited bacteria with being the cause of this alteration, but this is by no means certain. Beri-beri, the well-known disease of Japan and of other islands in the Pacific, is commonly ascribed to the use of damaged rice.

Examination of Poisonous Foods.—A description of the various kinds of food poisonings would be incomplete without some statement of the methods to be pursued in making examinations of suspected material. It not infrequently happens that the amount of food that is left over from a meal is very small and for that reason it should be put to the best possible use. Inasmuch as a chemical analysis is of very little value it is not advisable to use up the greater part of the material in such work. At all events it should be deferred until a complete bacteriological examination has been made. The chemical substances will in no wise suffer by such delay.

A considerable amount of time can be saved, and perhaps wrong conclusions avoided, by determining at the outstart whether or not the suspected food is really poisonous. This is apparently a simple proposition but not always one that can be easily carried out. Some animals are not susceptible to a given poisonous food, while others are. Consequently, as many different animals as possible should be fed or given, through a stomach tube, the material under investigation until some are found to be susceptible. In comparatively mild poisonings the experimenter has been known to make the crucial test on himself.

In the case of pork and its products the presence or absence of trichinæ should be determined at the outstart. In case the poisonous nature of the food is established by feeding experiments the affected or dead animals may be examined by the usual methods for bacteria. It should be remembered, however, that there are cases in which no bacteria can be detected in the dead body, for the reason that they may be unable to multiply in the living body, although they may elaborate powerful poisons in the food itself. Death in such instances would be the result of a true intoxication. On the other hand, the poisonous organism may grow in the body and an infection proper may result, in which case the germ will be found distributed through the body.

The feeding experiments should be supplemented by injections, subcutaneous and intraperitoneal, of macerations of the food in sterile water. Eventually, aërobic and anaërobic cultures should be made with the poisonous food and the toxic organism should be isolated and its effects, in pure culture, studied upon susceptible animals. The presence of soluble poisonous products in such cultures may be demonstrated by filtration through porcelain.

Frederick G. Novy.

FOOT.—It is natural to compare the foot, as the distal member of the lower extremity, with the hand, the corresponding member of the upper; and by such a comparison we get most valuable aid to a comprehension of its structure. It has been said that the foot is merely a hand altered by the functions of support and locomotion which it has had to perform. While it is in general true that foot and hand are constructed upon a similar plan, it must be remembered that the differentiation commences far down in the animal series. The similarity between the anterior and posterior extremities of a quadruped, such as the horse for instance, disappears to a considerable extent when the anatomical structure is closely examined. Even in quadrupedal locomotion the posterior extremities are the ones most active in propelling the body, the anterior limbs being mainly for support and equipoise. The impression of the forefeet of an unshod horse is different from that of the hindfeet on this account. As the forelimbs come to be more used for the purposes of prehension and dexterity, the difference in structure becomes more marked. The higher apes were improperly called quadrumana, for no animal, speaking strictly, has four feet anatomically similar; still less has any animal four organs that can properly be called hands. The differences are various, according to the adaptation of the anterior and posterior members for the special activities of the animal. The bones of the carpus are never found to be the same as those of the tarsus, varying either in number or in the union of the various osseous elements. There is not, properly speaking, any opposability of the great toe in apes, as it cannot be carried around and placed at will against the various other toes; but it is set at a wider angle than the others, so that it can be used like the curve of a pincers or of a cramp-iron for grasping and climbing. The posterior extremities of apes are merely feet adapted for walking upon trees, the resemblances of the foot or "hind-hand" to a true hand being only skin deep (Huxley [1]).

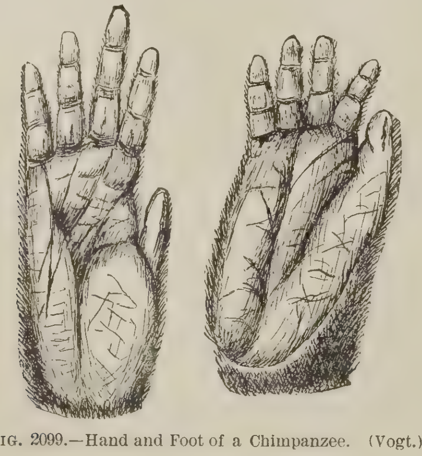

FIG. 2099.—Hand and Foot of a Chimpanzee. (Vogt.)

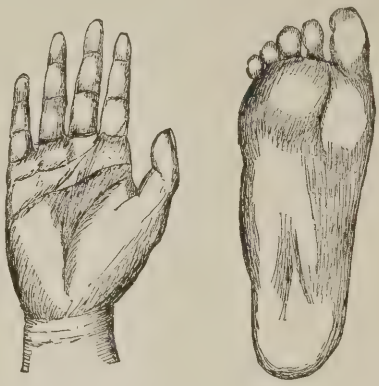

FIG. 2100.—Hand and Foot of Man. (Vogt.)

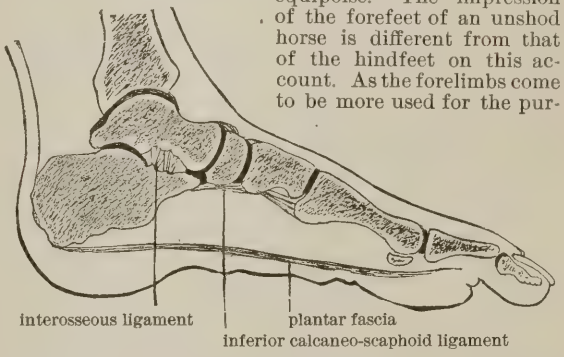

FIG. 2101.—The Antero-posterior Arch of the Foot. The bones shown are those cut by a longitudinal section through the axis of the great toe. The calcaneum forms the posterior branch of the arch; the scaphoid, internal cuneiform, the first metatarsal, the anterior branch; and the astragalus is at the summit. A sesamoid bone is seen under the head of the first metatarsal. In front are the phalanges of the great toe.

There seems from the structure of the human foot no reason to doubt that it has been developed from an organ adapted for the same use. Strong evidence of this is found in the fœtal condition of the foot, which approaches in many respects that of the anthropoid apes, there being less development of the heel, an arrangement of the joints which permits more inversion of the sole, and a difference in the corresponding length of the first and second metatarsal bones, indicating that the adult condition, in which the great toe is as long as, or longer than, the others, has been gradually acquired. Leboucq[2] determined the average proportion of the first metatarsal to the second to be in the child before birth as 1 is to 1.37; at fourteen years, as 1 is to 1.21; and in the adult as 1 is to 1.17.

Fig. 2099 shows the hand and the foot of the chimpanzee contrasted, while Fig. 2100 shows the same members in adult man. In the gorilla the resemblance to the human hand and foot is still greater. The feet of a child that has never walked show decided differences in power of using the toes, there being considerable grasp and the same imperfect opposability of the great toe as is seen in apes. The markings upon the sole show this to some extent.

The markings on the foot of a child that has never worn a shoe, nor stood alone upon its feet, resemble somewhat those of the palm of the hand, indicating considerable freedom of flexion and a certain amount of independent use of the great toe. They almost entirely disappear after the foot is used as a support. The power of the great toe may, however, be kept up if the feet are not confined, and many savage tribes use the foot for grasping. Among Australian savages this grasping power is of great assistance in climbing trees, and they habitually pick up a spear or similar object with the foot. Nubian horsemen are said to use the reins, and Chinese boatmen to pull an oar, by means of the great toe. Occasionally persons may be found who, either born without hands or, losing them early in life, have acquired the habit of using the foot for various acts ordinarily performed by the hands, and can thread a needle (as do the Hindoo tailors), use scissors, or even write, with the toes. The fact that walking in the erect position is learned only with difficulty shows that it is a late acquirement.

The main characteristics of the human foot are, therefore, those which adapt it for support and locomotion. For this purpose a most beautiful structural arrangement has been effected, combining great strength with peculiar elasticity and lightness. The bones are set in the form of a vault supported at the points connected by arches, two of these starting from the same point of the heel (the tuberosity of the calcaneum), and extending forward, one to the ball of the great toe (head of first metatarsal), the other to a corresponding point on the little toe. The third arch is transverse, connecting the anterior ends of the longitudinal ones.

The inner arch is formed by the calcaneum behind and the first, second, and third metatarsals, the cuneiform, and scaphoid bones in front, with the astragalus set at the vertex as a keystone (see Fig. 2101). The outer arch, which is much flatter, is formed by the calcaneum, cuboid, and two outer metatarsals which articulate with it. The transverse arch is formed behind by the three cuneiform bones and the cuboid (Fig. 2102), in front by the metatarsal bones. It should be noted that this arch becomes shallower and shallower as the toes are approached, until at last upon reaching the heads of the metatarsals the weight is borne fully upon them all. The imprint of a normal human foot, shows this clearly. The height of the arches forms the instep, a feature peculiar to man, and which varies considerably in different races, being generally higher in the Indo-European than in others. Arabs are said to boast that their insteps are so high that water will run under them without wetting the sole, and the Andalusian instep is famous. A popular saying has it that the foot of the negro is so flat that it makes a hole in the ground. A very amusing proof of this primitive condition of the negro foot may be noticed in Southern cities, where, during the heat of summer, it is customary to wet the pavements in the evening. It is not unusual to see barefooted negro boys, whose feet are so flat that atmospheric pressure makes them adhere slightly when applied to the wet and smooth pavement, in the same way that a boy's leather sucker adheres to a smooth stone, and it is a favorite pastime with such gifted individuals to walk the streets, producing a somewhat startling report every time the foot is withdrawn from the pavement. It is perhaps not without some reason that the height of the instep is considered a mark of pure blood, as it appears to be one of the signs of complete adaptation to the erect posture and to locomotion in that position.

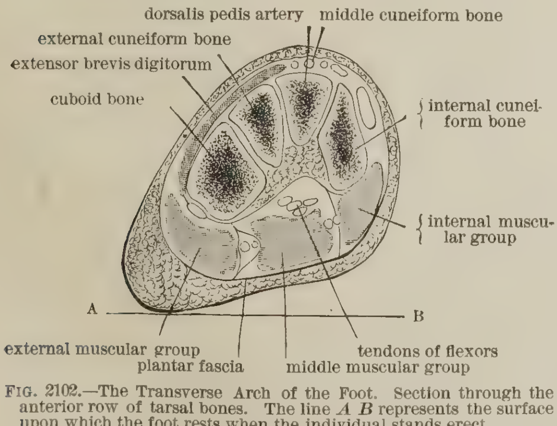

FIG. 2102.—The Transverse Arch of the Foot. Section through the anterior row of tarsal bones. The line *A B* represents the surface upon which the foot rests when the individual stands erect.

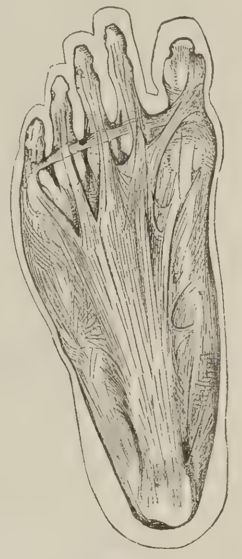

FIG. 2103.—Dissection of the Foot showing the Plantar Fascia. (Marshall.)

Man is the only animal that has the foot placed at right angles to the axis of the body, most mammalia not touching the ground with the calcaneum at all. The horse, for instance, literally walks upon the points of the toes, the hoof being comparable with the nails of the human foot, and the hock or "knee" being the tuberosity of the calcaneum. There appears to be some relation between this ascension of the calcaneum and the fleetness of the animal, as those which are the swiftest have the bones so arranged that they walk merely upon the tips. If support alone were needed there would be no necessity for the metatarsal bones and toes, as may be seen in those who have had them amputated. The anterior part of the arch is therefore for purposes of locomotion, and it may be noted that in running the heel is raised off the ground, and the anterior part only is used, the anatomical relation of the bones to the soil being similar to that which occurs ordinarily in the foot of the carnivora. The great swiftness and lightness of motion of a *première danseuse* is owing to her ability to dispense entirely with the posterior portion of the arch.

Owing to this difference of formation the anterior and posterior pillars of the longitudinal arches differ—the posterior, being for support, is short, thick, and strong, being of but one bone; the anterior, composed of several bones, is longer, so that the motion of raising the heel can be quickly performed. The length of the heel in the African race is merely apparent, and caused by the flattening of the arch rather than by a real projection. The number of bones in the anterior arch greatly aids in the distribution of the force, as any one may see who will take the trouble to note the difference in shock which occurs when alighting upon the heels rather than upon the balls of the toes.

This system is sustained by ligaments, tendons, and fascial bands in such a way as to form a most elastic and adjustable support. The longitudinal arches are held up by a strong sheet of connective tissue, one of the thickest aponeurotic structures in the body, the plantar fascia (Figs. 2101 and 2103), which is attached behind to the calcaneum, and in front divides into five slips, one for each toe, which pass forward and are mainly united to a band of transverse fibres which runs across the foot just behind the clefts of the toes.

This braces up the arches of the foot in the same way that a tension rod prevents the rafters of a roof from spreading. This arrangement is found only in the human foot, other animals having a plantar fascia movable like that of the hand, and usually with a special tensor like the palmaris longus of the arm. The little plantaris muscle of the human leg, which does not reach the foot, but unites with the tendo Achillis at the ankle, is the relic of such a structure.

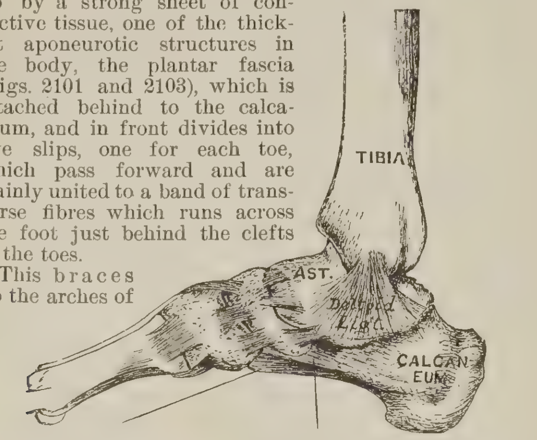

FIG. 2104.—The Ligaments on the Inner Side of the Right Foot.

When this fascia is very tense, it may draw the arch so closely together as to prevent the outside of the foot from touching the ground. This condition is not usually found in the normal foot, being the result of contracture of the fascia.

Besides this arrangement, the longitudinal arches are braced at the top by strong ligaments. A glance at Figs. 2101 and 2104 will show how necessary these are. The astragalus at its inner side overlaps the calcaneum, and would, in case of a lateral thrust, be shoved downward and inward into the space between that bone and the scaphoid were it not for the inferior calcaneo-scaphoid ligament, which passes from the projecting shelf of the calcaneum known as the sustentaculum tali, forward, under the astragalus, to the scaphoid. Its upper surface is lined with synovial membrane, and the cavity of the joint between the anterior part of the astragalus and the calcaneum is continued forward over it to the astragalo-scaphoid articulation. The tendon of the tibialis posticus passes forward under this ligament, and its fibres are united with it, strengthening it materially, and by its pull upon the scaphoid assisting the firmness of the joint exactly at that period of the step when the arch is most in danger; that is to say, when the heel is being raised and the weight thrown forward upon the scaphoid. If this ligament becomes weak or the muscle atrophied, the arch is depressed, the head of the astragalus descends below its proper level, and flat foot, or valgus, results. This is usually associated with arthritis, and is a very painful affection, differing much from the congenital form of the defect. It is found especially among those who stand for long periods of time.

On the outer side of the foot the arch is trussed up by means of a strong band called the long plantar ligament (Fig. 2104), passing from the tuberosity of the calcaneum forward to the base of the second, third, and fourth metatarsals.

To produce the transverse vaulting, certain short and oblique ligamentous bands are used, radiating from the scaphoid, the cuboid, and the external cuneiform bones, and these are assisted in a marked degree by the action of the muscles.

Fig. 2105 shows that the tendons of the peroneus longus and of the flexor longus digitorum are so arranged that they pull obliquely upon the bones of the foot, crowding them together and consolidating them transversely. Duchenne[3] was of the opinion that flat foot is frequently associated with an insufficiency in the peroneus longus. The members of the inner arch are decidedly more movable than those of the outer, which recalls the fact that it is only the outer part that is used for support among anthropoids.

The various interosseous ligaments assist considerably to keep the bones in place. The strongest of them is the one between the astragalus and the calcaneum (Fig. 2101), separating the articular surface into two distinct portions. It lies within a canal formed by grooves upon either bone, and known as the canalis tarsi, surrounded in that situation with fat.

The joints of the foot are adapted to the arch-like form above described. An inspection of Fig. 2101 will show that there is an approximation in these joints to arcs of circles, the larger arcs being in the posterior part of the arch, the smaller and more numerous forward. A study of the cancellated tissue of the bones shows that these arcs are continued to some extent by strengthening bars within the bone, showing that conditions of stress have occasioned this arrangement. The movements are generally those of rotation and not purely gliding (Bradley[4]). A uniformity of distribution of pressure is thus obtained. The ligaments which unite the different bones are of two classes: those which are special, surrounding and supporting particular joints; and those which are general, mainly employed in bracing and sustaining the arches of the foot. To the first class belong the capsular ligaments which are found at every joint, and are strengthened more or less by special bands, which receive names from the bones which they unite. The principal ligaments of the second class have already been mentioned. The movements are of two classes, one of which is a simple flexion and extension, mainly expressed in the joint between the astragalus and the leg bones (see *Ankle Joint*), and in the various metatarsal and phalangeal joints; the second a movement of inversion and eversion of the sole, sometimes called, rather inaccurately, adduction and abduction, or supination and pronation, and which takes place in the astragalo-calcanean joints. As already mentioned, the joint between the astragalus and the calcaneum is double, with two synovial sacs, the anterior being continuous with the astragalo-scaphoid articulation. The joint has been carefully studied by Miss Clark,[5] who made many measurements of it, both in fœtal and adult subjects. The facets on the astragalus are concave, and the axis of motion is a line extending from the insertion of the dorsal ligament binding the astragalus to the scaphoid through the head of the astragalus and the body of

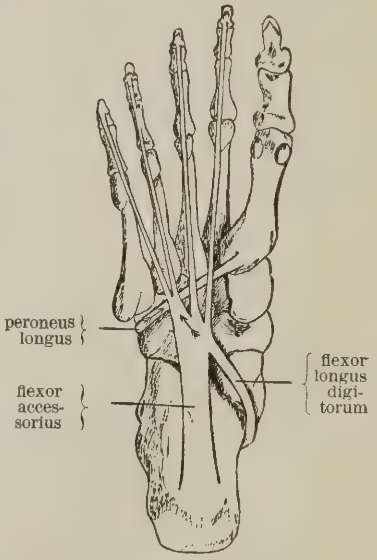

FIG. 2105.—Diagram of the Action of Some of the Principal Tendons which Consolidate the Transverse Arch of the Foot.

the calcaneum obliquely downward and backward to about the point where the middle band of the external lateral ligament is inserted. The movements which take place are really a nearly simple flexion and extension about this oblique axis, the former turning the sole inward (supination), the latter slightly outward (pronation). The arrangement of the axis of motion with reference to the axis of the astragalus is different in the fœtus, resembling that of anthropoids. The whole bone is quite differently shaped as regards the inclination of its articular surfaces, they being adapted to the fœtal position, which is that of dorsal flexion and inversion of the foot. The head of the astragalus is so directed as to make the axis of the bone more nearly coincide with that of the motion of the joint. Inversion is therefore easier and more complete. The shape of the articular facet on the head of the astragalus is also different, its greatest diameter being less oblique than in adults. In the ape's foot inversion of the sole is necessary for climbing, and among Australian savages it is similarly used. This movement is undoubtedly very useful in correcting slight disturbances of equilibrium when standing erect. The direction of the facets in the adult is such that when the posterior part of the calcaneum slips forward and downward the anterior facet moves backward and upward, carrying the distal end of the bone slightly inward. For this reason inversion is always accompanied by a turning in of the toes, and eversion by turning them out. A further degree of this movement of the toes is found in the astragalo-scaphoid, a shallow ball-and-socket joint, the round head of the astragalus being received into the posterior hollow facet on the scaphoid. It is this joint that gives to the foot the great freedom of movement that is enjoyed by dancers. A comparison of these joints with those of the wrist will show at once that there is no real homology possible between them. Dislocation may occur here, the interosseous ligament being torn and the malleoli usually fractured at the same time.

The peculiar condition of the fœtal foot, with reference to this joint, is probably the primary cause of the different varieties of club foot. The most common form, or varus, is the persistence of the fœtal condition of inversion of the sole. The articular surfaces between the calcaneum and the cuboid are saddle-shaped, and have a triangular outline. The movements allowed here are like those of the astragalo-scaphoid joint, but less in extent. The whole articular line between the astragalus and calcaneum behind, and the scaphoid and cuboid in front, is known as the medio-tarsal joint, sometimes called Chopart's joint by surgeons because of the operation frequently performed there. The movements of the other joints of the foot are similar to the corresponding ones of the hand. The great toe is the only one that lies perfectly extended, the others being more or less flexed. Together they give elasticity to the last act of walking, when the weight is thrown forward upon the other foot.

In considering the surgical anatomy of the articulations of the foot, it is necessary to note that the bones fall naturally into three grand divisions of tarsus, metatarsus, and phalanges, and that the tarsal bones are divisible into an anterior group, composed of the three cuneiform bones, the cuboid, and the scaphoid, and a posterior group, the calcaneum and the astragalus. The astragalus may itself be considered separately, as it lies more superiorly and with a horizontally directed joint surface. There are, therefore, the following lines in which disarticulation can be effected: First, between the different phalangeal and metatarso-phalangeal joints; second, the tarso-metatarsal line; third, the medio-tarsal line; fourth, the sub-astragaloid line; and, lastly, the cruro-tarsal line, by which the entire foot may be removed. The phalangeal joints are easily found by remembering that it is always the proximal phalanx that forms the prominence in flexion, and that the opening must therefore be somewhat forward from that. The same may be said for the metacarpo-phalangeal joints, the general line of which lies about three-fourths of an inch behind the skin fold connecting the toes. The exposed condition of this part of the foot, as well as its distance from the heart, renders it liable to some injuries, such as chilblains, and senile gangrene. The tarso-metatarsal line is used for the operations of Hey and Lisfranc, neither of which is frequently performed, as disease is very rarely confined to the metatarsal bones. Hyrtl's[7] rule for finding the joint on the inner side is that it lies exactly at the half-length of the sole. It is also about an inch and a half in front of the tubercle of the scaphoid, which may be easily felt on the inner side of the foot in front of the point of the internal malleolus. A slight eminence may usually be felt on the posterior extremity of the first metatarsal by holding the foot steady, pressing firmly on the skin, and thus following back the smooth internal surface of the shaft of the bone. On the outer side the line cannot be missed, as it lies directly behind the prominent tubercle at the base of the fifth metatarsal. The base of the second metatarsal bone is received between the inner and outer cuneiform bones, the middle cuneiform being correspondingly lessened in length. This adds considerable firmness to the arches, but makes the line quite irregular and is an obstacle to the speedy performance of the operation. Disarticulation is now usually practised; but Hey sawed through the metatarsal, leaving the base in place. Tillaux[8] remarks that although the irregularity of the line varies, the joint of the second cuneiform is always at a definite interval behind that of the first—about a centimetre. The interosseous ligaments are strong, and are the principal obstacle to the knife.

In the medio-tarsal line the operation known as Chopart's is performed. The line is not very difficult to find as it lies on the inner side just behind the tubercle of the scaphoid, and externally just in front of the prominent edge of the head of the calcaneum. This latter is midway between the external malleolus and the tubercle on the metatarsal bone of the little toe. There is no irregularity in the line, it being composed of two curves, one between the scaphoid and astragalus, convex forward, the other between the calcaneum and cuboid, convex backward. The principal obstacle to the knife is the calcaneo-cuboid or Y-ligament, which is strong and thick, radiating, as mentioned before, from the calcaneum to be inserted by two slips into the cuboid and the scaphoid. The calcaneo-scaphoid ligament which, it will be remembered, ties the vertex of the arch, is also divided in this operation. In old subjects it is occasionally found to be ossified.

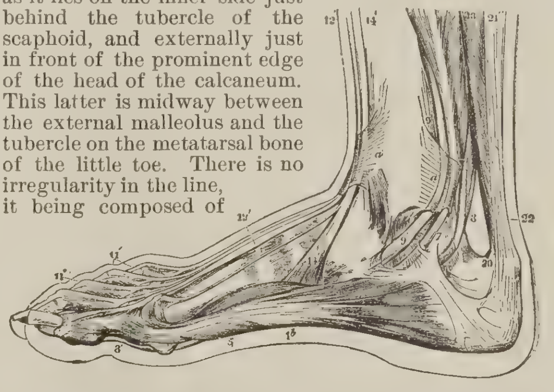

FIG. 2106.—View of the Muscles and Tendons on the Inner Side of the Right Foot. *a*, *a*, Annular ligaments; 1*b*, abductor pollicis; 7', tendon of flexor longus digitorum; 8', tendon of flexor longus hallucis; 9', tendon of tibialis posticus; 11', tendons of extensor longus digitorum; 12', tendon of extensor longus hallucis; 14', tendon of tibialis anticus; 22, tendo Achillis. (Marshall.)

Disarticulation under the astragalus is not often resorted to. As there are no muscles attached to that bone, it can be of little service even if left in place.

The muscles of the foot are divided by their position into intrinsic and extrinsic; those which have their origin above belonging to the latter class. The division is topographical rather than scientific, for there is no doubt that many of the muscles now found in the foot primarily had an origin higher up, and have become displaced in the course of phylogenetic development.[9] The extrinsic muscles are the most active agents, the intrinsic mostly aiding and supplementing them. They fall quite naturally into four groups—an anterior, supplied by the anterior tibial nerve and composed of the tibialis anticus, extensor proprius hallucis, extensor longus digitorum, and peroneus tertius; a lateral, supplied by the peroneal nerve and composed of the peroneus longus and brevis; and two posterior, the superficial supplied by the internal popliteal nerve and composed of the muscles inserted into the tendo Achillis (gastrocnemius, soleus, plantaris), and the deep, supplied by the posterior tibial nerve and composed of the tibialis posticus, flexor longus digitorum, and flexor longus pollicis. All of these pass over two joints, the ankle joint or astragalo-crural and the astragalo-calcaneal, and therefore occasion motion at both, but in very varying degrees.

FIG. 2107.—Synovial Sheaths on Back of Ankle and Foot.

The tendons of the anterior group may be seen in Figs. 2106, 2107, and 2113, and passing down over the ankle, where they are held in position by thickened bands of fascia known as the annular ligaments. There are two of these, an upper one (ligamentum transversum cruris), not shown in the figures, extending across the lower part of the leg from fibula to tibia, and a lower one (ligamentum cruciatum), in the form of a ≺, placed thus on its side (the shape best shown in Fig. 2107), the main stem being a strong loop-like band which lies on the outer portion of the ankle, springing from the fore part of the calcaneum in the deep fossa between that bone and the astragalus known as the sinus tarsi. It completely surrounds the tendons of the peroneus tertius and extensor longus digitorum (see Fig. 2108, *a*). This band was first described by Retzius, who gave it the name of ligamentum fundiforme tarsi. It is of considerable strength, and gives a new direction to the tendons, so that they pull more exactly in the line of the toes (see Fig. 2113), thus forming a sort of trochlea like that which the superior oblique muscle of the eye has. According to Hyrtl it usually becomes cartilaginous in old people. By a sprain the tendons may be torn from this connection, and will then be seen to take a much more direct line to the toes. From this band the two branches of the ligamentum cruciatum diverge, passing over the tendons of the extensor proprius hallucis and the tibialis anticus. The tendons which pass down over the dorsum are provided with certain synovial sheaths which are shown in Fig. 2107. The tendon of the tibialis anticus (14′ in Fig. 2106) is the largest and strongest, and may be easily made out whenever the foot is flexed and the sole at the same time bent inward. As it is inserted into the internal cuneiform and base of the first metatarsal, it necessarily flexes the foot and inverts the sole. It will be seen that the attitude is much like that of varus, and in fact this muscle is one of the most active agents in that deformity. In dividing the tendon care must be taken not to open the astragalo-calcaneal joint.

The tendon of the extensor proprius hallucis comes next (see Fig. 2113). It is also very large and strong and is the most prominent cord in front during flexion of the foot. On this account it is the first to suffer from any tightness of the covering about the ankle. It is inserted into the last phalanx of the great toe, which it strongly extends in the last act of walking just as the foot is about to leave the ground. Continuing its action, it flexes the foot on the leg and assists the tibialis anticus to invert the sole. It is more firmly enclosed by the cruciate ligament than the tibialis anticus, and its pull upon that band raises the arch slightly so that its impression is fainter.

The extensor longus digitorum sends tendons to the four outer toes which unite with those of the extensor brevis and are inserted into the second and third phalanges. Closely associated with this muscle is the peroneus tertius, a thin muscular slip which sends a tendon to the metatarsal bone of the little toe. It hardly deserves a separate name.

The action of the extensors upon the toes is reinforced by the lumbricales from the sole of the foot. These muscles arise from the *flexor* tendons and pass around the phalanges to be inserted into a triangular aponeurosis, which is common to the extensor muscles. In walking, therefore, as the flexors assist in raising the foot they give a firm basis for the pull of the lumbricales, so that in the final act of rolling the weight forward upon the toes they can assist the extensors. It should be remembered that the division of the muscles into flexors and extensors is not, in so far as it implies an antagonistic condition, entirely correct.[10] Those muscles which extend the toes also flex the foot, and *vice versa*. There is no loss of muscular force, as there would be did one set pull directly against the other.

The extensor brevis (see 10, Fig. 2108), though an intrinsic muscle, should be mentioned here, as it belongs morphologically to the same group. It was originally a leg muscle, and has gradually slipped down, all stages of its descent being seen in different animals.[9] It arises from the forepart of the upper and outer surfaces of the calcaneum, and presents, on the outer side of the foot, a considerable muscular belly, which contributes to the modelling of that part of the foot, and is soft and pulpy to the touch. This should be remembered in examining the ankle for suspected joint disease, or after a sprain. When struck lightly it will quiver, and this movement has been mistaken for fluctuation, and the muscle has been incised in mistake for an abscess. The tendon which goes to the great toe is usually somewhat separated from the others, and that part of the muscle has been described separately as an extensor brevis hallucis.

The extensor brevis varies considerably, especially with regard to the amount of division of the various muscular bellies of which it is composed, and there is occasionally seen a tendency for it to become merged with the dorsal interossei, elements of an entirely different origin.

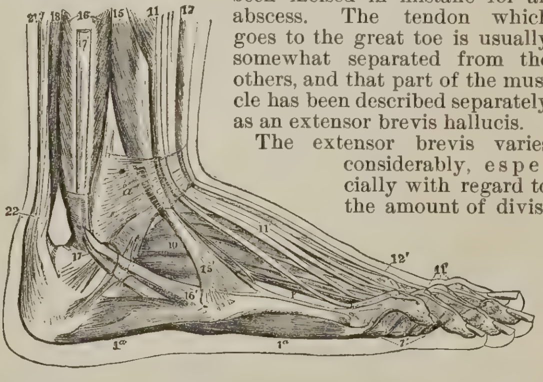

FIG. 2108.—View of the Muscles and Tendons on the Outer Side of the Right Foot. *a*, Ligamentum fundiforme; 1*a*, abductor minimi digiti; 7′, insertion of the tendons of the flexor longus digitorum; 10, extensor brevis digitorum; 11′, tendons of the extensor longus digitorum; 12′, tendon of the extensor longus hallucis; 15, tendon of the peroneus tertius; 16′, tendon of the peroneus brevis; 17′, tendon of the peroneus longus; 22, tendo Achillis. (Marshall.)

The peroneus longus and brevis (16′ and 17′, Fig. 2108) were primitively upon the front of the fibula, but their tendons have been shifted behind the outer malleolus for adaptation to climbing. They are here held by a strong sheet of fascia (retinaculum superius), and are similarly sheathed (retinaculum inferius) where they lie in a groove on the outer side of the calcaneum. Notwithstanding this secure attachment the tendons are more frequently displaced than any others in the body. Leaving the groove they diverge from each other, the brevis being inserted into the tubercle of the fifth metatarsal, and continued by a thin tendon as far as the toe, the longus passing across under the arch of the foot in the groove on the inferior surface of the cuboid, and being inserted into the tubercle of the first metatarsal bone (see Fig. 2105). They strongly evert the sole, producing a condition like that of valgus.

The peroneus tertius, the extensor longus digitorum, and the extensor brevis digitorum, were originally parts of the same muscle sheet which belonged to the back of the foot and front of the leg. The twisting over of the foot into its position with the plantar surface downward has caused them to appear in their present situation. Extra peroneal muscles are not infrequent, and in one dissection performed by the author a set of five were found.

The main body of the flexor tendons passes down on the inner side of the ankle. Fig. 2109 shows, in a diagrammatic form, how they are arranged, and their tendons are seen in Fig. 2106. Besides these there should be mentioned those muscles (the soleus and gastrocnemius) which are inserted through the tendo Achillis upon the calcaneum. Duchenne's experiments[3] in the faradization of muscles led him to the conclusion that these latter act as extensors and adductors of the foot, while the peroneus longus is an extensor and abductor. In order to get a powerful and equal extension of the foot both of these act together, and this may be increased by a simultaneous contraction of the flexor longus digitorum and flexor longus pollicis. He supposes that the reason for the peculiar action of the tendo Achillis in causing adduction is occasioned by the arrangement of the plantar ligaments. The strongest bands lie on the outer side of the foot, and this determines a deviation of the line of action in that direction.

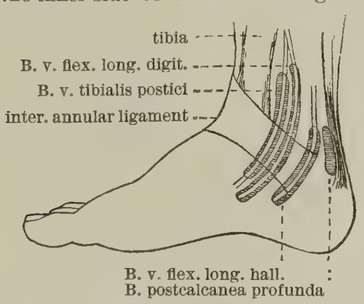

FIG. 2109.—Synovial Sheaths of Inner Side of Foot.

It was formerly supposed that the severing of the tendo Achillis was a necessarily fatal injury. Hippocrates was firmly of this opinion, and one of the names given to the tendon is chorda magna Hippocratis. It was undoubtedly a serious matter when the wound was an open one and proper drainage not secured; but with the modern resources of surgery it is often safely divided for the relief of club foot. For about an inch and a half above its lower end it is free from muscle fibres, and narrows slightly, and it may be cut there, care being taken to avoid the vessels and nerves at its inner side, and the bursa which exists just above its insertion (see Fig. 2109). Rupture of the tendon has occurred from violent muscular action in jumping.

The tendons of the tibialis posticus, the flexor longus digitorum, and the flexor longus hallucis pass down behind the internal malleolus in a special compartment, confined by a strong band of fascia known as the internal annular ligament, which passes from the malleolus to the calcaneum, enclosing not only the tendons but the vessels and nerves which accompany them. They have special synovial sheaths (Fig. 2109), and are so arranged that the tendon of the flexor longus hallucis is nearest the tendo Achillis, that of the flexor longus digitorum next, and that of the tibialis anticus nearest the malleolus, the tendon of the digital flexor twisting around it from without inward, and then passing downward, forward, and outward under the sole. Were it not for this the tendon of the tibialis posticus would be likely to slip from under the malleolus or the sustentaculum tali as it passes forward to be inserted into the tubercle of the scaphoid, and by a tendinous expansion into all the bones at the upper part of the vault except the astragalus. It strongly inverts the sole and raises the head of the first metatarsal. Spigelius called it musculus nauticus, because it was necessarily used by sailors in climbing masts.

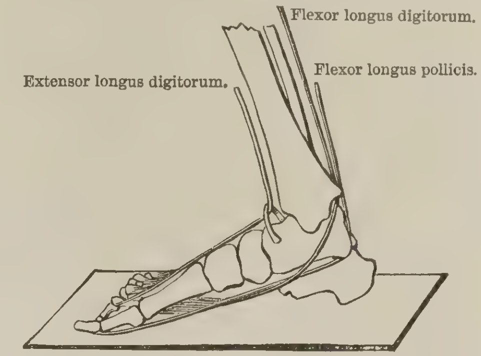

FIG. 2110.—Diagram Showing the Manner in which the Flexor and Extensor Tendons are Reflected around the Ankle. (Langer.[13])

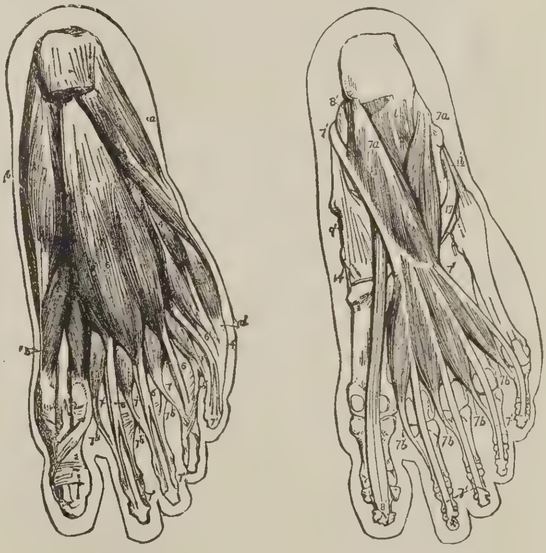
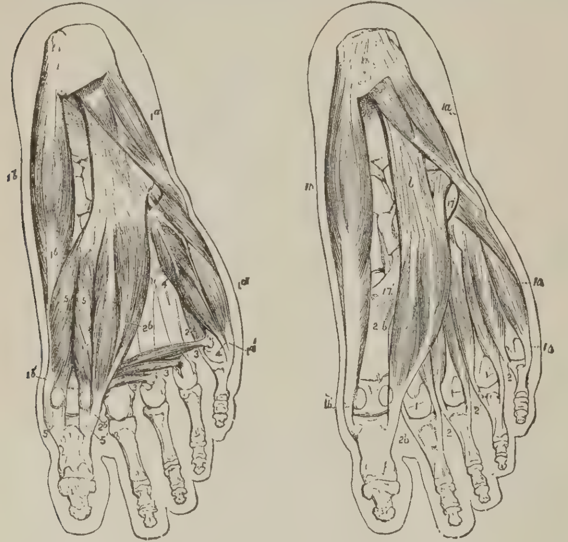
The flexor longus digitorum and the flexor longus hallucis are arranged somewhat like the flexor profundus digitorum and the flexor longus pollicis of the hand, as they have an arrangement of tendons which pass in a similar way through those of the flexores breves to be inserted into the terminal phalanges of the toes. But they are very differently related in the sole, for they not only decussate and unite there, but the flexor longus digitorum receives a reinforcement from an accessory head, the flexor accessorius, or caro quadrati Sylvii, arising from the tuberosity of the calcaneum, and inserted at



First Layer. Second Layer.

FIG. 2111.—The Muscles of the Sole of the Foot. 1*a*, Abductor minimi digiti; 1*b*, abductor hallucis; 6, flexor brevis digitorum; 7′, tendon of flexor longus digitorum; 7*a*, its plantar head, or flexor accessorius; 7*b*, 7*b*, lumbricales; 8′, tendon of flexor longus hallucis; 17, tendon of peroneus longus; 9′, insertion of tibialis posticus.

the decussation. The crossing in the sole is such that in the greater number of cases the tendon of the flexor hallucis sends to the decussation a lateral twig, which again divides in slips for the second and third toes, uniting with the tendons of the flexor digitorum. The slip to the third toe may be wanting, but sometimes one is sent to the fourth. This arrangement recalls the musculature of the ape's foot, where the hallucis tendon supplies the third and fourth toes, and sometimes the second, while the digital tendon is mainly confined to the second and fifth, or to the second only, the great toe receiving only a slender tendon which quite fails in the orang. The unusual development of the hallucis in man appears to be connected with the use of the great toe for preserving the equilibrium in the erect position.



Third Layer. Fourth Layer.

FIG. 2112.—The Deep Muscles of the Sole. 4, 4, Flexor brevis minimi digiti; 5, 5, flexor brevis hallucis; 2*b*, adductor pollicis, with its detached heads; 3, 3, 3, also called the transversus pedis; 1, 1, 1, dorsal interossei; 2, 2, 2, plantar interossei.

The plantar head mainly reinforces the tendons for the third and fourth toes.[11] The whole apparatus appears to indicate that the original plan was for a flexor fibularis (flexor longus hallucis) and a flexor tibialis (flexor digitorum), and that the flexor accessorius originally belonged to the latter muscle, but afterward lost its insertion upon the fibula. Variations are found which tend to confirm this.

It will be noticed that the most direct pull appears to be toward the second and third toes; the tendons there are supplied, not only from the common flexor, but also from the tendon of the hallucis. This would appear to show that the original axis of the foot, or line on which it rolls, is not through the great toe, as usually stated, but through the second and third toes, and would bear out the experiments of Beely,[12] who found that in a cast taken from the impression made by his foot while standing upon a layer of soft plaster, the heads of the second and third metatarsals made a deeper impression than any other portion of the anterior part of the foot.

The action of the flexor is to bend the toes and contribute to the stability of the foot in standing. After bending the toes they also flex the medio-tarsal joint.

So it follows that these muscles all co-operate in lifting the heel from the ground and flexing the foot, and that, as this is done, the toes are strongly flexed and pressed against the ground like an elastic spring (see Fig. 2110).

They are often divided in orthopædic operations, usually at the malleolus, as it should be remembered that the posterior tibial artery lies near the flexor longus digitorum, being exactly in the middle of the space between the posterior margin of the internal malleolus and the internal border of the tendo Achillis. The nerve is in the same sheath with the artery and behind it.

The intrinsic muscles of the sole, which are quite numerous, are shown on Figs. 2111 and 2112. They are arranged in three groups, separated from each other by appropriate layers of fascia, as shown in Fig. 2102. The external group is composed of muscles relating to the little toe, the flexor brevis and abductor minimi digiti; the inner is a similar group relating to the great toe, the flexor brevis and abductor hallucis; while the middle set is related to the muscles which come down from the calf, the flexor accessorius and the lumbricales, together with the flexor brevis digitorum and adductor pollicis. Deep under all these lie the interossei. The muscle sometimes described as transversus pedis is not entitled to a separate description, as it is clearly shown by the evidence of embryology to be a portion of the adductor pollicis.

These muscles are of special use in supplementing the action of the ligaments in supporting the arches, giving an elastic support variable according to the nature and direction of the strain. The interossei are in two groups, the plantar and the dorsal, the latter not being prominent on the sole. All originally developed upon the sole, the dorsal gradually passing up between the metatarsal bones during fœtal life. Cunningham[14] thinks that the primitive typical arrangement of the intrinsic plantar muscles is the same as that of the hand, viz.: that there is a plantar layer of adductors of the toes represented by the

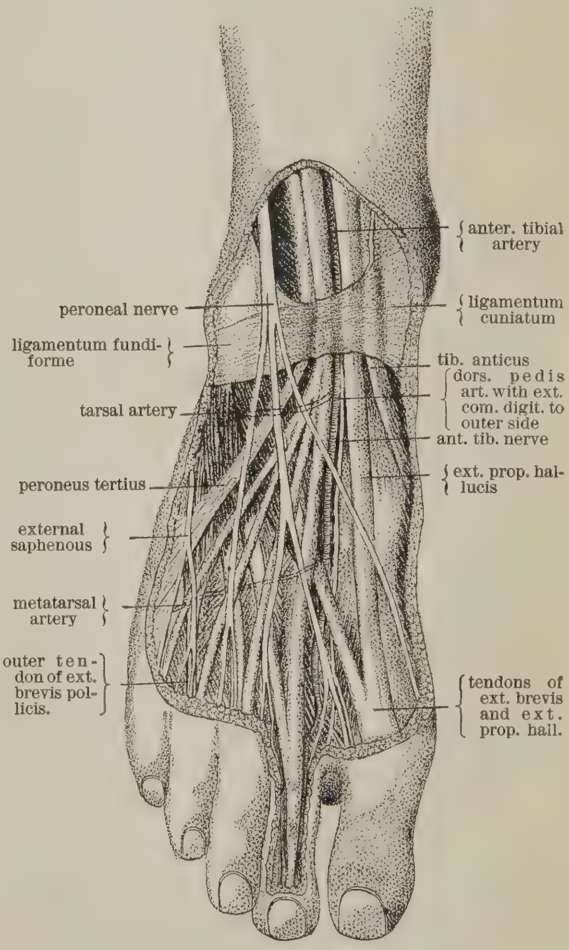


FIG. 2113.—A Dissection Showing the Deeper Structures on the Dorsum of the Foot.

adductor hallucis and its detached head, the transversus pedis, and the three plantar interossei; an intermediate layer of flexores breves, composed of the flexor brevis minimi digiti and the flexor brevis hallucis; and a dorsal layer of abductors of the toes represented by the abductor hallucis, the abductor minimi digiti, and the dorsal interossei. The layers have lost their relative planes in the foot partly because of the arched condition, and partly by suppression of the flexores breves for the second, third, and fourth toes.

The nerves of the foot give us important evidence with regard to the value and previous history of the muscles. Those derived from the lumbar plexus do not have any motor functions, but supply sensation to the integument of the inner side (long saphenous nerve). The sacral plexus gives sensations to the remaining portions, viz., by the external saphenous on the inner side, the musculo-cutaneous over the dorsum, and the plantar nerves on the sole, the internal plantar supplying the first three toes and half of the fourth, the external supplying the other half of the fourth and the fifth. The nerves of the dorsum are shown in Figs. 2113 and 2115; those of the sole in Fig. 2114.

FIG. 2115.—The Superficial Veins and Nerves of the Dorsum of the Foot.

The vessels of the foot (see the same figures) are not very numerous or large. Upon the dorsum we have the continuation of the anterior tibial artery, which, as it passes under the annular ligament, changes its name to dorsalis pedis. It is accompanied by two veins, and passes forward to anastomose, at the space between the first and second toes, with the external plantar. It is believed to correspond to the radial artery of the hand, and it will be seen that the twisting over of the dorsal surface has given it a less devious course. It is easily secured in the upper part of its course, where it lies quite superficially and just external to the tendon of the extensor longus hallucis. Aneurism has occurred in it as a sequel to a sprain. The posterior tibial artery, coming down behind the ankle, divides, just before entering the sole, into external and internal plantar, the latter being the smaller. The external runs outwardly across the foot, deep under the muscles, and then turns again to the inner border and anastomoses with the dorsalis pedis. It is not practicable to reach these for ligature in the sole, except by resection of the metatarsal bones.

The superficial veins are found mainly upon the dorsum. A reference to Fig. 2115 will show that the internal and external saphenous veins coming down from above anastomose with each other across the metatarsal bones, forming an arch with the convexity toward the toes. Tight boot-lacings may so compress these veins as to produce a stasis, with pain and swelling. Veins of any considerable size are wanting upon the sole.

The integument of the sole of the foot is intimately united with the layer of subcutaneous fat, which is here not loose and movable, but shut into distinct compartments by septa of connective tissue. This forms a very compact and elastic cushion for supporting the weight of the body.

Smallness of these members has been during all modern times considered a mark of beauty. There seems to be no

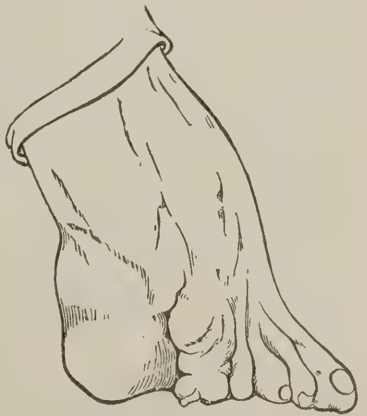

FIG. 2116.—Deformed Foot of a Chinese Lady of Rank. (Langer.)

good reason for this, except that it indicates a general delicacy of construction of the body and can hardly be associated with habits of labor. Structurally a small foot would seem to be an ineffective organ. The Chinese women of rank are, as is well known, so treated in infancy that the foot has no opportunity to grow, and soon becomes misshapen, as shown in Fig. 2116, reduced from a photograph by Welcker. The operation commences usually in the second year of the child's life, and consists in turning the toes under the sole and confining them there by bandaging. The procedure is said to be quite painful, and sometimes fatal to delicate children. If the parents belong to a class in which labor will be required of the child, nothing further is done, and the foot, though deformed, can still be used for walking. If they are wealthy, the deformity is carried further by so bandaging the foot that the great toe approaches the heel as nearly as possible. As to the motive for this strange custom, it seems probable that it originated in an attempt to increase the value of the female as an object of sexual appetite. As the woman can move about but little, a greater deposit of fat is found on the mons veneris, and the nymphæ are thickened. Besides this, it is said these deformed feet are kept carefully covered, because they resemble in appearance the vulva. Only prostitutes display their feet, and for the purpose of enticing customers (Stricker[15]). Fig. 2117 shows the skeleton of such a malformation. *Frank Baker.*

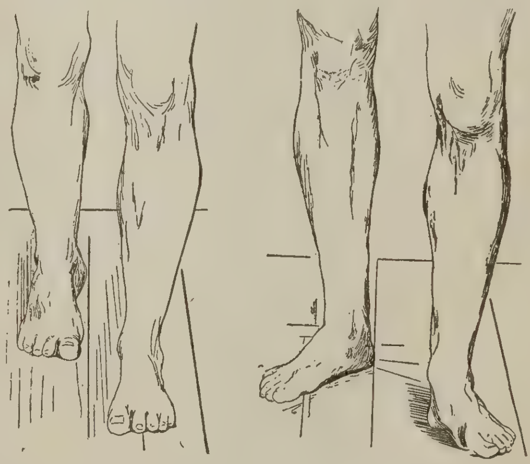
FOOT-AND-MOUTH DISEASE. See *Hoof-and-Mouth-Disease.*

FOOT, DISABILITIES OF.—I. THE WEAK FOOT. (Synonyms: Splay foot; flat foot.) The most common and by far the most important of the disabilities of the foot is the so-called flat foot. This affection, although so common, is still very imperfectly understood and in order to make its etiology, and the principles that should govern its treatment, clear, one must contrast the appearance and the functional ability of such a disabled foot with those of the normal member.

The foot is supported by ligaments, by the muscles, and by the strong plantar fascia that covers in the sole. When it is in active use it is in great part supported by the muscles, but when it serves as a passive support, as in standing, the ligaments bear the greater part of the strain, and its normal elasticity allows the bearing surface to expand slightly as the arches are slightly depressed. It must not be understood, however, that the longitudinal arch is simply flattened by direct pressure and by elongation of elastic ligaments and fascia. Ligaments and fascia are not elastic and they are not, in the normal foot, overstretched. The change in contour is the effect of normal motion in the joints of the foot, by which it is placed in the most favorable attitude for weight bearing without muscular exertion.

Of the changes of contour that distinguish the foot used as a passive support from the one that bears no weight, the most significant is the obliteration of the outward curve of its internal border. This change is due to the fact that the astragalus, bearing the leg, rotates inward and downward on the os calcis until it is checked by the resistance of the ligaments and by the interlocking of the bones. The head of the astragalus thus becomes slightly prominent; the inner border of the foot is depressed, and an attitude is attained in which the weight of the body may be supported with but slight muscular exertion. This position of the foot is one of a series of similar changes in the relation of the bones of the lower extremity, which are instinctively assumed when the limb is placed in the so-called attitude of rest.

The second function of the foot is as a lever to raise and to propel the body. The calf muscles supply the power and the heads of the metatarsal bones serve as the fulcrum on which the weight is lifted. When the foot is used as a lever it should be held in such relation to the leg that the line of weight, passing downward through the centre of the knee and ankle joints, is continued over the second toe or practically the centre of the foot. As the body is lifted over the fulcrum, the fore foot is turned inward in its relation to the leg or, more properly speaking, the leg is turned outward, because the inner side of the fulcrum, formed by the first metatarsal bone, is longer than its outer side. Thus the strain is directed toward the outer and stronger side of the foot (Fig. 2118, *A*).



A. *B.*

FIG. 2118.—*A*, The Proper Attitude in Activity, Illustrating the Adduction of the Fore Foot. *B*, The Improper Attitude of Outward Rotation of the Feet.

In the proper walk, which is the best illustration of the leverage function, the feet should be held practically parallel to one another, so that the line of strain may fall through the centre of the foot. As one foot is advanced it first bears weight momentarily on the heel, then upon its outer border; the heel is then raised and the body is lifted over the toes, the great toe giving the final impulse, so that if the walker is looked at from behind, he appears to be in-toeing at the termination of each step. Thus, during the walk, there is an alternation of postures, and the foot, under muscular control, assumes the attitudes most opposed to that of passive support.

The alternation of postures and the leverage action of the foot are by no means necessary to simple progression; for example, both feet might be fixed in plaster bandages yet walking would be possible just as it is possible on two wooden legs. Indeed an approximation to such a manner of walking is often seen, in which the passive attitude persists, leverage and its attendant motions being absent. Such a walk is necessarily jarring and ungraceful, and if it is not the result of weakness and deformity it predisposes to them because of the disuse of the proper function of the foot.

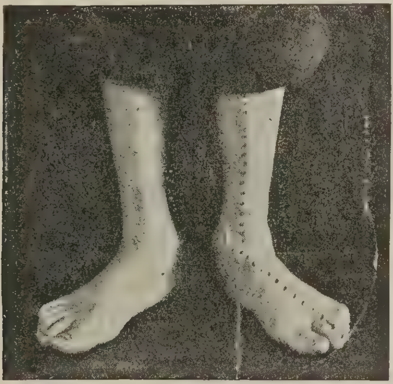


FIG. 2119.—Typical Weak Foot of Moderate Degree, Illustrating the Component Elements of Abduction and Depression of the Arch.

One of the most common causes of interference with the leverage function is the custom of turning the feet outward. Outward rotation of the feet is normal in the passive attitude of weight bearing, because it locks the joints and throws the strain upon the ligaments to relieve the muscles (Fig. 2118). On this very account it is the improper attitude for activity because the strain falls upon the inner border of the foot or to the inner side of the fulcrum, making the proper exercise of muscular power, and alternation of postures, impossible. Thus it will appear that a persistence of the passive attitude, or an approximation to it, is abnormal when the foot is in active use.

The persistence of an improper posture may be simply a habit, but it is evident that if an individual were overweighted by a heavy burden he could not walk with an elastic step, nor could he, if his muscular power were insufficient for normal activity, nor if the structure of the foot were weak, nor if active movements caused pain. In any one of these instances the passive attitude would be assumed habitually and the foot would approximate in appearance, to a greater or less degree, the so-called flat foot which is merely an abnormal persistence, and an exaggeration of, the attitude of rest.

If one contrasts the appearance of the foot in activity, under the control of, and supported by, the muscles, with one that is inactively supporting weight, he will appreciate the distinction between activity (strength) and passivity (weakness). If then the foot habitually assumes the passive attitude it may be properly called a weak foot, because it is weak in the sense that it is in danger of progressive deformity and because the sensation of weakness is the earliest and most constant symptom. Many weak feet, in the early stage at least, would not be recognized as deformed (flat) feet. Flat foot is therefore a misnomer, and it is an especially unfortunate term, in that it calls attention to deformity rather than to disability. The term weak foot will be used therefore to include all varieties of disability of the foot which are characterized by the habitual attitude of inactivity, of which the more advanced types might be properly described as flat feet.

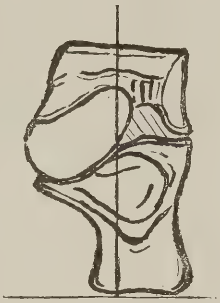

FIG. 2120.—The Normal Relation of the Astragalus to the Os Calcis.

The Anatomy of the Weak Foot.—As has been stated, a persistence of the attitude of rest or inactivity is characteristic of the weak foot. This attitude in which the weight falls upon its inner border is sometimes called pronation or eversion of the foot, and, when at all marked, it might be described properly as valgus. This latter term is, however, usually associated with more advanced or fixed deformity (talipes) and it is therefore rarely applied to the disability under consideration.

One may analyze the attitude and the deformity of the weak foot somewhat as follows. 1. The leg is displaced inward so that the weight falls upon the inner side of the foot. 2. The leg is rotated inward so that a line drawn through its centre prolonged from the crest of the tibia, instead of falling over the second toe, now points inside the great toe, or even over the centre of the internal border of the foot (Fig. 2119).

It has been stated that under normal conditions, in the act of passive weight bearing, the astragalus rotates downward and inward upon the os calcis, depressing its anterior and internal border until the movement is checked by the strong ligaments connecting the bones (the calcaneo-scaphoid, the deltoid, and the interosseus); in other words, the leg has a tendency to slip downward and inward from off the foot. In the weak foot this inclination has become an accomplished fact, for the normal movement has become so exaggerated by the distention of the ligaments and by the weakness of the supporting muscles that a partial dislocation has taken place (Figs. 2120, 2121). The astragalus has rotated and slipped far to the inner side of its normal position and is in an attitude of exaggerated rotation and moderate plantar flexion, so that its head can be plainly felt on the internal border of the foot. The anterior extremity of the os calcis is depressed and turned slightly inward and its internal border is lowered. The scaphoid bone is lowered together with the head of the astragalus, although to a less degree, and has been forced farther away from the os calcis, and with it the entire border of the foot is depressed also. Thus the depression of the arch, the third element in the deformity, is always accompanied by a bulging inward of the inner side of the foot. The foot is, as it were, broken in the centre, the posterior division having turned inward and downward; that is, the astragalus has rotated inward and downward to an extreme degree and has slipped from off the os calcis. The latter bone, although forced outward in its relation to the astragalus, still turns inward slightly, while the fore foot in its relation to the leg and to the posterior divisions of the tarsus is greatly abducted. The dislocation may be so extreme that the entire sole of the foot rests upon the ground, and a callus even may be found at the point that usually represents the high-

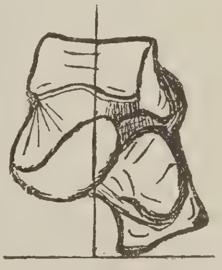

FIG. 2121.—The Relation of the Astragalus to the Os Calcis in the Confirmed Weak Foot.

est point of the arch, which now supports the greatest burden.

In this change of relation between the bones, the arched part of the foot, or waist, appears much broader than normal, even broader than the front of the foot; the heel projects, the external malleolus is depressed and carried forward by the rotation of the leg and is much less prominent than normal; the internal malleolus is more prominent and with the astragalus it overhangs the bearing surface of the sole. The foot, considered as a mechanism, is twisted and out of gear, its motion is therefore very much restricted. It is manifestly impossible for the patient to adduct the fore foot, that is, to turn it inward about the head of the misplaced astragalus. Plantar flexion is also much limited because of the permanent position of adduction and plantar flexion that the astragalus has assumed. Dorsal flexion, on the other hand, may appear to be abnormally free, because the fore foot is abducted and slightly dorsiflexed upon the head of the astragalus. When, however, the displacement is reduced adaptive shortening of the calf muscle becomes evident in many instances.

Supposing the foot to have been normal before it began to break down, it is apparent that such deformity could not have been acquired without marked changes in its internal structure. In a general way these changes have been indicated by the description; the ligaments on the internal aspect of the foot and of the ankle joint are weak and distended; the unused portion of the articular surfaces of the joints may be denuded of cartilage, while new facets may have formed to accommodate the changed relation of the bones—as, for example, at the junction of the external malleolus with the os calcis. Evidence of injury and of abnormal pressure may be found in thickened periosteum and in formation of osteophytes, while the internal structure of the bones has been changed as well, to adapt itself to the new conditions. The muscles which are no longer used in the leverage function, the plantar flexors and adductors, have become atrophied—a change that is made evident by the shrunken calf. The muscles on the inner border of the foot have been overstretched, while those on the upper and outer part have become shortened and contracted. Such a foot represents an extreme, it may be an irremediable, degree of deformity. The machine is completely broken down; it can no longer perform its proper function; it is even less efficient than the wooden foot, because use is attended by discomfort.

The disability and its accompanying deformity are found in every grade of severity. Pain begins when, the support of the muscles being insufficient, the ligaments begin to give way under strain, allowing the bones to occupy an abnormal relation to one another. It is evident therefore that the individual in whose foot the arch is accentuated and whose ligaments are firm, may suffer from the symptoms of strain long before the arch has been depressed or deformity has become apparent; also that the lateral inward bulging, characteristic of advancing deformity, must in such a case be very great before the astragalus can reach the ground and the arch be completely flattened. On the other hand, if the individual has inherited a low arch, or if, as the result of weakness in early life, the arch has been depressed or has never developed, accommodative changes in the bones will have taken place during growth, so that the flat foot of this type will not be attended with as much change in its relation to the leg, and therefore disturbance of function, as in the typical case that has been described. This latter class of cases exemplifies the popular type of flat foot that may exist without pain or disability.

It is very evident that the lowering of the arch is a secondary element of the deformity and that the popular significance of flat foot, as an inherited and irremediable weakness, is most misleading. It is misleading also in that in the most painful type of weak foot there may be practically no lowering of the arch, as shown by an imprint of the sole, while the actual flat foot may exist without symptoms.

As has been stated, there is one feature common to every grade of the so-called flat foot: the foot regarded as a machine is weak, as compared with the normal standard—weak because of the persistence of the attitude of rest and relaxation, as contrasted with that of activity and strength, and weak because the proper relation between the power and the fulcrum is changed. Even the inherited flat foot, or the flat foot which has never caused symptoms, is weak, in the sense that in use it lacks the spring and elasticity characteristic of the perfect machine.

The term weak foot may be used then to indicate all types of the disability. In one weak foot the arch has disappeared; in another weak foot the arch is of normal depth, but the foot is abducted or pronated in its relation to the leg. In one case the deformity appears only under weight; in another the foot is held rigidly in the deformed position by muscular spasm. In one instance there may be great deformity without pain; and in another disabling weakness and pain without deformity. In one case the foot is unable to perform its functions because of its inherent weakness, in another the disability may be due simply to the improper use of a normal structure. In all cases, however, disability as exemplified by the symptoms of pain and weakness is due to a disproportion between the burden or strain that is put upon the foot and the ability of the mechanism to perform this task.

This theory accounts for the fact that the weak foot, although very common in childhood, does not, as a rule, cause discomfort until adolescence, when the weight and strain put upon it are increased. It explains also why the foot which may be fairly normal in structure breaks down more often in later adolescence or early adult life when the continuous strain of regular occupation is undertaken. It is evident that an occupation requiring the long continuance of the passive attitude,—that of waiters, cooks, and bartenders for example,—exposes the feet to greater strain than one which permits alternation of postures, and that the symptoms are likely to be more severe and the deformity to be greater among those who are obliged to labor than among those who are not. Overwork or strain, of occupation or otherwise, may be temporarily disproportionate because of local or general weakness, as for example during pregnancy or after recovery from exhausting disease or because of local injury or disease of the foot itself or simply because of the strain of more constant use. On this theory one may very easily explain what has proved such a stumbling block for students, viz., that there is no constant relation between the degree of deformity and the severity of the symptoms; for although all flat feet are weak feet, yet all weak feet are not necessarily painful feet. Pain is not caused because the foot is flat; it is a symptom of progressive deformity, of strain and injury to the joints; it shows that the foot is becoming flat; it is a symptom of the injury that the weak or flat foot has received. The progress of the deformity may be temporarily or permanently checked at any stage, either by a removal of the exciting cause or because of the resistance of the tissues; then the pain ceases. On the other hand, this stability may not be attained until the entire sole of the foot rests upon the ground, and even then the patient may suffer from discomfort and pain.

This conception of the foot as a machine, of which grades of efficiency may be recognized, has a great advantage, since it enables one to perceive wherein a foot is weak even though the weakness causes no symptoms whatever. Thus one may prevent deformity by avoiding the extra strain that improper attitudes entail, and by strengthening the muscles on whose ability its integrity depends. Finally, from this standpoint one may better appreciate the etiological importance of improper shoes, in this as in practically all of the disabilities to which the foot is liable.

As has been stated, the symptoms of the weak foot, although similar in type, vary in severity according to the local condition and the disturbance of function, the work to be performed, and the susceptibility of the individual.

Symptoms.—The most characteristic symptom is the sensation of weakness. The patient begins to recognize as familiar, a feeling of discomfort, of tire and strain about the inner side of the foot and ankle, sometimes after long standing, a dull ache in the calf of the leg, or pain at the knee, hip, or in the lumbar region, symptoms more common in women than in men; or, after overexertion, a momentary sharp pain radiating from the point of weakness; thus the patient often dates the history of his trouble from a long walk. After a time the patient may become aware that he is accommodating his habits to his feet; he rides when he once walked; he sits when he once stood; he no longer runs up or down stairs or jumps off the street car. His feet have lost their spring as he expresses it, which means that the foot is no longer supported and controlled by muscular activity and is no longer used as a lever. Not infrequently, early symptoms are pain and sensitiveness at the centre of the heel, explained in part by the jarring heel walk which is always assumed when the foot is weak, and in part by the strain upon the attachments of the deep plantar ligaments. The patient may complain that he cannot buy comfortable shoes; the reason is that the weak foot under use is changed in shape, so that the shoe that was comfortable in the morning compresses the foot painfully at night. Thus increasing discomfort, due in part to corns, bunions, painful great toe joints, and deformities of the toes, is experienced. Coldness and numbness, congestion and increased perspiration, caused by the impaired circulation and weakness, are common symptoms in this class of cases. Actual pain is, as a rule, felt only when the foot is in use. It ceases under temporary rest or relief from disproportionate work, and it is this remittence of symptoms, together with the fact that the discomfort is usually more marked in damp weather, that leads so often to the mistaken diagnosis of rheumatism. The foot is weak and vulnerable; the patient recognizes the fact that he has what he speaks of as a weak ankle, or sprain, or gout, or rheumatism; but if he has accommodated himself to the weakness, but little discomfort is experienced. In many instances such relief or accommodation is impossible, and it is therefore among the working class that one oftener sees the rapid development of the disability and deformity. The range of motion becomes more and more restricted; the habitual attitude, at first exaggerated to deformity only under the influence of the weight of the body, becomes a permanent displacement. The weak and distorted foot is subjected to constant injury, to what may be likened to a succession of slight sprains; thus local congestion, swelling, and sensitiveness may appear together with muscular spasm, rigidity, and pain on passive motion. Because of the rigidity of the foot, which has lost the power to accommodate itself to inequalities of the surface, the patient dreads to cross a rough pavement, for every misstep is a source of pain. Another characteristic symptom is the discomfort felt on changing from a position of rest to activity. This, although it is usually present in slight degree at every stage, now becomes more prominent. The patient after sitting, or on rising in the morning, is unable to walk, but staggers and limps for several minutes, a symptom explained by the fact that when the foot is at rest there is a partial reposition of the displaced bones, which must be again forced into the deformed posture that has become habitual. The local tenderness and muscular spasm are increased by use, so that the patient may have difficulty in removing the shoe at night, and the symptoms relieved by the rest of Sunday become progressively worse during the week.

The pain and discomfort are more general in character, and are often referred to the dorsum of the foot, representing muscular rigidity and tension to the irritated plantar fascia, and to the outer side of the ankle, where the external malleolus is grinding out a facet in the projecting os calcis. The patient may now complain of discomfort in the feet and of cramps in the legs, even when in bed, and the appearance of weakness, awkwardness, and depression of spirits may be so noticeable that the case is sometimes mistaken for serious disease of the nervous system.

The appearance of such a foot has already been described, and the effect of the deformity on its function should be evident. The gait is slouchy and cloddy; the feet are simply pushed by one another in the attitude of eversion, the knees are slightly flexed and the weight is borne entirely upon the posterior segment of the foot. The muscles have atrophied, the foot is cold and congested from its continual inactivity, and it usually is bathed in perspiration. A certain range of motion remains at the ankle joint, but adduction is absolutely restricted by the shortened and spasmodically contracted muscles on the outer and upper surface. This type represents of course only the severe variety that is more likely to be seen in hospital than in private practice; and it would seem, were it not for the evidence to the contrary, which the histories of the patients present, that the nature of the trouble must be recognized at a glance, although in the milder and earlier cases the diagnosis is not always so easily made.

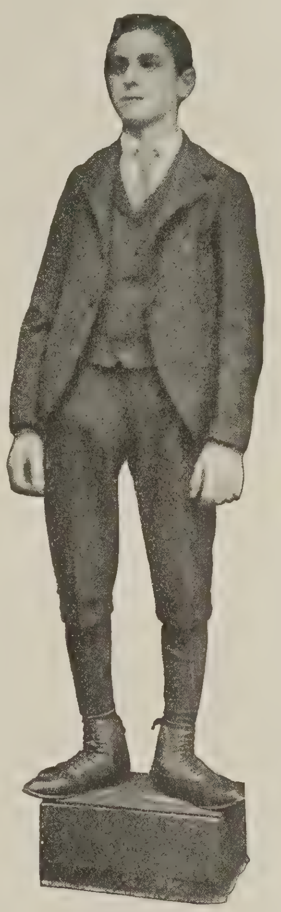

FIG. 2122.—Extreme Deformity in Adolescence.

Diagnosis.—In all cases in which weakness of the foot is suspected, a thorough and orderly examination should be made, not only of its appearance, but also of its functional ability and of the manner in which it is used. Such an examination is not merely for the purpose of confirming a diagnosis which is usually evident on inspection, but rather that the amount and character of the temporary or permanent changes in structure may be estimated.

Attitudes.—One begins the examination by noting the manner of standing and walking. The heel walk, the exaggerated turning out of the feet, the slouchy gait in which the leg is never completely extended, in which the power of the calf muscle is not applied and in which the essential postures of the foot are disused, are all elements of weakness that should be corrected whether they cause symptoms or not. The distribution of the weight of the body and the habitual use of the foot are often made evident by examining the worn shoe. If it is bulged inward at the arch or worn away on the inner side of the sole, it shows weakness. The same observations are then made on the bare feet, particular attention being paid to the line of strain or leverage. Thus, a line drawn down the crest of the tibia from the centre of the patella continued over the foot, should meet the interval between the second and third toes; if it falls over or inside the great toe, it shows that the foot is working at a disadvantage.

The contour of the foot should then be examined. Its internal border should curve slightly outward, so that if the feet are placed side by side with the toes and heels in apposition, a slight interval remains between the arches;

if this slight concavity is replaced by a noticeable convexity when weight is borne, the foot is weak. This change in contour is the earliest and sometimes the only evidence of deformity. The arch of the foot properly protected by the muscles and by a proper attitude, sinks but slightly under weight; there is a slight elasticity only, as the strain is thrown more to the inner side of the median line, and if the depression is marked it shows weakness.

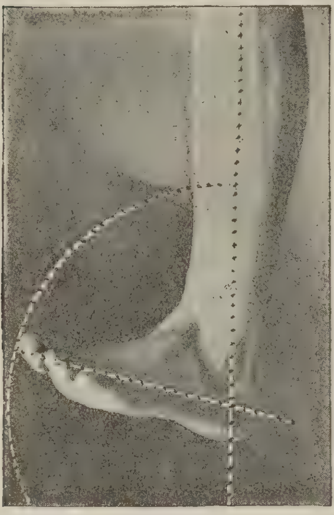

FIG. 2123.—Voluntary Dorsal Flexion.

Bearing Surface.—The exact amount of bearing surface may be shown by an imprint upon carbon paper or by smearing the sole with vaseline; then as the patient stands upon a sheet of white paper the outline of the foot should be traced, so that the relative size of the imprint to that of the foot may be shown and compared with the normal standard.

The Range of Motion.—The range of motion is next to be tested, for its limitation is one of the earliest signs of disuse of function and weakness. This range of motion varies somewhat within normal limits; it is usually greater in childhood than in adult life, greater in the slender than in the massive foot, and greater in the foot used properly than in one that is not. The first test is applied to simple dorsal and plantar flexion; the leg must be fully extended at the knee, the line of strain must be in its normal relation so that the foot is neither adducted nor abducted, and the observation must be made upon its outer border. The patient should be able to flex the foot from ten to twenty degrees less than the right angle, and to extend it from forty to fifty degrees beyond the right angle, the range of motion being from fifty to sixty degrees.

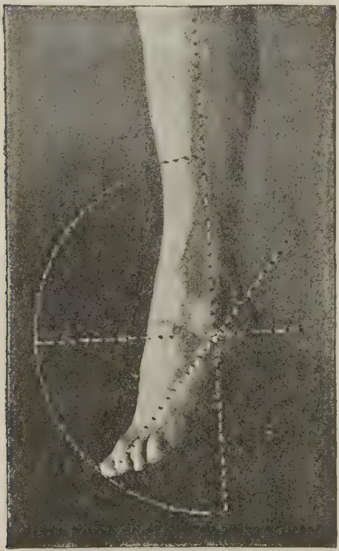

FIG. 2124.—Voluntary Plantar Flexion.

By far the most important test, however, is that of adduction or inversion of the foot, the test of the medio-tarsal and subastragaloid joints, a motion in which the os calcis is drawn forward and inward under the astragalus, as the fore foot is flexed about its head. With the leg extended as before, the foot is turned inward as far as possible. The elevation of its inner border (supination) and the turning in of the heel are shown in the accompanying figure. The actual range of adduction is somewhat difficult to measure, but it is about thirty degrees (Fig. 2125). Even the mild and early cases of weak foot usually show some limitation of this most important motion, and in many instances it is completely lost, the patient turning the entire leg in the effort to adduct the foot. The less important range of abduction may then be tested; normally it is about half that of adduction. It may be noted that the range of supination or inversion of the sole is nearly twice as great as that of pronation or eversion of the sole; in other words, the internal border of the foot can be raised twice as far from the floor as can the external border.

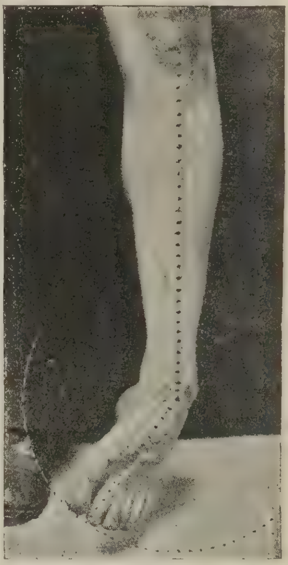

FIG. 2125.—Voluntary Adduction.

The range of passive motion is then tested. That of dorsal flexion is from five to ten degrees beyond that of voluntary motion, while passive extension, so far as it applies to the ankle joint, is about the same as the voluntary, although the fore foot may be still farther bent downward at the medio-tarsal joint. The limits of passive adduction and abduction are considerably beyond those of the voluntary range.

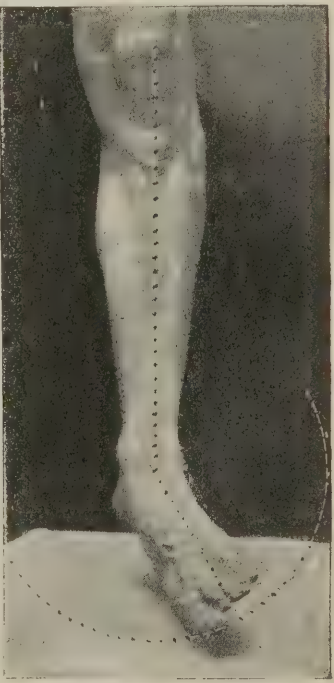

FIG. 2126.—Voluntary Abduction.

The test of passive motion serves several purposes; contrasted with the range of voluntary motion it shows the habitual use of the foot, since the motion least used is most limited. It also makes evident the slight restriction of motion and the presence of local tenderness, which, even in early cases, are usually present. Thus, if pressure be made just in front of and below the internal malleolus, at the astragalo-scaphoid junction, and if at the same time the foot be suddenly adducted, the patient will complain of pain at the point of pressure and of a feeling of constriction and tension about the dorsum of the foot, before the normal limit of motion is reached. When the foot is dorsiflexed the plantar fascia is put upon the stretch, and its condition may be noted, for a contracted and sensitive plantar fascia may cause symptoms of disability that induce, or are combined with, abduction and valgus. In other words, this mode of examination demonstrates the disability and permanent change in the machine which must be overcome before a cure can be accomplished. By it one will recognize several grades of weak foot.

Varieties of Weak Foot.—1. The normal foot improperly used, as shown by the manner of standing and walking.

2. The foot which, because of laxity of ligaments or insufficient muscular support, is forced by the weight of the body into an attitude of deformity. The foot when in use falls into an abnormal attitude of abduction in its relation to the leg, as evidenced by the inward projection of its inner border and by the overhanging internal malleolus, showing that the leg has been displaced inward on the foot. As a rule, in this class, the laxity of ligaments allows a depression of the arch, as shown by the imprint, but in other instances, although the arch seems lower because of the characteristic attitude (valgus) in which the leg as it were overhangs the foot, yet the imprint shows that there is no increase in the area of bearing surface. Indeed this may be even smaller than normal; thus an individual may suffer from so-called flat foot whose arch is in reality exaggerated.

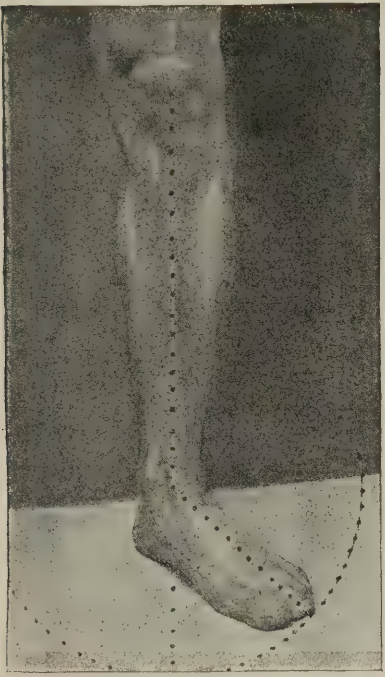

FIG. 2127.—An Attitude that Simulates Flat Foot.

3. The weak foot, which shows typical deformity under use and in which the range of voluntary motion is somewhat limited, particularly in the direction of plantar flexion and adduction. In this class forced motion causes discomfort and pain, showing a certain permanent accommodative change in structure which is not apparent when the foot is not in use. In these slighter grades of disability, the improper use of the foot, the loss of active leverage ("spring") is very evident when the patient walks.

4. The foot which presents typical and permanent deformity, whether it is in use or not, and in which the range of both voluntary and passive motion is much restricted.

This limitation of motion is an adaptation of structure to the habitual functional use and to the deformity. Such changes are first apparent in the muscles and ligaments; in more advanced cases, the articular surfaces of the bones are altered to accommodate the habitual subluxation. Added to this underlying limitation of motion there is usually a certain amount of muscular spasm, which varies in degree with the local congestion, irritation, and inflammation of the joints and tissues. In the quiescent weak foot it may be absent, but on renewed injury or overwork of the weak structure it again appears. It depends also upon the irritable condition of the overworked and contracted abductor muscles, practically the only group that retains functional power. Thus the spasm, as has been stated in describing the severe and painful type of weak foot, is greater after the day's use and relaxes somewhat during the night. The degree of muscular spasm and rigidity varies with the intensity of the symptoms. It is often greater in the early stage of the disability than in the cases in which the deformity is of long duration.

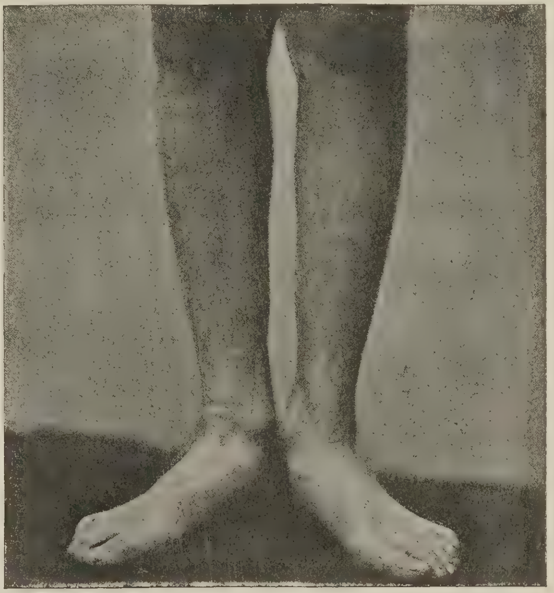

FIG. 2128.—Weak Foot in Childhood showing Habitual Abduction, without Depression of the Arch.

Two Extreme Types of Weak Foot.—1. Persistent Abduction.—In one type of rigid foot, the foot is twisted outward and upward. It may be pronated to such an extent that practically the weight is borne upon the heel and ball of the great toe. In such instances the astrag-

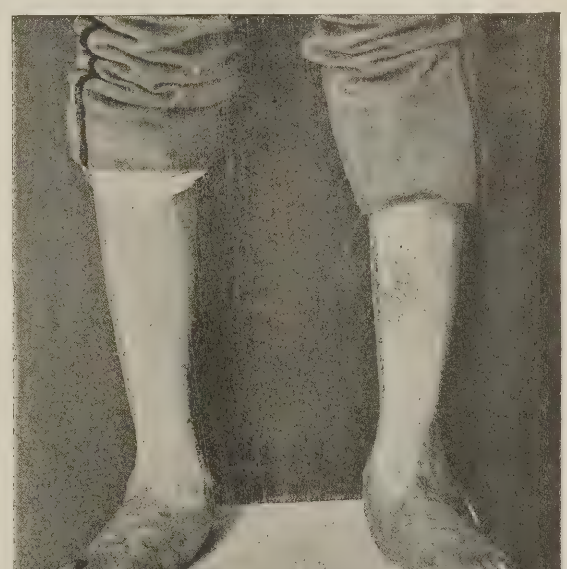

FIG. 2129.—Extreme Deformity in Adolescence; Abduction and Complete Sinking of the Arch.

alus, although rotated inward upon the pronated os calcis, is, of course, not plantar-flexed nor is the anterior extremity of the os calcis depressed. The entire foot is simply held in an attitude of extreme abduction and slight dorsal flexion, by the spasm and contraction of the flexors and abductors, so that the leg must be bent at the knee and inclined forward to bring the sole to the ground. Such extreme cases are uncommon. They are often the direct result of injury ("chronic sprain"), and when the deformity is reduced the arch will be found to be exaggerated in depth. Less extreme types of this class are often seen and they serve to emphasize the statement that the most important disability of the weak foot is due to the change from the normal relation between the leg and the foot (valgus) and not to the depression of the arch, (planus) which is, in most instances, a secondary deformity.

2. Pes Planus.—As has been stated already and as is well known, there is a type of painless deformity sometimes called pes planus. To this type the term flat foot may be properly applied because the flatness of the foot is more noticeable than the other components of the deformity that have been described. This class is probably the effect of inherited laxity of ligaments or of rachitis or other form of acquired weakness in early life, so that a normal arch was never present. Such a foot controlled by efficient muscles may be strong and serviceable, but it is nevertheless deformed, and it is doubtful if its possessor ever could attain the grace and elasticity of gait possible under normal conditions. It is said also that a low arch is normal in certain races, for example the negro, but it is certain that the American negro is not exempt from the pain and disability incidental to the broken-down foot, whether his arch was originally low or not.

It is evident that the breaking down of a properly shaped foot, provided with normal ligaments, must be attended by greater pain and disability than of one in which the arch was originally low and of which the ligaments were weak, because it is during the progression of the deformity, and particularly in its early stages, that such symptoms are most prominent. When the bones of the arch rest upon the ground or when final stability has become assured, pain may cease, and permanent accommodation to the new condition may increase the ability of the deformed member. Such an adaptation might be quickly accomplished in the foot originally flat, while in the other instance the symptoms, although remitting from time to time, might continue during the life of the sufferer.

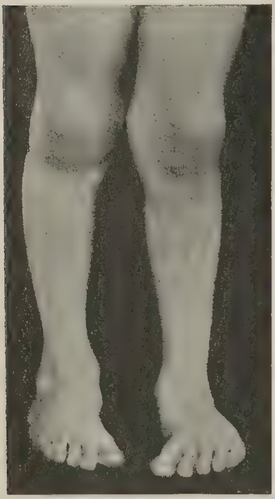

FIG. 2130.—Adduction of the Fore Foot Combined with Valgus; an uncommon type.

WEAK FOOT IN CHILDHOOD.—There can be no doubt that in many instances the origin of the weak foot may be traced to early childhood. Certainly, deformities and improper attitudes are very common at this period and it is much more likely that they are ingrown than outgrown. Actual pain from the weak foot is unusual at this age. The child may complain of fatigue and may be weak and awkward, but it is usually because of the very evident deformity, rather than because of symptoms, that advice is asked. In these cases, as in every case, the habitual attitudes and use of the feet are of the first importance.

One of the most frequent of the improper postures is that of exaggerated outward rotation of the feet, which is not only an ungraceful attitude, but a direct cause of weakness as well. The opposite attitude of inward rotation of the feet, the so-called "pigeon-toed" walk, is most offensive to relatives and friends, and it is for correction of the attitude that the child may be brought for treatment. The attitude is, in many instances, a sign of the weak foot, for on examination the bulging on the inner side, the inward rotation of the leg in its relation to the foot, and the flattened arch, show very plainly that it is the foot and not the attitude that requires treatment; in fact the attitude is, in this class of cases, really a safeguard against increasing deformity and it will correct itself when its cause is removed. Particular emphasis is laid upon this point, which is very generally overlooked, because the routine treatment of the "pigeon toes" in these cases might be the cause of direct harm.

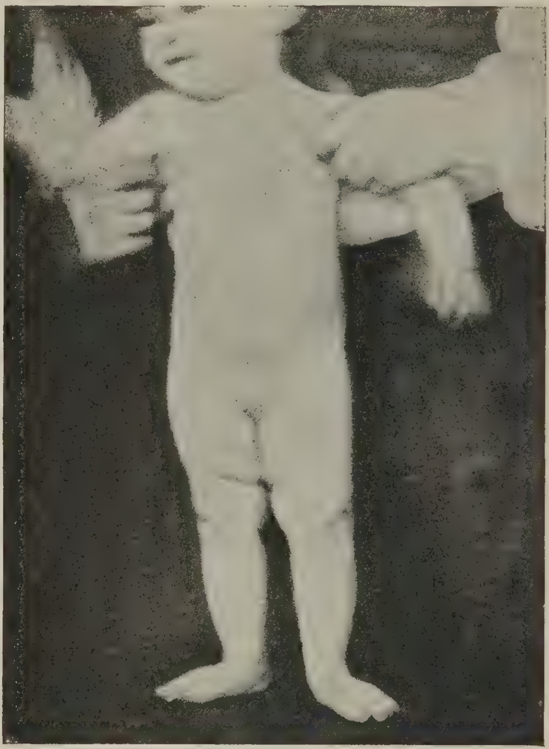

FIG. 2131.—Flat Foot in Early Childhood.

"Weak ankle" is a term popularly applied to the weak foot of childhood, in which the foot is in a position of valgus when in use, so that the shoe is worn away on its inner side. Weak ankles are very common in very young children and are often one of the results of general weakness due to defective assimilation. At this age the foot is, in addition, usually flat, although in the valgus or weak ankle of later years the arch is often normal in outline.

In older children prominent or "outgrown" joints often attract the mother's attention; the internal malleoli appear prominent because of the position of valgus, or, because of the eversion of the feet, the malleoli may strike against one another, "interfere," and thus there may be an actual hypertrophy of the projecting bones from local irritation.

Another type is the long slender foot in which the scaphoid bone is prominent because of the strain and pressure put upon it by the improper attitudes; its position is often shown by the point of wear in the leather of the shoe. In the weak foot of childhood, although restriction of voluntary and passive motion may be present, there are, as a rule, but little local tenderness and muscular spasm, and as has been stated, but little pain. Thus it differs greatly from the adult type, the reason being that the weak foot in childhood is not subjected to the strain of constant occupation or to the burden of the increased weight of the body. There is another important difference also: the foot in the adult is obliged to bear a greater burden than any other part, and although fairly normal in structure it may be overstrained. Thus in many instances the weakness of the foot may be the only disability. In childhood, on the other hand, a weak foot is very often a local indication of general weakness and loss of tone.

The direct effects of the weak and painful foot have been described in detail. It must be borne in mind that the feet are the foundation of the body, and that an insecure foundation affects the entire mechanism. General functional weakness and awkwardness, the flat chest, round shoulders or other curvatures of the spine, are often observed as accompaniments or effects of weak feet. As a rule, the systematic treatment of any form of postural weakness in childhood must include the treatment of the feet as well.

Recapitulation.—The disability and deformity of the weak or so-called flat foot are caused by disproportion between the strength of the foot and the weight and strain to which it is subjected.

The foot may be weakened by injury or disease; it may be overburdened by the body weight, or overstrained by laborious occupation, or the broken-down foot may be simply one indication of general bodily weakness. It is unnecessary to enumerate all the various factors that singly or combined lead to this disability.

It may be stated, however, that the painful weak foot as seen in adult life is in many, or most, instances the only evidence of weakness. The most constant of the predisposing causes are improper shoes, and the mechanical disadvantage to which the foot is subjected by the assumption of improper attitudes.

All weak or flat feet are mechanically weak, but all weak feet are by no means painful feet. Pain, the symptom of overstrain or injury, bears no definite relation to the degree of deformity.

In certain instances, exaggeration of the arch may be combined with persistent abduction of the foot; in others, the flattening of the arch may be the most noticeable deformity, but in most cases, the two are combined in varying degree. And as each deformity is an evidence of weakness, it seems hardly necessary to make a radical distinction between the two.

Treatment.—The principles of the treatment which leads to the permanent cure of the weak foot are very simple, but their application varies somewhat according to the grade and duration of the disability. The object of treatment is so to change the weak foot that it may conform, not only in contour but in habitual attitudes and in power of voluntary motion, to those of the normal foot, because cure is impossible until function is regained. The first step must be, therefore, to make passive motion free and painless to the normal limit. In other words, the obstructions to the motion of the machine must be removed before the power can be properly applied; for normal function is manifestly impossible, while motion is restrained by deformity or pain or by adhesions or contractions.

The weak foot, because of inefficient ligaments and muscles unable to hold itself in proper position, must be supported, in many instances, until regenerative changes have taken place in its structure. Such support is necessary to retain the joints in proper position, and to hold the weight and strain in normal relation to the foot. When these essentials are provided, the patient may cure himself by the proper functional use of the foot, and by the avoidance of attitudes that place it at a disadvantage.

It may be well to describe first the treatment that must be applied to all classes of weak foot in which a cure is to be attempted, and which by itself is sufficient in the milder types, before calling attention to the modifications that may be necessary in special cases.

The Shoe.—In practically all cases it will be necessary to provide the patient with a proper shoe, for the shoe is usually the direct cause of the minor deformities, and the indirect cause, in many instances, of more serious disability. Indeed most of the deformities and disabilities of the foot are incidental to civilization and are confined to the shoe-wearing people.

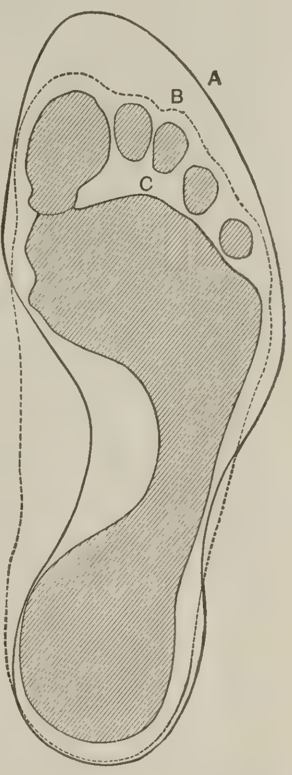

FIG. 2132.—The Proper Relation of the Sole to the Shape of the Foot. *A*, Outline of sole; *B*, outline of foot; *C*, imprint of foot.

The direct effect of the ordinary shoe is to lessen the size and balancing power of the fulcrum by cramping the toes together while the high heel throws more strain upon the arch and the ankle. Indirectly it causes deformities, corns, bunions, and the like, which serving to make active movement or leverage painful, induce the habitual assumption of the passive attitude which predisposes to deformity.

The proper shoe should contain sufficient space for the independent movements of the toes. This motion is illustrated in the walk of the barefoot child. As the weight falls on the foot the toes expand, and as the body is raised on the foot they contract. The important leverage action of the great toe and the support afforded by it to the arch of the foot have already been mentioned. The shape of the sole should correspond to the shape of the undistorted foot and the heel should be broad and low.

The prevention of distorted toes and the discomforts that result from the abuse of the foot is of great importance in childhood, but, unfortunately, little children are often seen wearing shoes of the shape usually assumed at years of discretion. In this regard, girls suffer more than boys, as women do more than men. The girl who may have worn comparatively harmless shoes until the age of ten years or thereabouts, changes suddenly to the high heel and narrow sole and the process of distortion begins, the amount of distortion and the degree of discomfort depending on the amount of work required of the foot. Wide soles without heels should be worn as long as possible by children because of the greater stability and because the high heel limits the necessity for, and therefore the use of, the entire range of motion of the foot and ankle.

A simple expedient in the treatment of the weak foot and an aid in balancing it properly, is to make the inner border of the sole and heel of the shoe slightly thicker in order to throw the weight toward the outer side of the foot. This is of especial importance in the treatment of the slighter degrees of what is known as weak ankle, but it is always of service in the treatment of any grade of weak foot.

Attitudes.—When the patient is provided with a proper shoe, his attention is called to the attitudes that protect the foot from strain. He should endeavor to hold the feet nearly parallel to one another in walking and to throw the weight as far as possible on the outer border of the sole of the shoe. The significance of the bulging on the inner side of the foot is pointed out to him and how this may be prevented by voluntarily inclining the weight to the outer side of the foot and by aiding the arch by the power of the great toe.

The importance of leverage is shown him, he is told that he must try to press down the sole of the shoe with his toes and employ the active lift of the calf muscles by fully extending the leg and raising the body on the foot from time to time. Finally, he must avoid long continuance in one position, especially the passive posture which simulates the attitude and deformity of flat foot. In short, he must be instructed in the mechanics of the foot and taught how the weak foot may be protected and strengthened.

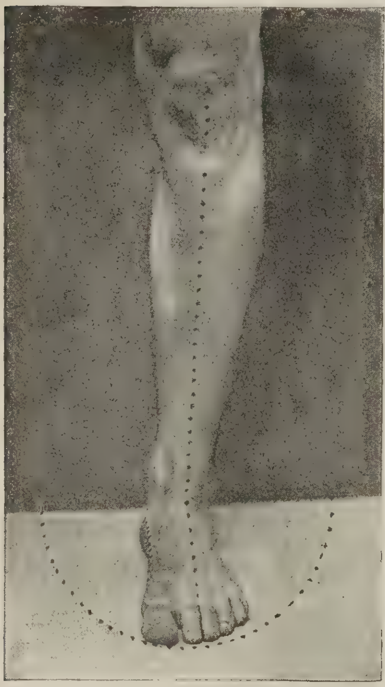

FIG. 2133.—Illustrating Voluntary Protection of the Foot from Over-Strain. (Compare with Fig. 2127.)

Exercises.—It is important also to demonstrate to the patient the normal range of motion of the foot, a range which if restricted must be regained by voluntary and passive exercise. Voluntary exercise should be devoted to strengthening the adductors and plantar flexors; thus the foot should be extended, adducted, and supinated over and over again at every opportunity. Tip-toe exercises are particularly useful. The patient holding the feet parallel to one another, or better in inward rotation, raises the body on the toes from twenty to one hundred times, the limbs being fully extended at the knees, resting in the intervals on the outer border of the feet. The best of all exercises is, however, the proper walk, in which at each step the leverage power of the foot is employed and in which it passes through the proper alternation of postures.

Treatment by massage and special gymnastic exercises is, of course, of benefit, if the patient can command it, although by no means essential to the cure.

Support.—In many instances the simple treatment that has been outlined is all that is required and the symptoms of tire and strain are quickly relieved. In the more advanced type of disability the patient is not able to prevent deformity voluntarily; consequently a support is necessary to hold the foot in proper position and to relieve discomfort. It is usually necessary in the treatment of the weak and flat foot of childhood, because one cannot command the aid of the patient.

In selecting a support for the weak foot the nature of the deformity that is to be prevented must be borne in mind. The acquired flat foot, for example, is not a direct breaking down of the arch, as is usually taught, but a lateral deviation and sinking—a compound deformity, as has already been described. Thus a brace to be efficient must hold the foot laterally as well as support the arch. In fact, as has been stated, the prevention of valgus is far more important than the direct support of the arch. The brace must not prevent the normal motions of the foot, and thus interfere with the increase of muscular strength and ability, on which ultimate cure depends.

The supports that are ordinarily employed do not fulfil the conditions; the pads and springs placed beneath the arch are intended to support it by direct pressure without regard to the lateral distortion; they are usually ill-fitting and are often of such length and shape as to splint the foot and thus prevent its motion. Leg braces which more directly control the valgus do not often hold the foot accurately, and their weight and unsightliness are fatal objections to their use in the early cases, in which prevention of subsequent deformity is of such importance.

A brace should never be applied to a deformed and rigid foot because it is not able to shape itself to the support; the spasm and rigidity must be first relieved by preliminary treatment, as will presently be described.

The Construction of the Brace.—If a brace suitable for meeting these conditions is to be constructed, it is necessary to provide the mechanic with a plaster cast of the foot, taken in the attitude in which one wishes to support it. Such a model may be easily and quickly made in the following manner:—

The Plaster Cast.—Seat the patient in a chair; in front of him place another chair of equal height; on it lay a thick pad of cotton batting and cover it with a square of cotton cloth. Put about a quart of cold water into a basin and sprinkle plaster of Paris on the surface until it does not readily sink to the bottom; then stir. When the mixture is of the consistence of very thick cream pour it upon the cloth. The patient's knee is then flexed and the outer side of the foot, previously smeared lightly with vaseline, is allowed to sink into the plaster, and the borders of the cloth being raised the plaster is pressed against the foot until rather more than half is covered. The foot should be at a right angle with the leg and the sole should be in the plane perpendicular to the seat of the chair. As soon as the plaster is hard, its upper surface is coated with vaseline and the remainder of the foot is covered with plaster; the two halves are then removed, smeared lightly with vaseline and bandaged together. The interior is dampened with soapsuds and is then filled with the plaster cream. In a few moments the plaster shell may be removed and one has a reproduction of the foot, which, when properly made, should stand upright without inclination to one side or the other. In many instances it will be of advantage to deepen in the plaster model the inner and outer segments of the arch, in order that the arch of the brace may be slightly exaggerated, especially at the heel, so that the depression of the anterior extremity of the os calcis may be prevented.

The Brace.—Upon the model, the outline of the brace is drawn as illustrated in the diagrams. The best sheet steel, 18 to 20 gauge, cut after the pattern is moulded upon it and tempered, so that, as it is applied for the purpose of preventing deformity, it may be practically unyielding to the weight of the body.

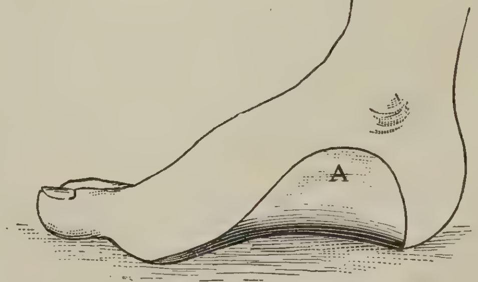

FIG. 2134.—*A*, The Astragalo-Scaphoid Junction.

It will be noted that the brace clasps the weak part of the foot and holds it well together; the broad internal upright portion covers and protects the astragalo-scaphoid junction, rising well above it. The external arm covers the calcaneo-cuboid junction and the outer aspect of the foot to a height sufficient to hold the foot securely. The sole part provides a firm, comfortable support, yet, reaching only from the centre of the heel to a point just behind the metatarso-phalangeal joint of the great toe, it does not restrain the normal motions of the foot.

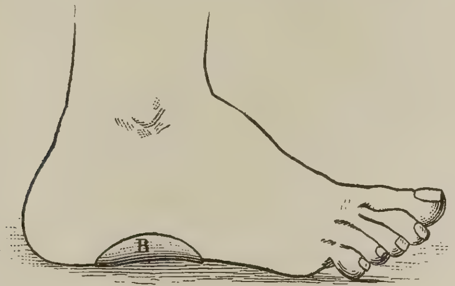

FIG. 2135.—*B*, The Calcaneo-cuboid Junction.

The brace may be nickel-plated and japanned, which makes a smooth finish, or tin-plated, which is a rather more durable covering. It may be covered with leather or an inner sole may be placed on its upper surface; but this is not usually necessary. As it is fitted to the foot it finds and holds its own place in the shoe, so that no attachment is required; thus it may be changed from one shoe to another. Not only does it hold the foot laterally and from beneath, but there is an element of suggestiveness in the slight leverage action which is very important. The patient, instructed to throw his weight upon the outer side of the foot and wearing a shoe which has been tilted in the same direction by thickening the inner border of the sole and heel, presses down the external arm and thus lifts the internal flange against the inner side of the foot, which is instinctively drawn away from the pressure and thus toward the normal contour. Thus he no longer everts the foot in walking because of the discomfort, and he is not likely to assume the passive attitude because of the suggestive lateral pressure of the support. This brace is therefore, when properly adjusted, a positive aid in the physiological cure as contrasted with the negative action of the ordinary sole plate.

The shape of the brace, in general like that of the diagram, may be modified in certain cases; for instance, the entire internal aspect of the foot may be weak and must be covered by the internal flange. In very heavy subjects the sole portion must be made larger, or other slight modifications may be necessary. If any portion of the rim of the plate causes discomfort, the edge may be turned away slightly at the point of pressure by a wrench. After a few days the patient no longer notices the presence of the brace, and as its presence in the shoe is not evident, it may be worn indefinitely. It is usually necessary to wear it for from three months to a year or longer, according to the condition of the part and the use to which the feet are put. The brace, properly made and adjusted under the proper conditions, causes no more pressure or discomfort than a well-made shoe, for its principle is quite different from that of ordinary supports that are in common use, to which this objection has been made. This brace supports the arch primarily by preventing abduction, consequently its pressure is first felt upon the lateral aspect of the foot, a pressure that the patient can relieve by improving the attitude. The brace should provide support when necessary, and at all times suggest and enforce a proper attitude; it is, however, but one of the essential factors in the general scheme of treatment.

In the treatment of children, passive movements of the foot should be carried out in all directions, but particularly in dorsal flexion and adduction to the full limit, at morning and at night, until the child has regained the normal muscular power and ability. Special gymnastics and massage are always desirable and they may be necessary in certain cases. Bicycling may be cited as one of the best, and roller skating as one of the worst, exercises for the weak foot. A year is about the time required for the cure of the weak foot in childhood, although attention to the shoes and the attitudes must be kept up indefinitely.

THE RIGID WEAK FOOT.—One may now contrast with these mild types of weakness that have been described, those cases of extreme deformity in which the symptoms are disabling and in which the foot is rigidly held in the deformed position by muscular spasm. Such cases, often considered hopeless as regards a cure or even relief, are in reality the most satisfactory from the remedial standpoint, and in no other type of painful deformity can so much be accomplished by rational treatment as in this class. The deformity must be considered as a dislocation, in which the astragalus has slipped downward and inward from off the os calcis, which in turn is tipped downward and inward and into a position of valgus. The remainder of the foot is turned outward, so that the relation of the fore foot and the leg is entirely changed; in fact the fore foot is almost entirely disused.

Corresponding to the duration of the disability, one finds the accommodative changes in the soft parts and in the bones, but such changes are by no means as marked as those recorded in the reports of autopsies which have been made in cases of advanced and irremediable deformity. In fact, by far the greater number of patients are young adults in whom the extreme deformity is of comparatively short duration, and in whom complete cure is possible.

In the treatment of such a condition, one must first reduce the dislocation and overcome the obstacles that contracted muscles and ligaments may offer to free and normal motion. Then rest must be assured to the injured and congested parts in order to relieve the patient from the pain that he has suffered so long.

Forcible Over-Correction.—By far the most effective treatment is forcible over-correction of the deformity, under anæsthesia. When the patient is under the influence of the anæsthetic the muscular spasm relaxes, and it will be seen that this accounts for about half the restriction of motion, the remainder being caused by the adaptive changes that have been mentioned. One now endeavors to overcome this residual obstruction and to assure the patient against a relapse, by fixing the foot in the position of extreme adduction and supination, the attitude directly opposed to that which has become habitual.

This is the object of forcible over-correction as the first step in the systematic repair of the disabled mechanism. Its principle must not be confounded with forcible correction carried out with the object of simply remoulding the arch of the foot, or in which the simple correction of the deformity is the object in view.

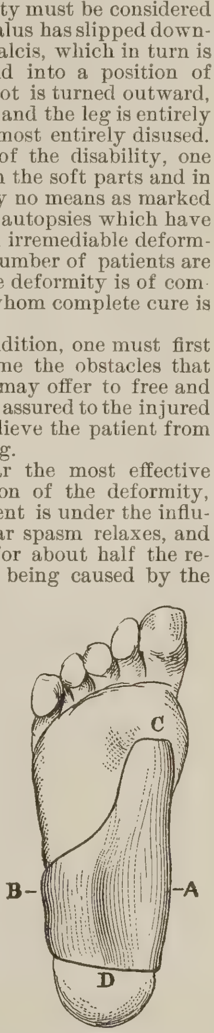

FIG. 2136.—*C*, The Metatarso-Phalangeal Joint; *D*, the centre of the heel.

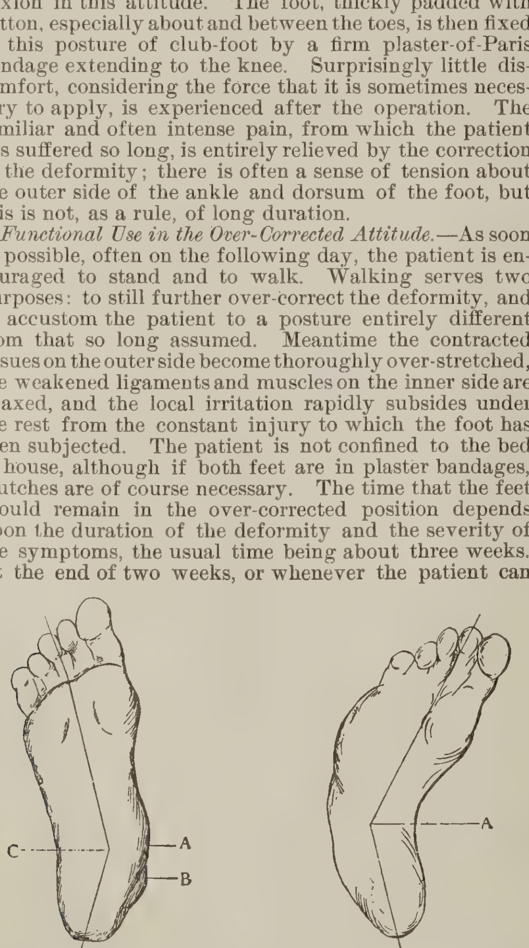
One first extends the foot forcibly, then flexes it to the normal limit, then abducts and adducts, the different motions being carried out over and over, until the rigid foot has become perfectly flexible. In cases of long standing it is often necessary to draw the patient to the end of the table so that the foot may be taken between the knees, in order to supply the required force by the thigh muscles. This forcible manipulation is accompanied by the audible breaking of adhesions, and the complete disappearance of the deformity. In certain instances it will be necessary to divide the tendo Achillis; when, for example, the range of dorsal flexion is limited by resistant accommodative shortening of the calf muscles, or when there have been very great pain and tenderness at the medio-tarsal joint, and it is desired to remove the strain of the calf muscle completely; traumatic cases come especially under this head. In other cases the peronei tendons may be divided if they offer especial resistance to adduction. Tenotomy has one great advantage: it necessitates longer fixation in the plaster bandage, and gives the patient the benefit of rest and the opportunity for prolonged after-treatment. When the passive range of motion has been regained, the foot is turned downward, then inward and upward into the position of extreme varus. By this manipulation the os calcis is drawn under the astragalus and thrown into the supinated position, and the scaphoid is flexed about and under the head of the astragalus, which is then lifted to the limit of normal flexion. The attempt is always made to bring the extreme outer border of the inverted foot up to a right angle with the leg, which is the limit of normal flexion in this attitude. The foot, thickly padded with cotton, especially about and between the toes, is then fixed in this posture of club-foot by a firm plaster-of-Paris bandage extending to the knee. Surprisingly little discomfort, considering the force that it is sometimes necessary to apply, is experienced after the operation. The familiar and often intense pain, from which the patient has suffered so long, is entirely relieved by the correction of the deformity; there is often a sense of tension about the outer side of the ankle and dorsum of the foot, but this is not, as a rule, of long duration.

Functional Use in the Over-Corrected Attitude.—As soon as possible, often on the following day, the patient is encouraged to stand and to walk. Walking serves two purposes: to still further over-correct the deformity, and to accustom the patient to a posture entirely different from that so long assumed. Meantime the contracted tissues on the outer side become thoroughly over-stretched, the weakened ligaments and muscles on the inner side are relaxed, and the local irritation rapidly subsides under the rest from the constant injury to which the foot has been subjected. The patient is not confined to the bed or house, although if both feet are in plaster bandages, crutches are of course necessary. The time that the feet should remain in the over-corrected position depends upon the duration of the deformity and the severity of the symptoms, the usual time being about three weeks. At the end of two weeks, or whenever the patient can support the weight upon the plaster bandage without a sensation of discomfort, it is removed; the foot is placed in the normal attitude and a cast is taken for the brace. Immediately after this is done the foot is returned to the club-foot position, and the plaster bandage is re-applied. When the brace is ready the plaster bandage is finally removed; the foot is now in good position, and in many instances the arch is exaggerated in depth. For the first few days, prolonged soaking in hot water or the use of the hot-air bath, with subsequent massage, at intervals during the day, will be found useful in overcoming the swelling and local tenderness that may persist. It is always insisted that a new shoe of the Waukenphast pattern shall be obtained, the sole and heel of which are raised a quarter of an inch on the inner border, to aid the action of the brace in the balancing of the weak foot. When the shoe is removed at night, the patient is instructed to turn the toes in and to bear the weight on the outer side of the foot until it has regained its strength; in other words, the deformity is never allowed to recur.



FIGS. 2137 AND 2138.—Illustrating Forcible Correction of the Deformed Foot. *C*, Medio-tarsal joint; *A*, the scaphoid bone; *B*, the internal malleolus.

Systematic Manipulation.—The systematic treatment is then begun by the surgeon and the patient, the first essential being the attainment of free and painless passive motion in all directions. These motions, which have been so long restrained by deformity, cannot be regained without effort, and during this critical stage treatment must be carried out by the surgeon himself; if he trusts to the patient or to his friends, a cure is out of the question. At least once a day the full range of motion is tested. Three motions, abduction, flexion, and extension, are usually free and painless; but the fourth, that of adduction, is almost invariably resisted by the same quality of muscular rigidity that was present before the operation. By far the most effective method of overcoming this resistance is conducted as follows. The patient being seated in a chair, the surgeon sits or stands before him. Let us suppose that the left foot is to be adducted, or, as the patients express it, twisted. The surgeon places the foot between his knees; his left hand encircles the heel, the fingers grasping the projecting os calcis and tendo Achillis; the ball of the palm lies against the medio-tarsal joint on the inner aspect of the foot; the right hand grasps the outer side of the fore foot and toes; then by steady pressure of the thigh muscles, the fore foot is forced downward and inward (adducted and supinated) over the fulcrum formed by the projecting palm which lies upon the left knee, the fingers holding the heel steadily in place. This inward twisting is at first resisted by a mixed voluntary and involuntary muscular spasm, which gradually gives way under steady pressure. When the limit of adduction has been reached the foot is firmly held until all pain has subsided. Then the patient is instructed to attempt voluntary movements while the foot is guided by the hands: in other words, the patient attempts to adduct the foot while the surgeon supplies the power, which, in all cases of this type, has been completely lost. This passive manipulation to the extreme limit of normal adduction, plantar and dorsal flexion, is continued from day to day until there is no longer a sensation of pain or tension; for as long as there is the slightest spasm or painful restriction, so long is the voluntary motion limited, cure delayed, and relapse of deformity probable. During active treatment the patient, by the use of massage, active and passive motion, is constantly working to one end, namely, to regain the lost power of voluntary adduction.

The time necessary to rest the feet, to overcome the local irritation and muscular spasm, to regain, in part at least, the range of passive motion, and to place the patient in the same position as regards a cure as that of the milder type of deformity, is from three to six weeks. Usually the patients are told that a month will be necessary, and that at the end of that time they may return to work, free from pain and from danger of relapse, and that the feet will constantly grow stronger under the work which before was too great for their strength. The time necessary to re-educate the adductor muscles in their proper function depends, in great degree, upon the intelligence and persistence of the patient. Although in after-treatment massage and special exercises are of benefit, the essentials are very simple; they are, an effective brace, a proper shoe, and the passive manipulation that has been described, until its object has been attained;

the proper walk, the best and easiest of exercises; and finally, one must force into the patient's understanding the method of protecting the weak foot by the alternation of strain and by the proper postures.

OTHER VARIETIES OF RIGID WEAK FOOT.—The foot which is fixed in the abducted position without depression of the longitudinal arch, is simply one variety of the rigid weak foot, and should be treated in the same manner.

It may be stated also that a very large proportion of the so-called chronic sprains of the ankle are of this type, and that the disability will yield very readily to treatment conducted for the purpose of restoring impaired function, in the manner that has been indicated.

There are other cases in which the deformity of flat foot is complicated by rheumatoid arthritis or chronic rheumatism, of which the evidence is seen in various joints, but in which the pain and discomfort seem to be concentrated in the feet, which are absolutely stiff and deformed. In such cases one can hardly expect a complete cure, but although the function of leverage may not be regained, still one may hope, by overcoming the deformity, to hold the weight of the body in its proper relation to the foot, so that the pain of a progressive dislocation may not be added to the pain of disease. In a number of instances, forcible correction has been employed by the writer in cases of this type, and in all the improvement in the general condition, consequently in the resistance to the disease, after the relief of the local pain and discomfort, has been very great.

Between the two classes of cases, the mild and the severe, one finds every grade of deformity. All cases in which there are marked muscular spasm, local tenderness, and swelling, require temporary rest, in many instances simply rest from functional use combined with massage; in others rest in a plaster bandage in the adducted position. In the milder and ordinary class of cases, the use of a brace and shoe will alone relieve spasm and pain, and the range of motion can usually be regained by manipulation, passive motion, and by the proper use of the foot.

Occasionally, even in childhood, one may encounter marked limitation of normal motion, particularly in dorsal flexion, not due to pain and muscular spasm but to actual shortening of muscle. This may be the accommodative shortening that is characteristic of long-standing deformity; in other instances it would appear to be the result of a slight and unnoticed neuritis or anterior poliomyelitis, which has resulted in muscular inequality. If the contraction does not yield readily to manipulation or to mechanical stretching, forcible correction, and if necessary tenotomy, should be employed in the manner already described; for whatever may be the theory of its causation, it is again emphasized that obstruction to motion in any direction must be overcome before a complete cure is possible.

Adjuncts in Treatment.—It must be apparent that in many instances the cure of the weak foot is out of the question, either because of the want of energy or opportunity on the part of the patient, or because of the local or general conditions, types familiar in out-patient practice. In such cases, raising and strengthening the inner side of the shoe by the wedge-shaped leather sole, as used by Thomas, splints the painful foot and aids in relieving the strain. If the symptoms are more acute the adhesive plaster strapping, as advocated by Cottrell and Gibney for the treatment of sprains, is often of service, although it is applied in a different manner, and with a somewhat different object in view. One end of a strip of adhesive plaster, about fifteen inches long and three inches wide, is applied to the outer side of the ankle just below the external malleolus; the foot is then adducted as far as possible and the band is drawn tightly beneath the sole and up the inner side of the arch and leg, and is stayed in this position by one or two plaster strips about the calf. Narrow plaster straps are then applied about the arch and ankle, in the figure-of-eight manner, and a bandage is applied. The object of the dressing is to aid in holding the foot in the proper position by the support and suggestiveness of the plaster, and to provide the firm compression about the arch that is always agreeable to the sufferer from weak foot. This treatment combined with the built-up shoe, and with the corrective manipulation that has been described, is often very effective in overcoming the acute and disabling symptoms of the weak and injured foot, which are, as has been stated, often the result of extra strain or injury, in other words, a sprain of a weak foot. Consequently when these symptoms are relieved, the patient, who has become habituated to the weakness and deformity, considers himself cured.

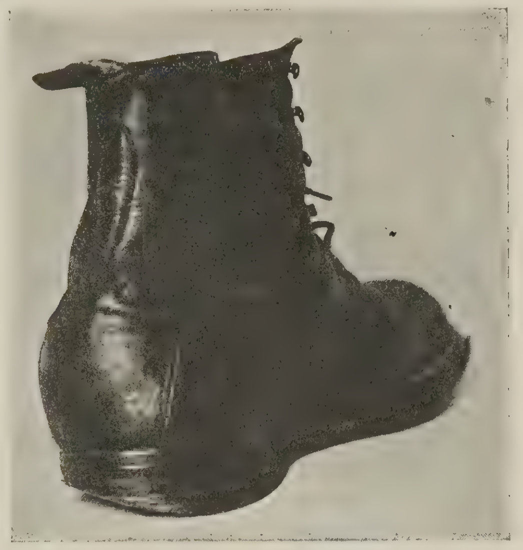


FIG. 2139.—The Internal Border of the Shoe Elevated According to Thomas' Method.

Operative Treatment.—The various cutting operations for the relief of flat foot do not call for extended comment. The typical operation, the removal of a wedge from the astragalo-scaphoid region, aims at removal of deformity simply; functional cure is made impossible by the destruction of the medio-tarsal joint. It would hardly seem possible that adhesion between the astragalus and scaphoid bones could for any length of time withhold a recurrence of deformity of the nature and origin of flat foot, and in all cases that the writer has examined in which this operation has been performed, there were still local tenderness and muscular spasm and even relapse of deformity. The operation of advancement of the posterior extremity of the os calcis, as proposed by Gleich, in order that it may be placed in a relation to the leg somewhat like that of a Pirogoff amputation, offers little hope of ultimate cure, for as the disability is not due to primary depression of the arch, it can hardly be cured by exaggerating its depth in this manner. The most innocent and rational of the operations for flat foot is the supramalleolar osteotomy of Trendelenburg, in which the bones of the leg are divided above the ankle, and the distal fragment is turned inward, with the aim of directing the weight upon the outer border of the foot. In practice, the operation is by no means always successful, while the bow-leg deformity that results, if the object is attained, is an unfortunate accompaniment of the treatment.

It may be mentioned in this connection that fracture at the ankle joint, followed by faulty union in a position of valgus, is a form of traumatic flat foot that may be cured by this operation. In operative treatment, the element of rest, necessary for weeks or months, must be taken into consideration, as explaining in part the immediate favorable effect of whatever procedure is adopted. An investigation of final results will prove, I believe, as might be predicted from the nature of the deformity and the complex structure of the foot, that there is no short and easy method by which a cure may be attained.

II. THE HOLLOW OR CONTRACTED FOOT. (Synonyms: Talipes cavus; Talipes plantaris.) The hollow foot in which the arch is exaggerated may be considered as the condition directly opposed to the flat or relaxed foot in which the arch is lessened or lost. In the latter instance the area of bearing surface is increased while in the hollow foot the bearing surface is diminished and the imprint of the sole may show that the entire weight is borne upon the heel and upon the metatarso-phalangeal region.

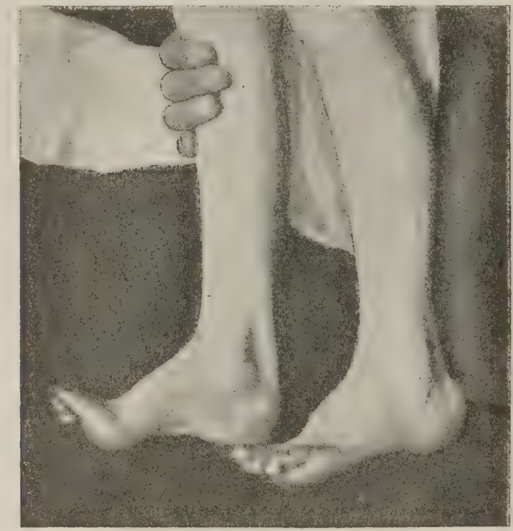

FIG. 2140.—The Contracted Foot—An Exaggerated Arch and Slight Limitation of Dorsal Flexion.

The contracted foot may be divided into two classes, the simple and the compound. In the first class the arch alone is exaggerated, "Talipes arcuatus." In the second there is a limitation of the range of dorsal flexion at the ankle joint as well, "Talipes plantaris." This latter variety was originally described by Schaffer under the title of "Non-Deforming Clubfoot" (New York *Medical Record*, May 23d, 1885).

Etiology.—The simple hollow foot may be, and often is, an inherited peculiarity. It may be induced by the habitual use of high heels or possibly by excessive exercise of the calf muscle as by professional dancers.

Compound hollow foot, in which there is limitation of the range of dorsal flexion at the ankle joint, or even slight persistent equinus, may be congenital also, but in most instances it appears to be a remote effect of a temporary weakness of the dorsal flexors of the foot, or of restriction of dorsal flexion from some other cause. This supposition is supported by the fact that the symptoms may date from a period of weakness and awkwardness following scarlet fever, rheumatism, or other infectious disease of childhood, symptoms attracting little attention in early life, but becoming more marked in adolescence or at a later period. In other instances the cause may be more direct, the slight deformity following a sprain or fracture, or it may be a result of an habitual attitude, as in patients who have been treated for disease of the hip joint by the traction appliance.

Symptoms.—The simple contracted foot may not cause symptoms; in fact it often passes as a particularly beautiful member rather than one that is deformed. As a rule, however, the patient complains of inability to buy well-fitting shoes, as the ordinary shoe does not support the arch while the upper leather presses uncomfortably upon the prominent dorsum. In cases of this type there may be actual exostoses on one or more of the projecting cuneiform bones of the dorsum surmounted by a sensitive bursa.

There is usually, in consequence of the rigidity of the foot, abnormal pressure upon the heel and fore foot, and sensitive corns or callosities at the latter point are often found. Pain beneath the great toe-joint or about the anterior metatarsal arch, which is often depressed, is a common symptom, and as a rule patients complain of discomfort in the hollow of the foot referred to the tense and sensitive plantar fascia. The gait is usually ungraceful, the patient everting the feet and walking heavily upon the heels. In many instances there is a persistent attitude of valgus, "weak ankles," and in cases of this type the most troublesome symptoms may be those characteristic of the weak foot. The symptoms described are usually more marked in the compound variety of the contracted foot than in the simple form.

On examination the nature of the affection is usually apparent. The arch is exaggerated, especially on the inner border, and the tense contracted bands of plantar fascia, usually very sensitive to pressure, can be demonstrated when the foot is dorsiflexed. In many instances there is an obliteration of the anterior metatarsal arch, the normal slight concavity being replaced by a distinct convexity, and at, or about, the head of the third metatarsal bone a sensitive callus is usually present. The prominence of the dorsum of the foot corresponds to the depth of the arch, and at this point, as has been stated, one or more of the cuneiform bones may project sharply beneath the skin. The range of dorsal flexion is often restricted at the right angle with the leg, and in this class there is usually habitual dorsiflexion of the toes, as if the direct result of the action of the accessory dorsal flexors of the foot.

Treatment.—In the mild cases of simple hollow foot the symptoms may be relieved in many instances by the use of a properly fitted shoe with a high "Spanish" arch.

If the symptoms are more persistent, a metal foot plate, modelled upon a plaster cast of the sole, may be employed, the object of the brace being to equalize the pressure on the sole, to remove the strain upon the sensitive fascia, and to lessen the pressure on the sensitive points of the anterior metatarsal arch. If the foot is habitually used in a valgus attitude, the sole of the shoe must be made thicker along the inner border in order to correct the inclination.

In addition to the supporting shoe or brace, daily forcible manipulation, with the object of stretching out the foot and increasing the range of dorsal flexion, if this be limited, is of service. The Schaffer traction brace is a useful appliance for this purpose.

If the deformity is well marked and of long standing it should be corrected by operative means. The patient being anæsthetized the fascia is divided subcutaneously and the exaggerated arch is then reduced to the normal depth by forcible manipulation with the hands, or by the use of the Thomas wrench. At the same time the slight limitation of dorsal flexion is overcome and the foot is fixed in a plaster bandage in which a thin wooden foot plate is incorporated. The patient is then encouraged to walk and he thus completes the cure by flattening the sole against the resistant sole plate. In severe cases tenotomy of the tendo Achillis may be required, but this is unusual.

III. PLANTAR NEURALGIA.—Pain referred to the hollow of the foot, combined with sensitiveness to pressure on the plantar fascia, is usually symptomatic of the hollow or contracted foot in which the fascia is subjected to abnormal tension. Occasionally it is present when the arch is weak or broken down. Sensitiveness of the fascia and pain at this point on standing are sometimes present in feet apparently normal. These symptoms may be induced by injury or by irritation or inflammation of the fascia, apparently due to infection, as it may follow influenza, typhoid fever, and the like.

Treatment.—If the foot is fairly normal in appearance, or if slight weak foot is present, the application of a well-fitting shoe may relieve the symptoms. In most instances, however, a properly fitted light steel foot plate is indicated, in order that the weight may be distributed, thus relieving the fascia from strain. If the foot is markedly contracted the fascia may be stretched or divided. (See Contracted Foot.)

IV. WEAKNESS OF THE ANTERIOR METATARSAL ARCH. (Synonyms: Anterior Metatarsalgia; Morton's Neuralgia.) Pain and discomfort referred to the metatarso-phalangeal articulations of the foot are symptoms that may be explained in most instances by an abnormal condition of the anterior metatarsal arch. Normally the anterior extremities of the metatarsal bones, although each bears its share of weight when pressure is put upon the foot in standing and walking, form an arch when the foot is not in use, the second and third bones being on a somewhat higher level than the others. In other words, there should be a certain resiliency of this part of the foot that lessens the liability to injurious pressure or strain. In many instances this resiliency is lost and one finds on examining the sole of the foot a persistent convexity in place of the normal arch. It may be noted in this connection that plantar flexion of the toes raises the heads of the adjoining metatarsal bones and increases the metatarsal arch. On the other hand, dorsiflexion of the toes lowers the arch, and as this attitude of persistent dorsiflexion of the first phalanges and consequent limitation of plantar flexion is one of the common effects of improper shoes, one recognizes the shoe as the most constant cause of weakness and of depression of the metatarsal arch.

Another type of weak arch is that in which there is, in consequence of weakness and flabbiness of tissue, an abnormal lateral expansion of the fore foot. Or again there may be apparently a local weakness of the muscles or ligaments of one of the component bones of the arch that allows it to assume an abnormal relation to its fellows.

Attention was first called to pain in this region of the foot by Dr. T. G. Morton of Philadelphia, in 1876, under the title of a painful affection of the fourth metatarso-phalangeal articulation, and as far as the symptoms of this type of what may be called anterior metatarsalgia is concerned, his description needs but little amendment. Typical cases of this class are characterized by a sudden cramp-like pain beneath the fore foot in the neighborhood of the fourth toe. It may begin as a burning pain beneath the toe or simply as a sensation of discomfort that gradually increases until it becomes unbearable. From the point of greatest discomfort the pain often radiates to the end of the toe or up the dorsum of the foot to the leg. Except in extreme cases, the pain is never felt except when the shoe is worn, and it may be relieved usually by removing the shoe and rubbing the foot. This need is so urgent that the removal of the shoe is one of the most distinctive signs of the affection. These cramp-like attacks may occur only at infrequent intervals, as for example when a certain shoe is worn, or they may recur so frequently as practically to disable the patient. After an attack of cramp the part may be sensitive for a time, and swelling even may appear, if it has been severe and prolonged. This is, however, rather unusual. The affection is relatively more common among women than among men, and among the well-to-do rather than the poorer classes. It is not infrequently found in several members of the same family, and it may be an inherited peculiarity. It is often bilateral, the second foot becoming affected usually after a considerable interval. The affection is usually chronic in character and not infrequently the patients are of a nervous or possibly neurasthenic type.

As has been stated, pain, although far more common at the fourth articulation, is by no means confined to this point. In some instances the patient is unable to localize the pain accurately, in others it is referred to the three adjoining toes, second, third, and fourth. In certain cases the greatest complaint is of sensitiveness of the metatarso-phalangeal joints to pressure, either direct or lateral. This complaint is more common when the arch is depressed and fixed in this attitude corresponding to the rigid weak foot. In other instances a painful callus beneath the second or third metatarsal head is the source of discomfort.

It should be stated that typical cases of Morton's neuralgia may be present although the foot is apparently normal in appearance.

Etiology.—As has been stated, the attacks of pain, although favored by "hot pavements," by "the sticking of a damp stocking to the foot," by thin soles, by sudden and unguarded movements, and the like, are practically always induced by the shoe, and it may be assumed that the pressure of the shoe upon a weakened and sensitive part induces the cramp. The influence of the shoe, as the author has suggested elsewhere (New York *Medical Record*, August 6th, 1898) may be explained as follows. Normally, lateral pressure on the hand or foot compresses it and increases the depth of the arch, as the tight glove does the hand. If, however, this increase of the arch is prevented, the adjoining bones cannot escape direct lateral pressure, a pressure that then becomes extremely painful, as one may demonstrate upon one's self by squeezing the hand suddenly while the metacarpal bones are fixed in the same plane; or if one finger of the hand be dorsiflexed so that the metacarpo-phalangeal joint is forced below the level of its fellows, pain on lateral pressure is always referred to this point. The same manœuvre causes pain in the foot at the corresponding articulation. It is evident also that in the foot an articulation that is depressed habitually will be constantly subjected to greater weight, or direct pressure as well, when it is in use.

Of all the causes of weakness and deformity of the anterior part of the foot the shoe is by far the most important. The lateral compression of the narrow and ill-shaped sole induces distortion of the toes and atrophy of the muscles that have lost their function. Thus the fore foot, deprived of its accessory supports, is subjected to abnormal pressure. The depression of the metatarsal arch is induced by the persistent dorsiflexion of the toes which is the attitude of shoe-wearing people, an attitude favored by direct compression by the rocker shape of the

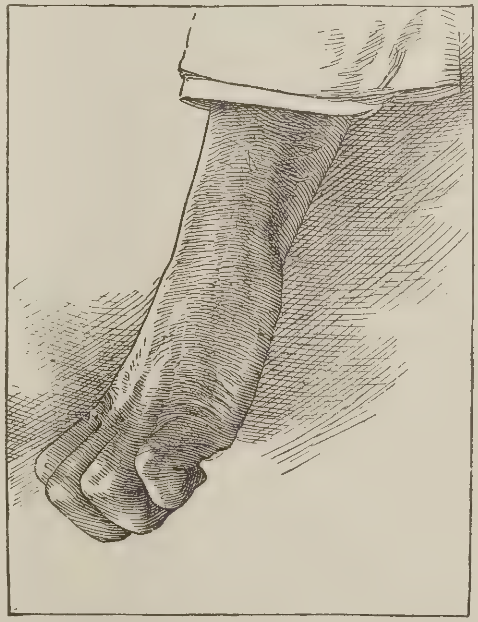

FIG. 2141.—An Attitude in which Lateral Pressure is Painful.

ordinary shoe and by the slight depression of the sole beneath its centre.

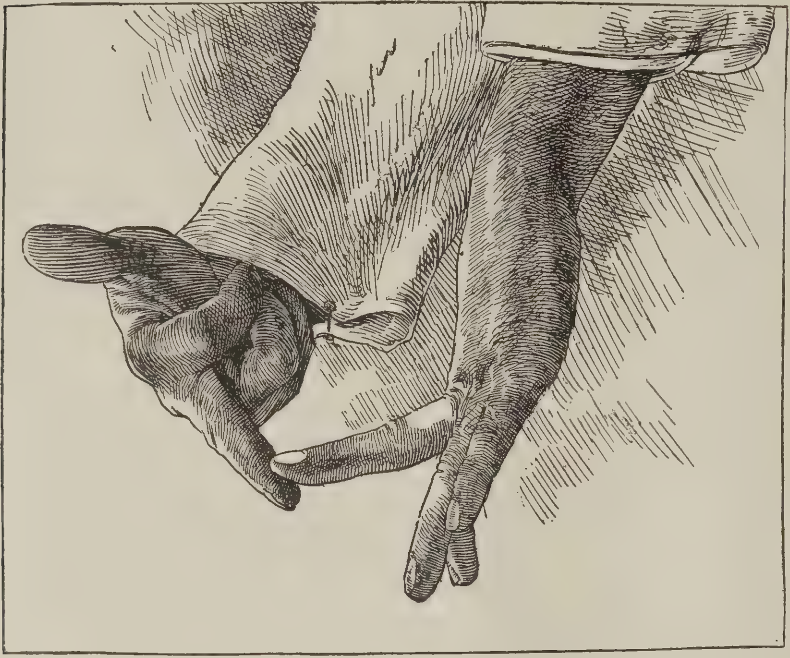

FIG. 2142.—In this Attitude Lateral Pressure Causes Pain at the Depressed Joint.

In the depressed arch, that metatarso-phalangeal joint that is lowest is subjected to abnormal pressure and it is liable to lateral compression as well, the latter being the direct cause of the characteristic cramp. The fourth articulation is that most liable to injury because it is practically the outer support of the arch, as the fifth joint is almost always on a higher plane or in an attitude that favors injurious pressure.

This may be readily illustrated by the school boy trick of suddenly compressing the hand when the fifth metacarpal bone is above the level of the fourth.

In many instances of Morton's cramp there seems to be simply a laxity of tissues that allows a sudden displacement downward of the fourth articulation or elevation of the fifth, a movement as of something slipping in the bone which is followed by the characteristic pain. This displacement may be induced by a misstep or by overexertion and not infrequently the first appearance of the affection dates from a sprain or twist of the foot, or is induced by extreme dorsiflexion of the toes. It may be stated also that extreme dorsiflexion may cause a subluxation of one of the joints which in itself may be the cause of the peculiar pain. There are, of course, other predisposing or exciting causes of this pain than the simple local causes that have been mentioned: for example, weakness of the longitudinal arch, the hollow foot, in which the plantar fascia is contracted; gout, rheumatism, or other local or constitutional affection that may make the foot abnormally sensitive.

Pathology.—It would appear, as has been stated, that the ordinary cause of the symptoms is pressure, which, as the attacks recur, makes the articulation in general sensitive. The more intense pain is due apparently to injury and pressure on the digital nerve and in certain instances a local neuritis may be present. Other changes in and about the joint are usually those secondary to the abnormal position of the part.

Treatment.—The treatment should be conducted with the aim of removing the direct causes of the discomfort and of restoring the normal condition of the weakened part. The first essential is therefore to provide the patient with a proper shoe. This must correspond with the outline of an undistorted foot; the sole should be thick and the shank should be arched to give proper support to the sole. A laced shoe that may be drawn tight about the arch usually adds to the comfort of the patient. The sole should be flat and it should be somewhat thicker in the centre so that it may form a slight convexity beneath the metatarsal arch. In fact the object of mechanical treatment is to support this anterior arch in its proper position. For this reason it is well in most instances to provide the patient with a light steel sole plate, fashioned on a plaster cast of the sole of the foot, of which the longitudinal and anterior arches have been somewhat exaggerated. This plate, as is shown in the diagram, usually extends from the centre of the heel to slightly beyond the metatarso-phalangeal joints, but in certain instances it is of advantage to extend it farther forward in order to splint the foot and prevent dorsal flexion of the toes if this motion induces discomfort or if the part is especially sensitive. As an immediate treatment the fore foot from the tarsus to the phalanges may be bound by strips of adhesive plaster, the metatarsal region being compressed somewhat as a tight glove compresses the hand; the elevation of the arch may be further assured by inserting a pad of felt or leather beneath it. This is a very effective means of relieving the discomfort and preventing the recurrent cramp.

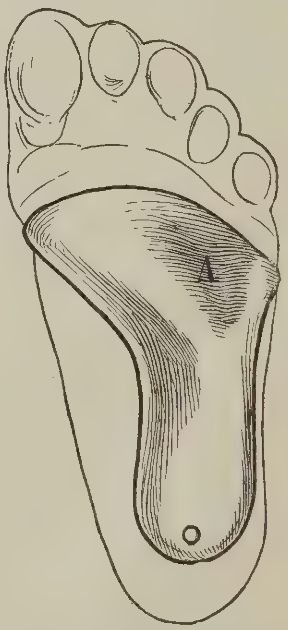

FIG. 2143.—A Brace to Support the Anterior Arch. *A*, The point of greatest elevation beneath the painful part.

In acute cases or when the part is very sensitive, and particularly in those cases that have resulted directly from injury, a plaster bandage may be applied, the foot being fixed in an attitude of slight dorsiflexion and adduction. The metatarsal arch should be exaggerated and the toes fixed in slight plantar flexion. If the arch is rigidly depressed, as in certain cases complicated by rheumatism and the like, the deformity must be overcome by forcible manipulation under anæsthesia before the bandage is applied.

In all cases the patient should endeavor, in the after-treatment, to regain the power of plantar flexion of the toes by manipulation and by exercise, and by pressing the toes firmly against the sole of the shoe to assist, as far as may be, the weakened arch in the performance of its labor.

Operative Treatment.—An effective treatment, and one that may be necessary in the persistent type of this affection, is excision of the head of the metatarsal bones, if, as is usual, the pain is localized at this point. This operation, the treatment of routine suggested by Morton, is easy of performance and it usually affords relief. The resulting deformity is but slight. In most instances it is, however, unnecessary.

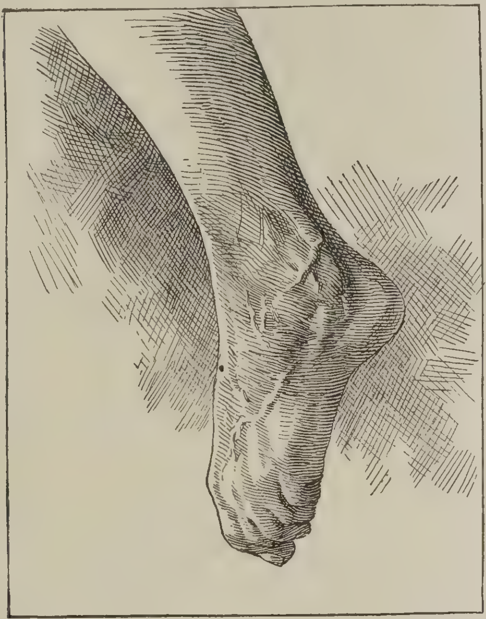

FIG. 2144.—Plantar Flexion of the Toes. An exercise for strengthening the anterior arch and overcoming deformity.

Depression or contraction of the longitudinal arch, which in certain instances may predispose to the discomfort, should be relieved if possible.

Massage, the hot-air bath, the application of various liniments are of some service in certain cases as adjuncts. Constitutional treatment is also indicated in those cases in which there is a gouty or rheumatic tendency or other complication.

V. HALLUX RIGIDUS. (Synonym: Hallux flexus.) Hallux rigidus is a painful affection of the great toe joint accompanied by restriction of motion. In well-marked cases the toe may be habitually plantar-flexed to a slight degree; hence the name hallux flexus suggested by Davies-Colley. In this class the motion may be much restricted, particularly in dorsal flexion, thus interfering with proper functional use of the foot. There is usually pain of a burning, throbbing character referred to the joint and increased by use, and a certain degree of congestion is often present.

Etiology.—Hallux rigidus is usually seen in adolescence as a complication of a weak arch which allows the fore foot to be crowded into the narrow part of the shoe, thus subjecting the great toe joint to lateral and longitudinal pressure. In some instances the habitual flexion is the effect of an instinctive effort of the patient to support a weakened arch by downward pressure of the great toe. (Hammer-toe flat foot. Nicoladoni.)

The affection may also be induced directly by injury, as by stubbing the toe or by kicking a hard object, or it may be a complication of rheumatism or gout.

There are no distinctive changes in the joint other than those secondary to long-standing restriction of function and deformity.

Treatment.—If the rigid joint is a secondary effect, as in most instances it is, of the weak or broken-down foot the first step is the treatment of the exciting cause (see Weak Foot). In any event a properly fitting shoe must be worn, which exerts no pressure on the sensitive part. The sole must be thick, so that movement in the joint may be restricted, and in certain instances it may be necessary to insert a steel brace between the layers of the sole of the shoe in order to prevent all motion for a time. If direct pressure on the toe joint causes discomfort, the sole of the shoe may be made very thick just behind the sensitive part, so that the weight is supported as it were on an anterior heel (Fig. 2145).

If the affection of the toe complicates a rigid flat foot, as is not infrequently the case, the deformities should be over-corrected under anæsthesia (the flexed toe being forcibly extended), and fixed in a plaster bandage in the manner described in the section on Weak Foot. In extreme, and very exceptional, cases of long standing, excision of the joint may be required.

VI. PAINFUL GREAT TOE. Pain, on motion and pressure, at the great toe joint, and symptoms resembling those of hallux rigidus, are not uncommon in older subjects. These symptoms are induced usually by a long walk or by strain or other injury.

The treatment is based upon essentially the same principles as those governing the treatment of the former affection. Thus, for example, splinting may be employed, when necessary, to restrain painful motion, and a proper shoe may be fitted for the relief of pressure.

Pain about the great toe is a common symptom of the weak arch, or of the contracted foot. It may be caused simply by the pressure of a tight shoe. It is often present as a symptom of hallux valgus and of its accompanying bunion. The joint may be directly involved in gout, rheumatism, and the like. The treatment must be directed to the cause.

VII. HALLUX VALGUS. Hallux valgus is a deformity of the foot, in which the first metatarsal bone is adducted and at its anterior extremity separated from its fellows, while the toe is turned outward or abducted to a greater or less degree. Thus although the area of the toes is contracted the fore foot is actually broadened.

In consequence of the distortion there is an actual displacement of the joint surfaces. In marked cases, the first phalanx of the distorted toe articulates only with the external condyle of the metatarsal bone, while the internal condyle, projecting on the inner side of the foot, is subjected to the direct pressure of the shoe. Here a bursa forms and this is in turn surmounted by a corn or callus.

The projecting condyle, sometimes irregular and hypertrophied by the deposit of periosteal bone, the bursa, and the overlying corn make up the enlarged joint or so-called bunion. In cases of this type there is usually more or less abduction of the other toes, and the great toe, often rotated on its long axis, may be displaced above or below its fellows.

Etiology.—By far the most important of the predisposing and exciting causes of the deformity, and of the consequent pain and discomfort, is the shoe. In fact a moderate degree of hallux valgus, shown by the projecting "enlarged" joint, is so common as to pass as the normal condition of shoe-wearing people. The influence of the shoe is increased when the longitudinal arch is weak, as the parts are then subjected to greater pressure. The deformity, or more especially the symptoms, may be increased by gout, rheumatoid arthritis, and the like, and by overstrain and injury as well.

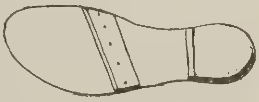

FIG. 2145.—The Anterior Heel.

Pathology.—The pathology does not call for extended comment. There are the usual changes in and about the joint that accompany similar subluxations, the cartilage disappears from the exposed parts of the internal condyle, and the ligaments and the muscles contract on the shortened side and oppose the rectification of the deformity.

Symptoms.—The most important sign of hallux valgus is the deformity. The most important symptoms are the pain and sensitiveness induced by the pressure upon the projecting joint. The discomfort is, of course, greatly increased by the inflamed bunion and accompanying corn. There may be pain also beneath and about the joint. Pain in the joint may be in part symptomatic of the irritation and changes secondary to the deformity itself. Pain beneath the joint is usually caused by the greater pressure to which the part is subjected by the outward rotation of the foot, an attitude that is almost always assumed by the patient if there be an accompanying weak foot. In certain instances pain beneath the joint may be due to irritation about one of the displaced sesamoid bones which are sometimes adherent and are sensitive to direct pressure.

Treatment.—In the slighter degrees of deformity the symptoms may be checked by the use of a proper shoe, straight on the inner side and with capacious upper leather. This removes the direct pressure and allows an opportunity for normal movement. Making the sole somewhat thicker on the inner border is of advantage also, as it inclines the weight slightly toward the outer part of the foot. In addition, daily manual correction of deformity, together with alternate voluntary flexion and extension of the toe while it is guided by the fingers in the normal direction, is of advantage from the curative standpoint.

A number of appliances have been devised to hold the toe in normal position while the foot is in use. In most instances, however, the incidental discomfort is sufficient to prevent their use. One of the simplest and most efficient of these devices is the Holden toe post, a thin upright of metal fixed in the front of the sole of the shoe, making a compartment into which the toe is guided and thus held in an improved position. This toe post necessitates a digitated stocking and a special shoe; like other appliances it is very uncomfortable unless it is perfectly adjusted, and until the patient has become accustomed to it.

It must be borne in mind that a part of the deformity of hallux valgus is caused by the adduction of the metatarsal bone. It is well, therefore, to lessen this displacement by the use of a bandage or by adhesive-plaster strapping about the fore foot, so applied as to exercise a certain amount of compression at this point.

It has been stated also that weakness of the arch or flat foot is a common accompaniment of hallux valgus. In such cases a proper support is an essential part of the treatment.

As a rule patients demand treatment rather because of the discomfort than because of the slight degree of deformity. This discomfort is due to the pressure on the sensitive bunion lying on the projecting condyle, and the removal of this projecting bone will practically relieve the symptoms.

A simple and effective operation is conducted as follows. A slightly curved incision is made below the joint, the bunion is dissected from the adherent skin, the joint is opened and the projecting bone, usually the greater part of the internal condyle of the metatarsal bone, smoothly removed with a chisel, after which the capsule is closed with fine catgut as in the external wound. The toe is then straightened by stretching the contracted tissues. The entire foot is slightly adducted, or turned inward, and together with the leg is enclosed in the plaster, the toe being fixed in the corrected position by the same means.

As soon as the weight can be supported without discomfort the patient is allowed to walk about on the foot. Afterward, manipulation, exercises, the use of a proper shoe together with a flat-foot brace, if this is indicated, will complete a practical cure.

Modifications of the Operation.—In certain instances there may be contraction of the extensor tendon of the toe. Weir has suggested that this may be divided and sewed to the periosteum on the outer border of the first phalanx, thus serving to prevent recurrence of deformity.

In more extreme cases of contraction and deformity, resection of the head of the metatarsal bone may be indicated. Cuneiform osteotomy of the metatarsal bone has been suggested, but this, to be effective, must include the projecting condyle.

Fowler's Operation.—In this procedure the incision is made between the first and second toes, the ligament is divided, and the toe is displaced inward. The bunion and the projecting portion of the internal condyle are then removed if necessary, the toe is replaced, and the wound closed. This operation appears to offer no advantage over the simple one that has been described, for, when properly performed, the scar is insignificant and is not subjected to pressure if it be made slightly below the most prominent part of the joint.

Bunion.—The treatment of the bunion, the inflamed sac and corn, may be summarized as rest with hot or cold applications during the active stage, with relief of pressure by the use of a proper shoe. In many instances a metallic support for the arch to remove the direct pressure on the toe is indicated. Operations should as a rule be deferred until the acute symptoms have subsided. An effective operation must include the removal of the projecting bone as well as the sac.

VIII. HALLUX VARUS AND PIGEON TOE. The term hallux varus is properly applied only to persistent adduction of the great toe, while pigeon toe is the popular name for in-toeing, an attitude usually caused by an inward rotation of the entire limb.

Hallux varus is usually congenital; the great toe turns inward, sometimes when in active motion, to a marked degree, in fact it may be almost prehensile in its movements.

In certain instances there is slight accompanying adduction of the foot at the medio-tarsal joint, constituting a mild degree of talipes varus. The mother's attention is usually attracted to the condition, not by an actual deformity of the toe, but by difficulty in putting on the baby's stocking.

Hallux varus is occasionally seen also as an acquired peculiarity in connection with certain varieties of weak foot (valgus). In such cases there is a marked inward bulging at the medio-tarsal joint which is compensated for by an exaggerated inward twist of the fore foot and adduction of the great toe (Fig. 2130).

Treatment.—Simple hallux varus, as a rule, requires no treatment since it is cured by the use of the shoe when the child begins to walk. In more extreme cases the prehensile movements may be restrained by a narrow band of adhesive plaster passed over the toes and fore foot. If talipes varus is present it should be treated in the ordinary manner (see Talipes).

PIGEON TOE.—Hallux varus is a rather unusual cause of the in-toeing gait, or so-called pigeon toe, which, as has been stated, is caused as a rule by inward rotation of the entire limb rather than by a deformity of the toe or foot. This rotation of the limb may be caused also by bow legs in which there is an accompanying inward twist of the tibiæ and occasionally it may be induced by a restriction of the range of outward rotation at the hip joints.

As a rule, however, pigeon toe is a compensatory attitude symptomatic either of weak feet or of knock knees, and it is therefore far more often a secondary than a primary attitude. The proper position of the feet in walking, at least in childhood, is one of parallelism. In fact the exaggerated outward rotation of the feet which is so commonly seen, is more abnormal than a slight degree of in-toeing. As the latter attitude, from the conventional standpoint, passes for deformity it usually attracts the mother's attention before the weakness, of which it is so often a symptom.

Treatment.—The rational treatment must be directed to the cause of the peculiar attitude, viz., the bow leg, the knock knee, or the weak foot. In many instances the in-toeing habit remains for a time, after the removal of its cause, and systematic training in walking with the feet rotated outward may be necessary to overcome it.

If there be actual limitation of the range of outward rotation at the hip joints, as is sometimes the case, this must be overcome by systematic stretching.

In the absence of knock knee or weakness of the arch the tendency to in-toeing may be lessened by making the sole of the shoe somewhat thicker on the outer border.

In the more exaggerated types, the use of elastic tapes attached to the front and outer margin of the soles of the shoe, passing about the back of the leg from without inward over the front of the thigh and across the buttock, to be attached to the middle of the waist band, is an efficient treatment.

IX. Hammer Toe. Hammer toe is a persistent flexion of a toe, usually of the second. In well-marked cases the first phalanx is dorsiflexed, the second plantar-flexed, and the third may be flexed and extended. The toe is usually compressed between its fellows, while its extremity, lying on a lower level, is flattened out against the sole of the shoe into a club or hammer shape. On the dorsal surface of the flexed joint which is subjected to pressure from above there is usually a sensitive corn or callus. The discomfort of the hammer toe is caused by the pressure of the shoe upon the corn above and upon the hypertrophied extremity below, of which the nail is not infrequently ingrown.

Etiology.—Hammer toe may be congenital, but in the great majority of cases it is an acquired deformity caused by narrow and short shoes. The second toe is more often involved because it is the longest and is subjected to greatest lateral pressure also. In cases of long standing all the tissues are shortened on the plantar or short surface, the most resistant contraction being in the ligaments of the first phalangeal joint.

Treatment.—Congenital hammer toe may be corrected in infancy by manipulation and by retention with a strip of adhesive plaster. The slight degrees of hammer toe in older subjects may be treated in a similar manner by methodical stretching and splinting with some light material such as celluloid. In such cases a digitated stocking is of advantage. In all cases a wide, capacious shoe which exerts no pressure whatever, is the first essential.

Confirmed hammer toe may be treated by division of the resistant parts, particularly of the ligaments of the first interphalangeal joint, and by correction followed by retention for a time with a digital splint of elastic material or a leather inner sole. In most instances, however, patients demand treatment for the relief of the discomfort caused by vertical pressure upon the flexed toe, rather than for the absolute restoration of symmetry. For this class the most efficient procedure is resection of the prominent joint, sufficient bone being cut away from the adjoining phalanges to remove the projection completely. By such a procedure permanent relief may be secured.

X. Overlapping Toes. Irregularity in the line of the toes is sometimes observed in infancy; for example, a congenital hammer toe may be present or the little toe may be set upon a higher level than its fellows.

The irregularities may be treated by methodical manipulation and by retention of the distorted member by straps of adhesive plaster passed above and beneath it, fixing it to its fellows. Irregularities of this character in older subjects are almost always caused by improper foot wear, with the exception of distortions caused by rheumatism or by lesions of the nervous system, and the like. In this class, the use of a proper shoe will usually relieve the symptoms.

XI. Achillo-Bursitis. (Synonym: Achillodynia.) In 1893 Albert* suggested the title Achillodynia to characterize a group of symptoms caused, in most instances, by irritation or inflammation of the bursa lying between the tendo Achillis and the posterior surface of the os calcis.

Etiology.—In certain cases the bursitis may be caused directly by pressure, injury, or overstrain, but in many instances rheumatism, gout, gonorrhœa, and the like, appear to be predisposing or exciting causes of this, as of similar affections of bursæ and tendon sheaths elsewhere. Concretions within the bursa or exostoses beneath it may be mentioned as possible causes, or complications.

Pathology.—In chronic cases the bursa is thickened and enlarged and the lining membrane is fringed and reduplicated. The contents may be serous or semisolid and concretions may be present. Suppuration may occur within the sac or it may be the seat of syphilitic or tuberculous disease. The periosteum in the neighborhood is usually thickened, and the underlying bone may be congested and softened.

Symptoms.—In typical cases there is sensitiveness to pressure over the back of the heel, and pain or discomfort exaggerated by functional use, particularly by motions and attitudes that increase the strain upon the tendon. The pain may radiate up the leg or it may be referred to the bottom of the heel. Patients often complain also of a sensation of laxity and insecurity in the subastragaloid articulation. In a large proportion of the cases the symptoms of the weak foot accompany or follow those of achillodynia. In the latter instance this is explained doubtless by the fact that the loss of the leverage function of the calf muscle induces an awkward gait with a strong inclination toward pronation of the foot, an attitude that throws an increased strain upon its inner border and upon the longitudinal arch. In cases of long standing there is marked atrophy of the calf due to disuse of function and in many instances a broadening of the posterior part of the heel caused by the infiltration or irritation of the periosteum about the insertion of the tendon. The enlarged bursa is usually demonstrable on inspection and palpation. The affection may be unilateral or bilateral, the latter being more common in chronic cases. As a rule the symptoms begin in one foot, the second becoming involved after an interval of several months.

When the symptoms have persisted for any length of time, there appears to be little tendency toward spontaneous recovery, a fact that is explained by difficulty in securing relief from pressure and strain in this situation.

Treatment.—In acute cases, particularly those that have followed injury, the treatment should be—functional rest combined with the application of heat or cold, as may be indicated. When the immediate symptoms have subsided the part may be supported by adhesive plaster so arranged as to relieve the strain upon the sensitive part. A long band of plaster about two and a half inches wide is closely applied to the sole of the foot and calf of the leg, reaching from the toes nearly to the knee, with the foot in slight plantar flexion. This is supported by additional straps about the fore foot and leg, the ankle and heel being completely covered with narrow strips; a bandage is then applied. By this means the direct pull of the muscle on the sensitive part is checked and compression is exerted upon the bursa. The dressing should be renewed when its efficiency is lessened.

If more complete fixation is indicated by the symptoms a light plaster bandage may be applied to hold the foot at a right angle with the leg and slightly adducted. The patient can then use the foot without discomfort. In many instances the application of the cautery seems to hasten the absorption of the effusion. If relief from

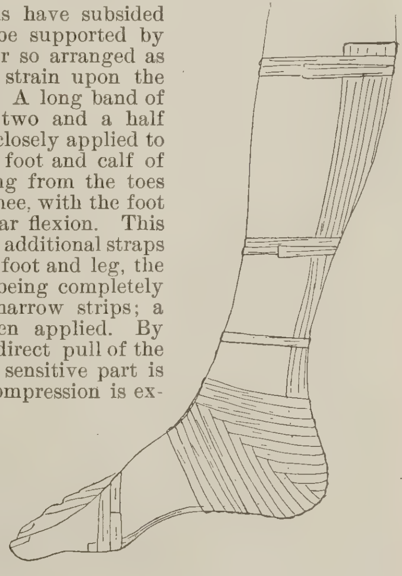

Fig. 2146.—The Manner of Applying Adhesive Plaster.

---

* Wien. med. Presse, January 8th, 1893.

function is necessary for any length of time, as in the chronic cases, it is well to apply a leg brace to the shoe with a joint at the ankle so arranged as to prevent dorsal flexion beyond a right angle. As patients are usually sensitive to direct jar, a rubber heel should be employed, and an increased height of the heel sufficient to throw the weight forward upon the front of the foot usually lessens the discomfort.

As has been stated, in the chronic cases there is usually an accompanying weakness of the longitudinal arch. This may require the application of a support and further treatment as described in the section on the weak foot.

Operative Treatment.—In persistent cases, particularly those in which the bursa is palpable and in which the adjoining tissues of the os calcis are infiltrated, the removal of the bursa is indicated. This is accomplished by an incision beside the insertion of the tendon where the bursa is most prominent. Irregularities of the underlying bone should be removed at the same time. The wound is then closed and a plaster bandage is applied. This should be worn until the patient can walk without discomfort. Support may or may not be required in the after-treatment. Operative intervention is of course indicated when suppuration of the sac is present or when it is the seat of primary or secondary tuberculous disease. As has been stated, the local disability may be induced or prolonged by systemic disease. In such instances appropriate remedies should be employed.

XII. Achillo-Bursitis Posterior.—A small sensitive bursa over the insertion of the tendon, between it and the skin, sometimes causes symptoms resembling those of the preceding affection. This bursa is usually caused by the pressure of the shoe, and it may be relieved by removing the exciting cause and by strapping with adhesive plaster.

Bursæ or sensitive points elsewhere on the heel are to be treated in a similar manner. Irregular projections on the bone may require removal.

XIII. Strain of the Tendo Achillis.—Pain on use of the foot referred to the tendo Achillis may follow strain or overuse, the symptoms may resemble those of Achillo-bursitis, but the sensitive point is often localized at the middle of the tendon or at the junction with the muscular substance. Apparently there is, in these cases, an irritation within the fibrous sheath of the tendon or injury to the muscular fibres.

The treatment is functional rest. As a rule the application of the adhesive-plaster strapping, as described in the treatment of Achillo-bursitis, is effective.

XIV. Painful Heel — Calcaneo-Bursitis.—Pain and sensitiveness to pressure referred to the bottom of the heel are common symptoms of the contracted or hollow foot, in which there is abnormal pressure on the anterior and posterior pillars of the arch. It may be in normal feet a symptom of overuse, as when the tissues beneath the heel become sensitive after long standing or walking, and it is a common symptom of the weak foot of which the so-called heel walk is characteristic.

In rare instances the point of tenderness is distinctly localized and is due to a small inflamed bursa lying over the periosteum of the inner tuberosity of the os calcis.

Treatment.—This must be directed to the condition of which the pain is a symptom. The treatment of the weak foot and of the contracted foot is described elsewhere. If the sensitiveness is due to overuse or to abnormal pressure, the use of a rubber heel combined with frequent change from the passive attitude, in which the weight is supported entirely on the sensitive part, may relieve the symptoms. In many instances the use of an arched foot plate, to distribute the pressure along the entire sole, is of service.

Painful bursæ may be protected from direct pressure or removed if necessary. *Royal Whitman.*

FOOT, DISTORTIONS OF.—Talipes.—In the preceding article, the disabilities of the foot of which the discomfort is of greater importance than the deformity have been described. One may now consider those of congenital and acquired origin of which deformity is the most noticeable feature. A distortion of the foot of this class is simply an abnormal retention of a normal attitude, or what is an exaggeration of a normal attitude. In other words the centres of motion, at which the foot is deformed, are the centres of normal motion and the different distortions may be simulated by a normal subject. If the foot has been fixed in the abnormal attitude during fœtal life, or if it has been used for any length of time in the abnormal position, the deformity becomes exaggerated beyond the possibility of imitation, and secondary variations in its shape, size, and nutrition follow.

The deformities of the foot are grouped under the generic name talipes, derived from talus (ankle) and pes (foot), signifying therefore a form of deformity in which the patient walks upon his ankles. Talipes was therefore originally synonymous with the popular term club foot, but at the present time it is used preferably as a prefix to the descriptive titles of the different distortions, while club foot is usually applied only to the most common of the deformities, equino-varus, in which the distorted foot is club-like in form.

Varieties.—There are four *simple* varieties of the distorted foot or talipes:

1. *Talipes Equinus*, the extended or plantar-flexed foot. In well-marked cases the patient walks upon the heads of the metatarsal bone, an attitude that suggested the name equinus (horse-like).

2. *Talipes Calcaneus*, the dorsi-flexed foot in which the heel is prominent, and which alone bears the weight in walking; hence, calcaneus from calcaneum, the heel bone.

In these forms the centre of motion is at the ankle joint. Under the terms equinus and calcaneus are included not only the cases of marked deformity, but also those in which the range of dorsal or plantar flexion is sufficiently limited to cause a change in the contour of the foot.

3. *Talipes Varus*, the inverted foot. In this deformity the foot is turned in or adducted, and combined with the inward twist, which exaggerates the normal curve of the inner border, there is always a certain amount of supination, or inversion; that is, the inner border of the sole is elevated and the outer border is depressed, so that the weight falls to the outer side of the centre of the foot.

4. *Talipes Valgus*, the everted foot. This deformity is the reverse of varus. The foot is abducted, that is, the foot is twisted outward at the centre and pronated, so that in use the weight falls on the inner border.

In these forms of lateral deformity the centres of motion are at the mediotarsal and subastragaloid joints.

These simple deformities in which the foot is persistently extended or flexed, or twisted in or out, are comparatively uncommon.

Compound Deformities.—As a rule, the deformities are combined in varying degree; thus, the over-extended or the over-flexed foot is usually twisted inward or outward, making four varieties of compound deformity. 1. *Talipes equino-varus*—downward and inward. 2. *Talipes equino-valgus*—downward and outward. 3. *Talipes calcaneo-varus*—upward and inward. 4. *Talipes calcaneo-valgus*—upward and outward.

In the simple and compound varieties of talipes the arch of the foot may be increased or diminished in depth. It is, for example, usually increased in calcaneus and equinus, and it is usually diminished in valgus; but this secondary or subordinate deformity is not recognized in the ordinary classification. If the arch of the foot is exaggerated, the condition is sometimes called *talipes cavus;* if it is lessened or lost, *talipes planus.* These slight degrees of distortion, in which the functional disability is far more important than the deformity, are rarely classed as forms of talipes. Simple cavus, the hollow or contracted foot; and planus, one of the forms of the common weak or flat foot, have been described already.

Etiology.—From the remedial standpoint, the cause of the deformity is of far greater importance than its form. Thus the distortions of the foot fall primarily into two groups: 1. *The congenital form*, in which the foot has become deformed in process of formation. 2. *The acquired form*, in which the foot, perfect at birth, has at a later time become distorted.

Congenital Talipes is simply a twisted foot, of which the component parts, although malformed to a greater or less degree, are capable of regaining perfect form and function. This is practically true of the great majority of cases, although there are exceptional instances in which congenital deformity is complicated by defective formation of the foot or leg, or in which the deformity is caused by, or at least accompanied by, paralysis, as, for example, in certain forms of spina bifida or other congenital defect or disease of the nervous apparatus.

Acquired Talipes is almost always a consequence of paralysis of spinal origin (anterior poliomyelitis) in early childhood. Certain muscles or groups of muscles being paralyzed, the muscular force is unbalanced and the foot is drawn into a distorted position by the action of the unopposed muscles, and by the influence of gravity. This distortion is confirmed and increased by the accommodative changes that accompany functional use and growth in the abnormal attitude.

Far less often acquired talipes may be the result of paralysis of cerebral origin, of other forms of spinal disease, of local paralysis following neuritis or injury to a nerve trunk. It may be caused by scar contraction, as after a severe burn, or by direct injury to the bone, or by disease that may interfere with subsequent growth. Such are, however, extremely uncommon causes, and the statement holds good that congenital talipes is a simple distortion capable of perfect cure, while the acquired talipes is a deformity and disability usually secondary to disease of the spinal cord. It is therefore capable only of rectification, not of perfect cure unless recovery from the original disease, of which it is a result, has taken place.

CONGENITAL TALIPES.

Etiology.—The etiology of congenital talipes as of other congenital deformities is somewhat conjectural. In some instances the influence of inheritance is apparent, and again two or more children with club foot may be born of the same mother, but, as a rule, there is nothing in the family or personal history that can in any manner explain the deformity. The most reasonable explanation applied to the majority of cases is that the foot has from some cause remained for a longer or shorter time in a constrained or fixed position, and has thus grown into deformity.

It has been claimed by Eschricht, and by Berg (Berg, *Archives of Medicine*, New York, December 1st, 1882) that at about the third month of intra-uterine life the thighs of the embryo are abducted, flexed, and rotated outward, the legs are crossed, and the feet are plantar-flexed and adducted so that the inner surfaces of the thighs, the tibial borders of the legs, and the plantar surfaces of the feet are held in close apposition to the abdomen and to the pelvis of the fœtus. Later there is an inward rotation of the legs so that the feet are turned gradually outward until the soles are brought into contact with the uterine wall, the feet then being in the attitude of abduction and dorsal flexion. According to this theory there is a regular succession of attitudes during intra-uterine life. If the inward rotation of the lower extremity is prevented, or if it is incomplete, the foot remaining in the original position becomes deformed. Thus, equinovarus being the normal attitude of the early and middle period of intra-uterine life, is the most common and the most intractable of the congenital deformities. If the constraint or pressure is not exerted until a later period, after rotation has taken place, when the foot has attained or nearly attained its normal size and shape, it will then induce the less common and comparatively slight grades of deformity such as calcaneus or valgus.

This theory which seems interesting and reasonable, appears to rest on an insecure basis. Bessel Hagen states that in embryos of 30 mm. in length, the foot is in extreme plantar flexion; in those of 90 to 100 mm., the foot is at a right angle to the leg; and from this size to that at full term, the foot may be found in any position, abducted, adducted, or dorsiflexed. He states also that supination is not the usual attitude at an early period, but is more common near the termination of intra-uterine life, and that when it is present it is more often combined with dorsiflexion. In other words, there is no time when the foot regularly and normally assumes the attitude of club foot, from which it is changed by the rotation of the legs. Scudder (*Boston Medical and Surgical Journal*, October 27th, 1887), after similar investigations, arrived at practically the same conclusions. He states that there is no necessary relation between the age, the rotation of the legs, and the position of the feet.

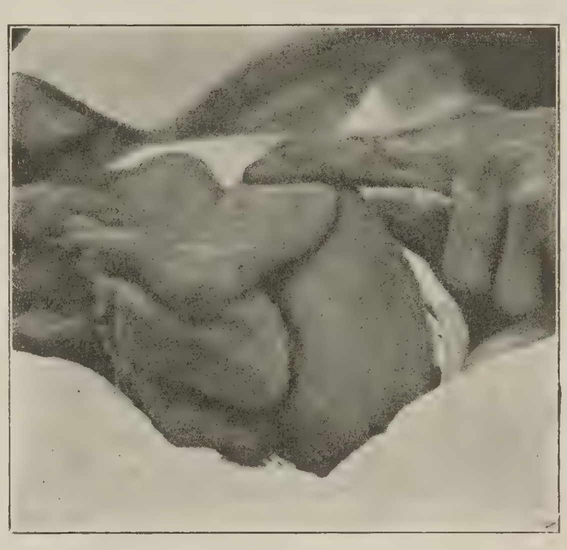

Fig. 2147.—Congenital Talipes Illustrating the Attitude of the Limbs at Birth.

It would appear, however, that there is during the process of development a normal alternation of attitudes and postures. If the feet for any reason are fixed in one position during this period of rapid growth, distortion must follow; if the constraint is slight, and if its influence is exerted at a late period, the deformity will be slight; if it occurs at an early period, the deformity will be more resistant.

One of the causes of constraint, and thus of ultimate deformity, appears to be the interlocking of the feet. Many museum specimens show this, and in some of the cases of talipes seen during the first weeks of life, the feet may be replaced in the attitude in which they had been fixed before birth. Intra-uterine pressure, although not necessarily direct pressure, undoubtedly has an influence in aggravating the deformity. The effect of pressure is not infrequently shown in atrophic areas of skin, and bursæ even are sometimes found over prominent bones. Entanglement in the umbilical cord, the direct pressure of extra- or intra-uterine tumors, and the like, may be mentioned also as possible causes of restraint or fixation of the foot that induces deformity. Further evidence of restraint of normal movements and of abnormal attitudes of the limbs is seen not infrequently in connection with club foot. For example, there may be hyperextension or fixed flexion of the knees, and in cases of extreme deformity the foot is often smaller than normal or otherwise asymmetrical. In certain instances the distorted foot may be imperfect in structure; toes may be absent ("spontaneous amputation"), or constricting bands about the leg or foot may be present. Such abnormalities are usually ascribed to amniotic adhesions. Talipes may be combined with evidences of impaired or arrested development, with harelip, exstrophy of the bladder, spina bifida, absence of patellæ, or with other deformities, such as club hand and wry neck. Or there may be evidence of intra-uterine disease, as shown by ankylosis of joints or by so-called fœtal rickets. Finally, deformities of the foot may be complicated by absence of bones of the foot or of the leg, indicating original defects in the germ itself. This latter group, which includes the complications of club foot and imperfection of structure, is comparatively small. As has been stated, congenital club foot, in the great majority of cases, is a simple deformity capable of perfect cure.

The relative frequency of the congenital and acquired forms of talipes has given rise to much discussion in the past, and statistics on this point are at considerable variance with one another. This may be explained by the fact that acquired paralytic talipes is, as a rule, a preventable deformity. At the present time the extreme degrees of acquired talipes are comparatively infrequent and the deformity is usually of a much slighter grade than the corresponding form of congenital distortion.

SEX OF CONGENITAL TALIPES.*

Males.	Females.	Total.
1,066	585	1,651
64.5%	35.5%	

SEX OF ACQUIRED TALIPES.

Males.	Females.	Total.
975	828	1,794
54%	46%	

Congenital talipes is much more common among males than among females. All the statistics are in accord upon this point. Acquired talipes is more equally divided between the sexes.

FOOT AFFECTED IN CONGENITAL TALIPES.

COMPARATIVE FREQUENCY OF THE DIFFERENT FORMS OF TALIPES, CONGENITAL AND ACQUIRED.

	Congenital.	Acquired.
Equino-varus	77.0 per cent.	32.5 per cent.
Valgus	7.4 "	9.7 "
Varus	5.1 "	2.7 "
Calcaneo-valgus	3.1 "	4.4 "
Equinus	2.4 "	26.1 "
Calcaneus	1.7 "	12.6 "

According to these statistics, in three-fourths of the congenital cases the deformity is equino-varus. Equinus and calcaneus, rare as congenital deformities, comprise 38 per cent. of the acquired forms.

Occasionally the deformity of each foot is different, far more often in the acquired than in the congenital form. In 7 of the 18 congenital cases the deformity was equino-varus on one side, calcaneus on the other; in 3 equino-varus and calcaneo-valgus, and in 3 simple varus and valgus. The 50 cases of acquired talipes represented every combination of deformity.

In 31, or 4 per cent., of the 735 cases of congenital talipes, the distortion was combined with other congenital defects or deformities, viz.: In 12 cases with double club hands; in 6 cases with defective development of the hands, webbed fingers, and the like; in 7 cases with spina bifida; in 3 cases with absence of one or more bones of the leg; in 1 case with torticollis; in 1 case with harelip; in 1 case with dislocation of the knee and ankylosis of an elbow; in 2 cases with general rigidity and deformity of the joints.

THE ANATOMY OF CONGENITAL TALIPES EQUINO-VARUS (CLUB FOOT).—Congenital talipes is, in the great majority of cases, the form in which the foot is twisted inward and downward, or in the more extreme cases, inward and upward, and in its club-like appearance justifying the popular name. The ordinary congenital club foot in early infancy is simply a foot held in an attitude of plantar flexion, adduction, and supination. The dorsum of the foot looks forward and slightly outward and

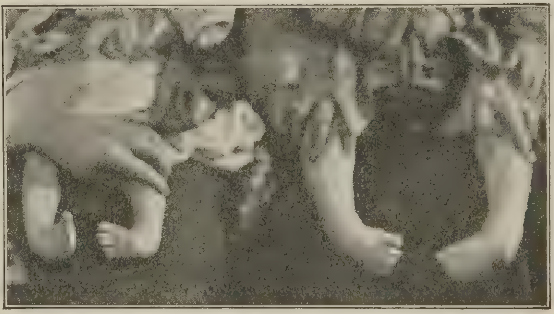

FIG. 2148.—Congenital Club Feet in Sisters, the Twelfth and Thirteenth Children; All the Others Normal.

---

* Statistics from Whitman's "Orthopædic Surgery."

upward, the plantar surface is abnormally concave and looks backward, inward, and downward. In many cases the equinous element of the deformity, masked by the extreme inversion of the foot, does not appear until this has been corrected in part. The foot often seems somewhat smaller than normal, and the heel appears to be ill formed. Upon the outer dorsal surface the prominence of the astragalus and os calcis may be felt beneath the skin, the external malleolus is prominent, while the internal malleolus lies deep beneath the redundant tissue of the internal aspect of the foot.

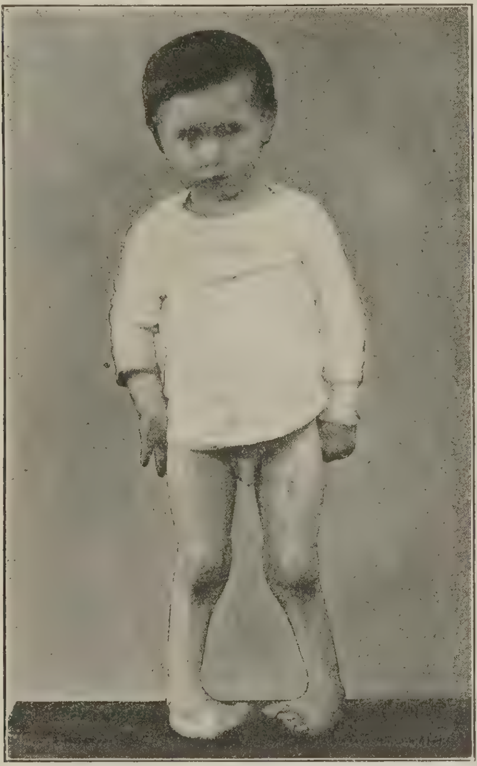

FIG. 2149.—Resistant Club Foot Showing the Secondary Knock Knees.

The internal structure of the foot corresponds to the external contour; thus the relation of the bones to one another, and the shape of the individual bones even, are more or less altered as the deformity is more or less of an exaggeration of the attitudes that the normal foot is capable of assuming. These changes are most marked in the astragalus and os calcis. The astragalus is somewhat wedge-shaped from without inward; it is plantar-flexed so that a large part of its body protrudes from between the malleoli. Its neck is often somewhat longer than normal, and it is, as a rule, depressed and deflected inward. The os calcis is also in an attitude of plantar flexion; the external tuberosity is drawn upward to the vicinity of the external malleolus, its anterior extremity looks downward and inward, and it is often twisted inward on its long axis corresponding to the deformity of the neck of the astragalus. Its external surface looks downward and forward, and it lies directly beneath the astragalus, instead of to its outer side as in the normal relation.

The scaphoid bone is drawn inward and upward, and articulates with the inner part of the deflected head of the astragalus, lying in close proximity to, and often articulating with, the internal malleolus. The cuboid is displaced upward and inward and lies to the inner side of the anterior extremity of the os calcis. The remaining bones are changed in position, but not materially in shape. In many instances the tibia is rotated inward upon the femur at the knee joint, and combined with this inward rotation there may be an inward twist of the tibia on its long axis.

The ligaments are altered to correspond to the changed relations of the bones. Those on the short side are more or less resistant according to the duration of the deformity. The muscles are normal as to their structure and their origin and insertion, but the direction of the tendons as they pass across the foot is changed. Those attached to the inverted side, the extensor and adductor group, are shortened and are relatively stronger than those on the outer side, which are lengthened and atrophied from disuse.

To sum up: all the component parts of the foot participate in the deformity. The most noticeable changes in the bones are in their position and relation to one another, but the astragalus, os calcis, and scaphoid bones are usually somewhat distorted.

The most resistant structures in the deformed foot are the plantar fascia and the ligaments that bind the scaphoid, the os calcis, and the internal malleolus to one another. The muscles that are most active in retaining and increasing the deformity are the tibialis anticus, the tibialis posticus, and the combined gastrocnemius and soleus.

The changes that have been outlined, which are comparatively slight and which may be easily rectified soon after birth, become more marked as the part develops. And when the child begins to walk, the weight of the body, combined with growth and functional use in the abnormal position, increases and fixs the deformity.

In the adolescent or adult type of club foot the deformity may be so extreme that the patient actually appears to walk on the outside of his ankles, as the term talipes implies. The feet turn directly inward, or even inward, upward, and backward, and the peculiar walk, by which interference of inverted feet is prevented, has given another name (reel foot) to the deformity.

Genu valgum is usually present in such cases. This deformity may be congenital, but it is oftener a secondary or accommodative distortion. The legs are shrunken from disuse. The foot itself is atrophied, and is much smaller than the normal. The changes in the bones are much more marked; only a small part of the articulating surface of the astragalus lies between the malleoli, and this posterior extremity is flattened out to the shape of a wedge. There is consequently an apparent backward displacement of the fibula.

All the bones of the foot are more or less atrophied, and the normal area of cartilage has, to a great extent, disappeared from the proper articular surfaces. In this advanced stage the foot serves practically as a simple rigid support.

In these extreme cases cure, in the sense of perfect functional recovery, is of course out of the question; but relief of the deformity, that is, replacement of the foot in the axis of the leg at a right angle to it and in the plantigrade attitude, is nearly always possible.

SYMPTOMS.—The symptoms of congenital club foot are practically included in the description of the deformity. The functional disability is of course considerable, although some patients are surprisingly active and are able to walk long distances. Discomfort from club foot is due almost entirely to the corns or inflamed bursæ over the bony prominences, and its degree depends of course upon the use to which the foot is subjected.

TREATMENT.—Although congenital club foot is an eminently curable deformity, yet perfect and permanent cure often requires minute attention to details during the active stage of treatment, supplemented by long-continued and careful supervision after the cure is supposed to be complete. No other deformity presents such a record of failures and incomplete cures; of relapses after apparent cure; of tedious and ineffective treatment by braces, often for many years, and of unnecessary and mutilating operations. Some of the failures may be explained by the neglect of the parents and by want of opportunity. A few are due to the unusual obstacles in the deformity itself, but by far the greater number must be accounted for by failure of the physician to apprehend the true nature of the deformity, or by his inexperience in the practical details of treatment.

Proper treatment implies suitable opportunity. Under such conditions the treatment of congenital club foot would be included in the first of the following sections:

The infantile club foot is, as has been stated, simply a twisted foot. It is true that there are slight changes in the bones, but the bones of an infant's foot are represented by yielding cartilage which will rapidly reform under changed conditions. The shortening of the muscles and ligaments may be overcome, and when the relation of the bones to one another is set right, the joints will become normal. The treatment of a club foot may then be divided into three stages:

1. The rectification of the external deformity.
2. The support of the foot in proper position during the process of transformation of its internal structure, and until the normal muscular power, unbalanced by the deformity, has been regained.
3. The period of supervision. This would include the treatment of possible complicating deformities of the knee, the laxity of ligaments, and the like, as well as the oversight of the functional use of the foot and the leg during the early years of life.

The First Stage of Treatment: Rectification of Deformity.—It should be stated at once that "rectification of deformity" does not mean apparent symmetry, a misapprehension to which the majority of failures in treatment may be ascribed. It means that when deformity is really rectified all contracted and resistant parts must have been so elongated that every passive motion and attitude possible for the normal foot is equally possible and as easily attained in that which was deformed. This is actual functional rectification, as contrasted with the simple straightening of deformity.

The most important part of the club-foot deformity is varus. The foot that is rolled over and twisted inward to the attitude of extreme adduction, must be untwisted and forced into the attitude of extreme abduction or valgus, the so-called over-correction. Until this is accomplished no attention whatever need be paid to the residual equinus. There are two reasons for dividing the procedure into two parts: first, in order that the attention of the surgeon may be concentrated on one and the most important part of the deformity; second, because by this preliminary untwisting the os calcis is brought into the upright position, into its proper relation to the astragalus, to the bones of the leg and to the tendo Achillis, so that the true degree of equinus may be appreciated.

Preliminary Manipulation. For obvious reasons, the second or third week of life is as early as mechanical treatment can be undertaken. Until then, preliminary manipulation by the nurse, more particularly manual rectification of the deformity by gently drawing the foot toward abduction and retaining it in the improved position for a few minutes, as often as is possible, may be of service in overcoming its resistance. As a treatment by itself, however, simple manual rectification is tedious and ineffective, although partial cures have been attained by perseverance with this means alone.

Mechanical rectification is the treatment of choice and routine in infantile club foot. In this treatment two methods may be described: (1) by the plaster bandage; (2) by some form of simple splint.

The principle of the two is essentially the same. The foot is drawn toward an improved position and retained there by the plaster bandage, or it may be fixed to some form of metal splint or brace whose shape is gradually changed from week to week, as the resistance lessens.

Gradual Rectification of Deformity by Means of the Plaster Bandage.—In this treatment care should be taken to avoid undue pressure, irritation of the skin, or insecurity of the bandage. Shreds of cotton should be placed between the toes, and the outer aspect of the ankle, where the skin is thrown into folds when the foot is straightened, should be smeared with vaseline. A narrow strip of adhesive plaster long enough to reach from the knee to a point an inch or more below the heel is applied to the outer side of the leg. A thin layer of cotton is wound about the leg, just below the knee, in order to protect the skin from the hard margin of the plaster bandage, and a similar strip is carried about the toes. The foot is then drawn gently toward the abducted position, often as far as the axis of the leg at the first dressing, without causing discomfort. While it is held in this position a narrow flannel bandage is smoothly applied to the leg and foot, the band of adhesive plaster being drawn out between the folds about the ankle. A very light plaster bandage is then applied from the knee to the extremities of the toes, and into this bandage the projecting strip of adhesive plaster is incorporated, so that no displacement of the dressing is possible. The turns of both the plaster and the flannel bandage are made from within, downward, and outward, in order that the tension may aid in retaining the foot. When the plaster bandage, which during the hardening process has been constantly rubbed and manipulated so that it may fit the part perfectly, has become firm, a long stocking is drawn over it and is attached to the body clothing. At the end of a week the bandage is removed. The leg and foot are gently bathed with alcohol, thoroughly dried, powdered, and protected as before, and the bandage is again applied. At this second dressing the irritated adductor muscles, after the interval of complete rest, will be much less active and the contracted tissues will be less resistant, so that the foot may be easily turned somewhat outward, or beyond the line of the leg.

After four or five applications of the bandage at weekly intervals the foot, in ordinary cases, can be held without resistance in the attitude of extreme equino-valgus. The sole, which at first looked backward, inward, and upward, is now turned in the opposite direction, forward, outward, and downward, and the inner border of the foot, which was concave, is now convex. When the varus has been completely overcome, treatment is directed to the equinus. At this stage it is sometimes of advantage to cover the bottom of the foot with a plate of thin wood (splint wood or cigar-box cover) to give the plaster bandage more solidity to aid in flattening the rounded sole. At the first application of the dressing one carries the foot upward (toward dorsal flexion), while it is still retained in the abducted position; but when the right-angled position has been attained, it is brought nearer to the axis of the leg. The pronation or eversion of the sole is retained, however, until correction is completed. In correcting the equinus, a certain amount of

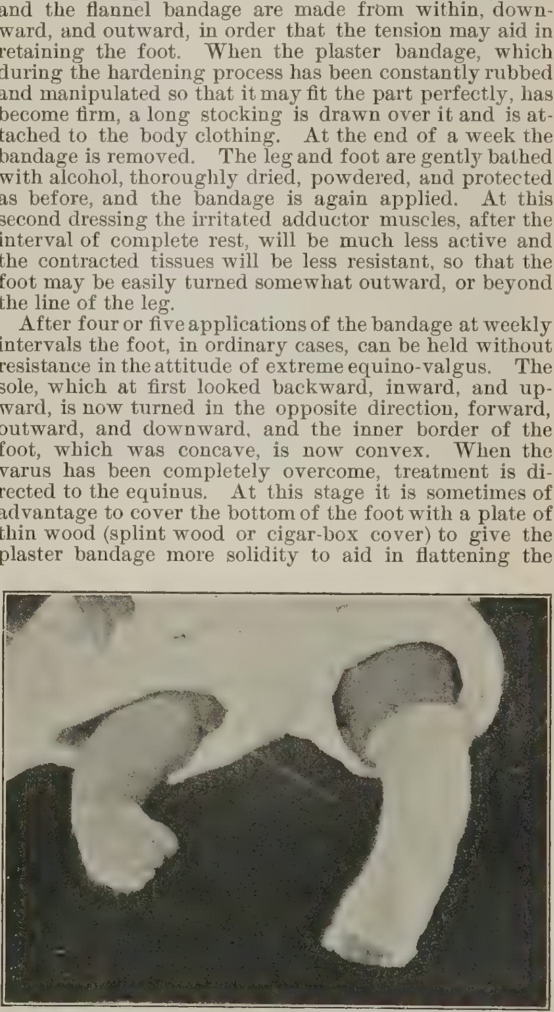

FIG. 2150.—The First Application of the Plaster Bandage, Showing the Improved Position.

force is required, sufficient to cause some discomfort during the application of the plaster, but not sufficient to cause suffering afterward. The force is applied by means of the sole plate to the entire foot so that the posterior extremity of the os calcis may be drawn downward by actual lengthening of the tendo Achillis, and not, as is often the case, by an over-correction of the forefoot, while the heel remains in its original position of plantar flexion. By the proper application of force the equinus is gradually overcome; the sharp indentation or fold at the insertion of the tendo Achillis is lessened, and the heel becomes more prominent.

The reduction of the equinus may be somewhat more difficult than that of the varus, but it should be entirely corrected in three or four months from the time of beginning the treatment.

As has been stated, correction of the deformity implies over correction; and it is well when this has been attained to hold the foot for several weeks, by means of the plaster bandage, in an attitude of extreme pronation and dorsal flexion (calcaneo-valgus) in order to impress, as it were, the new position upon its structure.

This concludes the first stage of the treatment, the simple rectification of deformity.

Correction by the plaster bandage has the great advantage of placing the treatment entirely under the command of the surgeon. When properly applied, the support fits perfectly and holds the foot in the desired attitude without undue pressure.

The disadvantages of the treatment are almost entirely due to its improper application. For instance, the bandage may be too heavy, or the padding may be so thick that it does not retain its position. Excoriations are usually due to carelessness in the application of the bandage or they result from a failure to remove it in proper season. The fear of compression, of atrophy of muscles, of stunting the growth of the limb, is groundless. At the end of the retention treatment the corrected foot is, as a rule, larger than one that has remained untreated. The stunted foot is the result of non-treatment, or of ineffective treatment by braces or otherwise; not of the enforced rest necessitated by the methodical reduction of deformity.

It may be noted in this connection that the normal infant moves the foot in various directions in a more or less regular alternation of postures, while in club foot motion is in one direction only, that toward which the foot is turned. The muscles on the back and inner side of the leg, which are alone active, become relatively irritable and hypertrophied as compared with those on the front and outer side that are disused. Thus, muscular activity of the deformed foot is in reality harmful, because it increases deformity and still further disturbs the muscular balance. For this reason the temporary restraint of motion, necessary during the rectification of the deformity, may be considered rather of advantage than otherwise. When movement is again allowed and encouraged, it must be in the directions opposed to the attitudes of deformity, with the aim of so strengthening the weakened group of muscles at the expense of the stronger, that the balance of muscular power may be re-established.

Correction of deformity may be accomplished by holding the foot in an improved position by strips of adhesive plaster, or by the elastic traction of rubber bands attached to the leg and foot. As compared with the ease, rapidity, and certainty of correction by the plaster bandage, such methods are uncertain and ineffective and they will not therefore be described in detail.

The Rectification of Deformity by Splints and Braces: Of mechanical supports there are many varieties. Complicated appliances should be avoided because they are unnecessary, and because they serve to distract attention from the prime object of treatment, the rapid and systematic correction of deformity.

Of the simpler braces, that used by Judson of New York is one of the best and will serve as a type to illustrate this form of treatment. The method of application may be described in Judson's own words:

"The apparatus which I have conveniently used to effect this reduction before the child learns to stand is a simple retentive brace which acts as a lever making pressure on the outer side of the foot and ankle, at *A*, in Figs. 2151 to 2153, inclusive, and counter-pressure at two points, one on the inner side of the leg, at *B*, and the other at the inner border of the foot, at *C*. It is advisable to keep in mind that this simple instrument is a lever, because, if we know that we are using a lever with its three well-defined points of pressure, we can make the apparatus more efficient than if we view it, in a more general way, as an apparatus for giving a better shape to the foot.

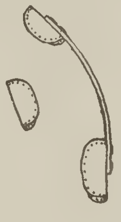

FIG. 2158.

"I use a little brace made of sheet brass, doing the work with a few simple tools. An advantage of doing the work one's self is that there is no room for doubt as to where the blame lies if the apparatus does not work well. Two curved discs, *B* and *C*, Figs. 2152 and 2153, are riveted to a shank, *D*, and thus is formed that part of the brace which applies the two points of counter-pressure, while, on the other hand, the point of pressure is brought into action by a third disc, or shield, *A*, which is drawn tightly against the outer side of the foot and ankle, and held in place by a strip of adhesive plaster *E*, which includes the limb and the piece which connects the two discs, *B* and *C*. The discs are lined with two or three thicknesses of blanket, easily renewed, when necessary, with a needle and thread. These braces are so cheap and easily knocked together that it is nothing to apply new and larger ones, using heavier material for the shank as the child grows. In general, three sizes will be enough, the shanks being 12 gauge, ⅜ in. wide; 14 gauge, ½ in. wide; and 16 gauge, ⅝ in. wide. The discs are conveniently made from 22 gauge, 1¼ in. wide. The rivets are copper belt-rivets, No. 13. A lip turned on the edge of the discs, with the flat pliers, gives stiffness to the thin brass, and protects the skin from the rough edge. If more easily obtained, tin discs, light bars of iron or steel, and ordinary iron rivets, would doubtless answer. (See Figs. 2152, 2157, and 2158.)

"The brace is applied with three strips of adhesive plaster. The upper and lower pieces, *F* and *G*, Fig. 2153, are simply to keep the apparatus in place, which they do effectively if ordinary gum plaster is used, while, by drawing the middle strip, *E*, tightly over the shield, and straightening the brace from time to time, the deformity is gradually and gently reduced. At each re-application the brace is made a little straighter than the foot at that stage. This may readily be done by the hands, and then the adhesive strip is to be tightened over the shield till the shape of the foot agrees with that of the brace. After a few days, the brace is to be made still straighter and again re-applied, and made tight till another point of improvement is gained. The brace is applied very crooked at the beginning of treatment, as in Figs. 2152 and 2153, and is straightened from time to time, and a longer brace applied as the deformity is reduced and the patient grows. It should be removed every week, or two weeks, and an interval of a few days allowed for freedom from the brace, when the mother is advised to manipulate the foot constantly, using as much force as she will in the direction of symmetry. Manipulating the foot during these intervals is of great importance, as cases have occurred in which varus and equinus have been entirely overcome by the mother's hand alone.

"By this simple and prosy treatment, carried out systematically and without haste, or violence, or pain, the foot, unless it is a frightful exception, may with certainty be changed from varus to valgus. At the same time the tendo Achillis is lengthened till the position of the foot is near the normal, or at right angles with the leg, as the result of manipulation and giving the brace from time to time a partly antero-posterior action. Figs. 2152 and 2153 show approximately the shape of the brace at the beginning of treatment, Fig. 2154 when the varus is reduced, and Fig. 2155 when valgus has taken the place of varus. The foot, in this latter stage, may not hold itself valgus, when left to itself, but with almost no force and with one finger it may be pushed into valgus."

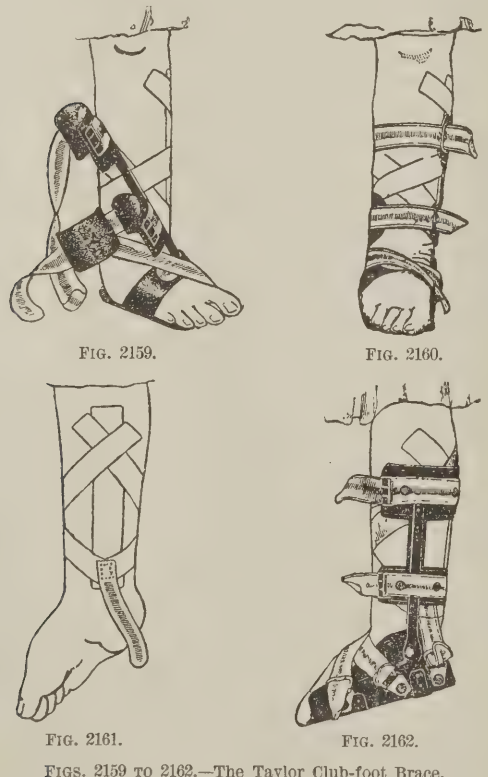

FIG. 2159. FIG. 2160.

FIG. 2161. FIG. 2162.

FIGS. 2159 TO 2162.—The Taylor Club-foot Brace.

When the varus deformity is reduced, the equinus is gradually corrected by carrying the splint behind the internal malleolus, and finally, if necessary, direct upward pressure may be obtained by lengthening the brace and applying it to the posterior aspect of the foot and leg.

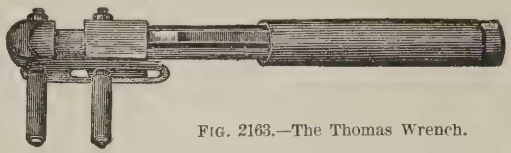

FIG. 2163.—The Thomas Wrench.

It may be noted that manipulation and stretching of the contracted parts when the brace is removed, is of much importance in the correction of deformity by this or other means. Splints of wood, tin, felt, and the like may be employed, but they present no particular advantage over that which has been described.

Tenotomy: The equinus has been spoken of as the secondary deformity, but its complete correction is sometimes more difficult than that of varus. The mechanical stretching of the contracted parts by means of the plaster-of-Paris bandage, or the brace, is often accomplished with ease, but in more resistant cases time will be gained after the foot has been forced into the position of equino-valgus, by the division of the tendo Achillis, which is the most resistant of the shortened tissues. After division of the tendon it may be necessary to use considerable force to stretch the other contracted parts, and to force the foot up to the limit of normal dorsal flexion, which is the object of the operation. Occasionally the obstacle seems to be in the posterior ligament of the ankle, and it is sometimes of service to re-insert the knife and to divide this structure, in part at least, so that it will give way under manipulation. When the foot has been forced into the position of over-correction, it is fixed in a plaster bandage which is allowed to remain for several weeks, until the interval between the separated ends of the tendon is filled in with the new tissue.

In many instances the leg is rotated inward upon the thigh, an attitude that is accompanied by accommodative changes in the ligaments of the knee joint. During the rectification of the club foot, this secondary distortion may be corrected, in part at least, by forcible manual rotation of the leg outward on the thigh, several times daily.

The management of the first stage of the treatment of infantile club foot is then—manipulation by the nurse or parents from birth until systematic rectification can be begun,—mechanical correction, first of the varus and then of the equinus deformity, terminating with a period of retention in the over-corrected position (calcaneo-valgus). Division of tendons, other than the tendo Achillis, is not often necessary. The time required for the first stage of treatment, or over-correction of deformity, should not under favorable conditions exceed three months.

The rapid and complete correction of deformity in the manner described, begun as early as possible and accomplished as quickly as possible, cannot be too strongly urged. In the first months of life the tissues are not resistant, the bones are in large part cartilaginous, and when the foot in its external appearance is rectified, the rapid growth in the first months of life will change the internal structure to conform to the normal conditions. The fear of atrophy, compression, or other harm from the temporary fixation necessary during rectification is groundless, and in fact exercise, so-called, except in the direction opposed to deformity is harmful rather than beneficial.

The Second Stage of Treatment: Support and Restoration of Function.—When the deformed foot has been corrected, in the sense that all normal motions are unhampered, the first and most difficult part of the treatment will have been completed, and in some instances a practical cure is assured. Such a result is unusual, however, for although the foot may be normal in appearance, its muscular balance has not been restored. This is shown by the fact that there is little power in the dorsal flexors and abductors to draw the foot upward and outward. For this reason, the foot must be supported in proper position until the slack of the lengthened tissues has been taken up by development in the normal attitude, otherwise the deformity must recur. Practically, support is always necessary until the child has begun to walk.

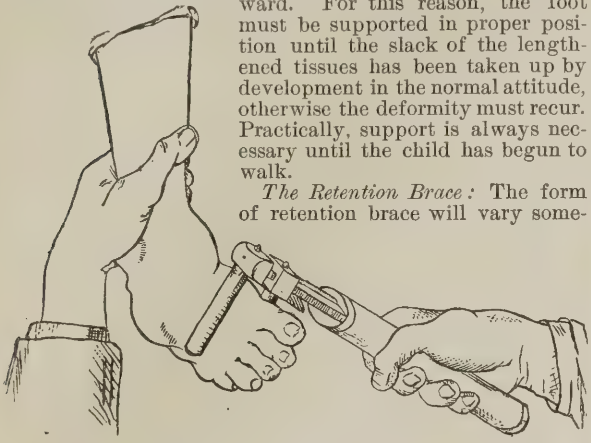

FIG. 2164.—The Thomas Wrench Applied to a Case of Talipes Equinovarus.

The Retention Brace: The form of retention brace will vary somewhat according to the indications of the individual case, the one essential being that the foot shall be supported in normal position, or better, in an attitude of slight dorsal flexion and abduction. One of the best supports is the Taylor brace, the invention of Dr. C. F. Taylor of New York. This consists essentially of a light upright that extends along the inner side of the leg to the knee, and a thin steel foot plate of the exact size of the sole, with an upright flange on the inner side rising to a point just above the dorsal surface of the foot, against which the foot is closely pressed so that recurrence of the varus deformity is prevented. The joint at the ankle is provided with a catch that prevents plantar flexion, but allows dorsal flexion (Figs. 2159, 2160, 2161, and 2162). By bending the upright and the sole plate the foot may be held in slight abduction. The apparatus is applied with straps as illustrated, and if necessary its position is further fixed by a band of adhesive plaster applied on the inner side of the leg to hold the heel firmly against the foot plate. The foot is thus held constantly at a right angle to the leg, or better, in the early stage of treatment, in an attitude of dorsal flexion and valgus. Occasionally, after complete rectification of the deformity, the foot still turns in. In most instances this is due to an inward rotation of the tibia on the femur at the knee joint, but in some cases it is caused by a spiral twist of the tibia itself. In order to correct this secondary deformity the upright of the brace is carried beneath the leg, provided with a joint at the knee, and is extended up the outer side of the thigh. At the hip it is attached by a free joint to a padded pelvic band of light steel. The band holds the upright in the proper relation to the thigh; thus, by twisting the part below the knee the foot can be rotated outward to the desired degree. In less marked cases, the retention bands used for pigeon toe may be employed. (See Pigeon Toe.)

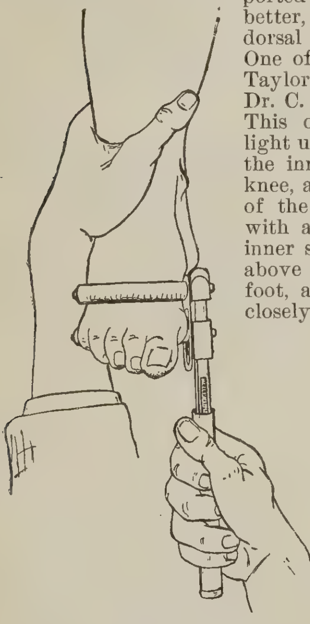

FIG. 2165.—The Deformity Partially Corrected by the Wrench.

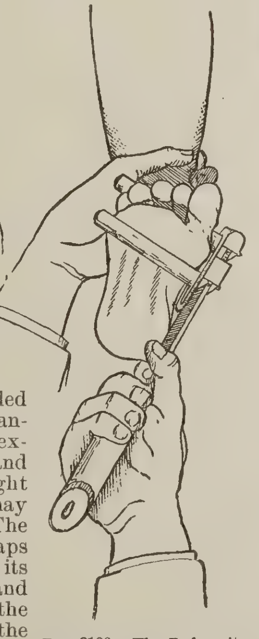

FIG. 2166.—The Deformity Fully Corrected by the Wrench.

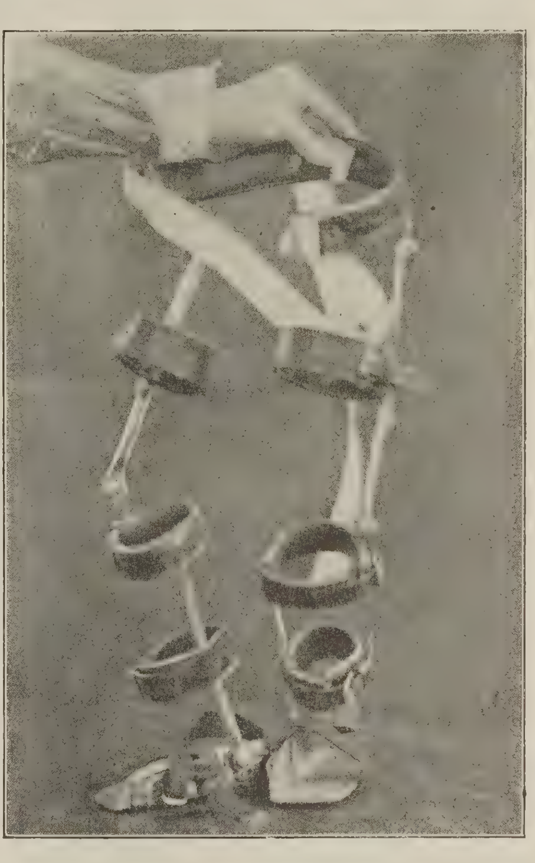

FIG. 2167.—Club-Foot Braces, to Correct Inward Rotation.

Methodical Manual Correction: Several times during the day the brace should be removed in order that the foot may be thoroughly massaged and forcibly abducted, that is, twisted outward at the medio-tarsal joint so that the inner border is made convex, and then to the extreme limit of dorsal flexion and abduction. If the leg is rotated inward, it is forcibly turned outward on the femur. Even if the tibia is actually twisted on its long axis, the influence of the brace and forcible manipulation will usually correct the deformity. If not, an osteotomy of the tibia may be required at a later period; this, however, is not often necessary. Active contraction of the weak muscles may be induced by tickling the sole of the foot or by the use of electricity; and finally, the entire limb should be thoroughly massaged before the brace is re-applied.

When the ability to dorsiflex and abduct the foot has been regained, the brace may be removed for a part of the day; later it is used only at night, and finally it may be discarded if the child walks normally. But it is best to continue the daily manipulation, more particularly the systematic stretching or over-correction of the foot, for a long time. Thus one may check the tendency toward deformity of which the first sign is always a slight limitation of the range of dorsal flexion and abduction.

In many instances the deformity may have been so thoroughly over-corrected by the plaster-of-Paris bandage or by the brace, and the after-treatment of massage and stretching may have been so efficiently applied by the nurse or parent that no support is required after the child begins to walk. On the other hand, the inclination toward deformity may be so marked that it may be necessary to hold the foot in slight abduction and valgus for a year or longer.

In other cases, the use of a light brace to hold the foot in the over-corrected position during the night is alone required. These are points to be decided by the circumstances of each case. The period of observation and supervision is included in the final stage of the treatment.

Third Stage of Treatment: Supervision.—During this period the attitudes of the limb and foot of the child in walking must be carefully watched and one should observe the signs of wear on the sole of the shoe. If it shows greater wear on the outer side than is usual, it is an indication that the weight does not fall on the centre of the foot and that there is therefore a tendency toward deformity. This must be counteracted by making the sole thicker on the outer border, or somewhat wedge-shaped, so that the weight may be deflected toward the inner side.

This third period of treatment, or rather of oversight of the functional use of the foot, must be continued indefinitely. In fact, it is the quality of this final supervision that decides in most instances whether the ultimate outcome is to be what is called a satisfactory result, or a perfect cure.

The Treatment of Neglected Club Foot.—The treatment of club foot, under what may be called the proper conditions, as outlined in the preceding pages, applies practically to all cases before the completion of the first year of life, and mechanical rectification may be successfully employed in cases far beyond this limit of age. As a rule, however, when the patient has walked for any length of time, the resistance of the tissues has increased to such an extent that more rapid and effective treatment is indicated. The investigations of Wolff have shown that the internal structure of the bones corresponds to their external contour, and that the structure and contour are adaptations to functional use. This internal structure is not, however, permanent, but is readily transformed to conform to changes in form or function. If then the external contour of the club foot were suddenly reversed, and if use of the foot were permitted in this new attitude, a transformation of the internal structure of the bones and at the same time of their shape would begin at once. This would continue until both structure and shape had become adapted to habitual function. It is upon this natural power of transformation that one depends for the final and complete change of the distorted bones to the normal; and what is true of a resistant structure like bone is equally true of the other constituents of the deformed foot.

Age as Influencing Treatment.—There is then this very essential difference between the indications for treatment in infancy and in childhood. In the first instance the foot has no essential function. In the walking child, however, the weight of the body and habitual use tend to confirm and to increase the deformity. As a general principle of treatment, therefore, walking should not be permitted until the weight of the body may aid rather than retard the correction of deformity. This is another point in favor of rapid, as opposed to gradual, correction of deformity.

The Rapid Correction of Deformity.—The principles on which operative treatment is conducted are the same as those which govern mechanical treatment. Thus the deformed foot must be over-corrected, and it must be held in the over-corrected position, until the immediate tendency toward deformity has been overcome. It must then be supported until the foot has become adapted to its new position and until the balance of muscular power has been regained. No surgical operation, however radical, can be, in childhood at least, curative by itself alone. Operative procedures are undertaken simply for the purpose of making the primary over-correction possible, and that operation by which this object can be accomplished, with the least interference with the structure of the foot, should be selected. Such an operation is what may be called forcible manual correction.

*Forcible Manual Correction.**—The patient having been anæsthetized, one first attempts to correct the sharp inward twist at the medio-tarsal joint. Supposing the right foot to be deformed, one grasps the heel with the right hand, in such a manner that the projection or muscular part of the palm lies on the outer aspect of the foot, against the most prominent part of its outer border, which is at the junction of the os calcis and cuboid bones. This hand serves as a fulcrum, over which the inverted foot may be bent. The forefoot is then grasped firmly by the left hand and one begins a series of outward twists over the fulcrum of the opposing palm, gently at first with alternate relaxation of pressure, but with gradually increasing force as the resistant tissues stretch under the tension.

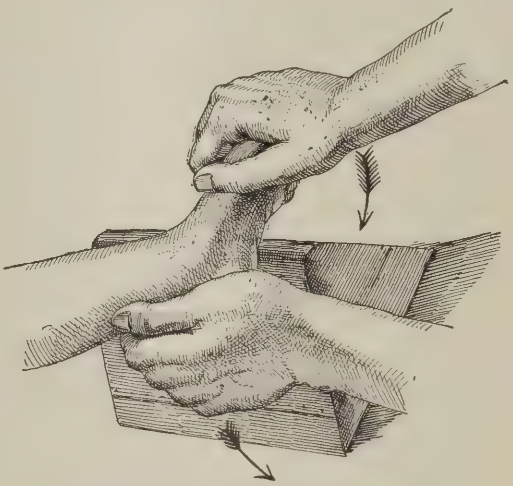

FIG. 2168.—Reduction of Varus. (After Lorenz.)

If greater force is required, a triangular block of wood, well padded, may be used as the fulcrum (Fig. 2168), one hand pressing on the heel and the other on the forefoot; but there is a great advantage in using nothing but the hands, because one feels sure that no injurious force is likely to be exerted. Under this steady manipulation, the foot soon loses its rigidity and its elastic recoil toward deformity; it becomes so limp that with two fingers one can not only hold the sole straight, but can push it or bend it outward. Thus the first stage of the methodical correction has been accomplished.

One then turns his attention to the supination which makes the outer border of the foot lower than the inner border. The leg is grasped firmly near the ankle with the left hand, and with the right the foot is forcibly twisted in a direction downward, outward, and upward, over and over again, with steadily increasing force as the tissues slowly yield, until it may be forced into a position of extreme abduction, so that the sole may be made to look outward and downward—the reverse of the former attitude.

One next stretches the contracted plantar fascia and reduces the cavus, which is usually present, by forcing the forefoot toward dorsiflexion, against the resistance of the contracted tendo Achillis, until the sole is made perfectly flat (Fig. 2169). Finally, the fourth, and often the most difficult part of the rectification, that of forcing the displaced astragalus into its proper position between the malleoli, is attempted. To accomplish this, the tendo Achillis is first divided subcutaneously, and if necessary the posterior ligament of the ankle is also divided at the same time. The patient is then turned upon his face so that with the knee resting on the table the leg is held upright. This allows one to hook the fingers about the extremity of the os calcis while the hand and arm, lying along the sole of the foot, may be used as a lever to force it toward dorsal flexion as the os calcis is drawn downward. In this manner forcible stretching is continued until the dorsum of the foot can be brought almost into apposition with the crest of the tibia. When the operation has been completed, the foot should be perfectly limp. It is usually somewhat congested from the pressure of the fingers, but it is warm and the circulation is unimpaired.

---

* First described by Delore, of Lyons.

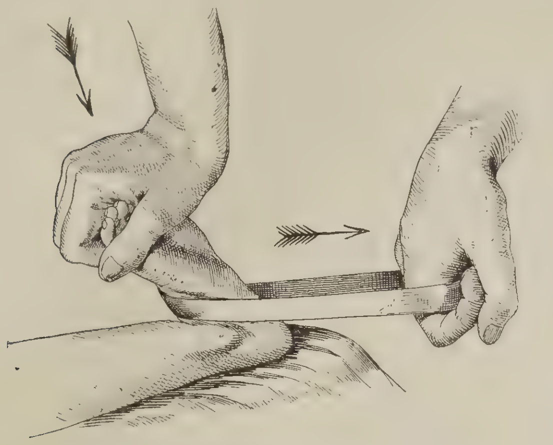

FIG. 2169.—Reduction of Cavus. (After Lorenz.)

One may assume that in the change that has taken place from rigid deformity to a limp foot that can be moulded into any position, the component parts of the deformed foot must have been subjected to considerable violence; that ligaments and muscles must have been stretched and, it may be, ruptured; that new surfaces are now opposed to one another in the articulations, and that the bones have been forced into approximately normal position. This method of treatment has a great advantage over the ordinary operative treatment, in that the entire foot has participated in the correction, instead of a limited portion, as when, for example, bone is removed by cuneiform osteotomy; and it has a second and almost equally important advantage, in that the immediate use of the corrected and yielding foot is possible in the place of the necessary rest that must follow cutting operations. For these reasons forcible massage should be the operation of choice, and preliminary, at least, to more severe procedures in the treatment of resistant club foot in childhood. The only disadvantage of the operation is the actual labor which it necessitates on the part of the surgeon, usually twenty minutes or more of rather exhausting work.

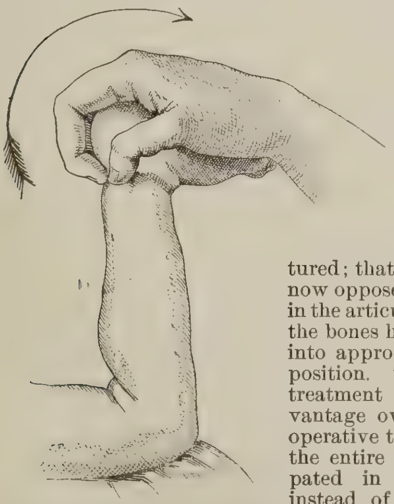

FIG. 2170.—Reduction of Equinus. (After Lorenz.)

The foot must now be fixed by a plaster bandage in an over-corrected position. It is first evenly covered with a layer of cotton and a bandage of canton flannel, and while it is held by the assistant, the plaster bandages are applied from the tips of the toes to the upper part of the thigh. It is important that the toes should not project beyond the bandage, because of the swelling that sometimes follows. It is important, also, that the foot should be held in the proper position while the bandage is hardening, and that it should not be manipulated to any extent after the bandage is applied, in order that no rigid wrinkle may press against the skin. The bandage is applied to the thigh in most instances in order that the tibia may be rotated outward to its normal position and held there, and because more effective fixation may be assured and greater pressure exerted on the foot in walking. To utilize this pressure to better advantage the bandage is made very thick beneath the sole, and a thin foot plate of wood should be incorporated in the plaster. When the bandage is applied the position of the foot should be that of over-correction of deformity, flexed beyond the right angle, twisted far outward, and the outer border should be elevated considerably beyond the level of the inner border (Fig. 2171).

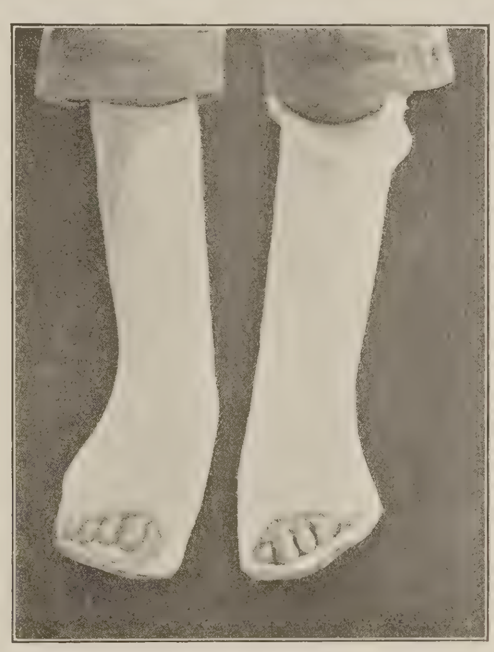

FIG. 2171.—The Feet Fixed in an Attitude of Over-Correction.

One would suppose, after using the force that has been necessarily applied, that much pain and swelling would follow. This is, however, not the case. Often, on the following day, the patients are able to stand upon the foot, and always within the first week if the bandage has been properly applied. The pain following this operation is far more often caused by pressure of an ill-fitting bandage than by the violence that has been used. Thus one should be careful to remove sections of the bandage if it appears to cause undue discomfort. These points are usually the front of the ankle, the back of the heel, and the inner border of the great toe.

The immediate use of the foot is encouraged, and although only the heel and inner border bear weight directly, yet the pressure of the foot plate on the parts that do not come in contact with the floor is usually sufficient to mould the foot into its proper shape. If greater pressure is thought necessary, wedges of wood or cork may be attached to the sole of the plaster bandage so that all parts may bear weight equally. The bandage is covered by a stocking, a slipper may be worn indoors, and an ordinary overshoe for street wear.

The first bandage should be removed at the end of about three weeks, as by that time it will have become loose. The foot will then be found to be extremely flexible, and by an enthusiast it might be considered cured. But knowledge of its previous condition should make it evident that a much longer time is necessary to allow for its consolidation in the new position. At this time almost no evidence of the operation remains, except, it may be, slight discoloration of the skin. The foot is again held as far as possible in the over-corrected position and another plaster bandage is applied, usually as far as the knee only. This should remain for eight weeks, or longer if it is still unbroken. The patient uses the foot constantly, and is drilled in the proper method of walking, so that the muscles of the leg may become accustomed to the new and normal attitudes.

At the end of another month or more, the plaster is replaced by a brace to be worn inside the shoe, usually of the simplest description, consisting of an upright bar with a calf-band, attached to a steel sole plate by a joint that will allow dorsal flexion but checks extension at a right angle. This is applied because the dorsal flexors, after years of disuse, only slowly recover sufficient power to resist the action of the opposing group and the force of gravity.

The second stage of the treatment is now begun. This may be divided into a period of active treatment and one of supervision. The first, or treatment stage, consists in massage of the entire leg and of the foot to stimulate the growth of the atrophied muscles, and methodical manipulation of the foot several times a day by pushing it with the hand to the extreme of the range of motions possible immediately after the operation, viz., eversion, abduction, and dorsal flexion, in the same order as at the time of operation. At the same time the patient attempts voluntarily to carry out these motions by his own muscles, the power being supplied by the hand of the masseur. Slowly the muscles gain in strength and ability and when normal muscular power and balance have been regained the patient is practically cured; but for long afterward supervision is kept up of the patient's attitude, of the manner of using the foot, of the wear of the sole of the shoe, and the like, and by constant drilling and stimulation the attempt is made to restore the normal appearance and function.

One cannot exaggerate the importance of this after-treatment, and of supervision at least on the part of the surgeon. The active treatment may often be left to the parents. But constant supervision is necessary to keep this after-treatment, which seems so commonplace and simple, up to the proper pitch; and to assure one's self that the range of motion regained by the operation does not gradually become more and more restricted, even though the contour of the foot appears to be normal.

Forcible manual correction may be employed with advantage from the second to the tenth year, although the limits may be extended in either direction in special cases. In this operation, as described, the tendo Achillis is the only structure divided. There is no particular objection to subcutaneous division of other tendons or ligaments in connection with forcible manual correction; but in such prolonged manipulation it is much better if the skin, which itself must be stretched, is unbroken and dry, rather than moist from the bleeding from punctured wounds. For this reason it is well to correct the deformity without extensive tenotomy if possible.

Treatment of Secondary Deformities.—In cases such as have been described a certain amount of secondary deformity of the leg is often present. Knock-knee rarely requires other treatment than daily manual correction in connection with the massage of the foot and leg.

Hyperextension at the knee will correct itself during the treatment of the foot, which, being fixed in an attitude of dorsal flexion, obliges the patient to walk with the knees slightly flexed. Inward rotation of the leg upon the thigh may be sufficient to require a brace, but, as a rule in childhood and adolescence, the patient has so long walked with exaggerated outward rotation of the femur that after correction of the deformity no inward rotation of the foot appears, even though inward rotation of the tibia be present. Osteotomy of the tibia, to correct the inward twist, is rarely necessary.

Malleotomy.—In confirmed club foot of the type under consideration, the chief obstacle to perfect correction may be the astragalus. This is often displaced forward, downward, and inward, so that only the posterior portion of its articulating surface is contained within the malleoli. In the cases of long standing the spaces between the bones may have become insufficient for the anterior and wider part of the body of the astragalus. In such instances, even after division of the tendo Achillis and the posterior ligament of the ankle, dorsal flexion still remains restricted, and examination shows that the astragalus still projects as before, although the foot has been forced into a position of apparent dorsiflexion and abduction. This apparent correction is the result of over-correction at the medio-tarsal joint, of outward rotation of the tibia upon the femur, and of backward displacement of the fibula. In such cases the malleoli may be separated from one another by dividing the ligaments that hold them in apposition.

A straight incision, about two inches long, is made on the outer side of the ankle directly over the anterior aspect of the articulation, the ligaments are divided and by inserting a thin chisel the bones are pried apart, and the astragalus is replaced in the proper position. This is usually easy if the restraining tissues on the posterior part of the ankle have been divided. The wound is then closed and the foot held in the over-corrected position by a plaster bandage. Complete correction of the varus deformity should, of course, precede this operation.

It would seem on first consideration that if immediate correction of deformity could be so easily accomplished in the confirmed case, it should be employed even in infancy. There are, however, practical reasons against it; first, because the foot is so small that it cannot be easily manipulated; second, because even after it is corrected it must be supported until the child begins to walk; and third, because the foot can be so easily straightened without an operation, which, even of so slight a character, is sometimes cause of much anxiety to the parents. For these reasons, although immediate reduction of deformity is a thoroughly practical and safe operation, it is rarely advised until a later time.

Subcutaneous Tenotomy.—The division of tendons and other tissues by the subcutaneous method has been mentioned incidentally, but as it has so long occupied an important, and even at one time the most important, place in the treatment of club foot, the operation and its effects may be described somewhat in detail.

Tenotomy, as has been stated, is performed for the purpose of removing an obstacle to the correction and over-correction of deformity. In the acquired or paralytic form of club foot, one or more shortened tendons may be the chief obstacles to reposition, but in the congenital form, in which all the tissues have grown into deformity, the shortened tendons are by no means the only resistant parts, and tenotomy should be considered, therefore, merely as an incident in correction. In the ordinary treatment of infantile club foot, tenotomy may often be dispensed with, and in the great majority of cases division of the tendo Achillis is alone required.

When the tendon has been divided, the deformity is immediately over-corrected; thus the two extremities are separated to the extent necessary to allow the improved position. At the end of three weeks or more, when the first dressing is removed, the space will be filled with new material, and in another month the splice, which will be somewhat larger and thicker than the normal, should be strong enough for use. The slight thickening at the site of the operation may be felt for a year or more, but for all intents and purposes the new and lengthened tendon is perfectly normal, as is the function of the muscle of which it is a part.

The process of repair is somewhat as follows: Immediately after the operation the space between the divided ends of the tendon is filled or partially filled with blood; then leucocytes appear, which with those in the blood clot serve as pabulum for the plasma cells which migrate from between the fasciculi of the tendon and from the tendon sheath. The fibrin and red corpuscles of the clot are absorbed, the extremities of the divided tendon soften and become fused with the new material, which begins to take on the form and consistence of true tendon, and to separate itself from the adherent sheath. This new tendon, according to Tubby, differs from the normal structure in that the fibrous fasciculi are more irregular and its substance is more like scar tissue, but practically it is perfectly normal in its appearance and function.

Since the tendon sheath serves an important purpose in repair, it should be disturbed as little as possible, and for this as well as for other obvious reasons, subcutaneous tenotomy of the tendo Achillis, which is so prominent and so distinct from other important parts, is to be preferred; but if more extensive division of other tendons is required, the open operation is often indicated.

Division of the Tendo Achillis: For this operation anæsthesia is usually required, preferably by means of nitrous oxide gas, and it is hardly necessary to state that surgical cleanliness, even in so slight a procedure, is essential.

The instrument should be small and very sharp so that no force is required in the operation; the blade should be as long as the tendon is wide. The patient is turned upon the side or to the prone position, so that the foot may be held with the heel upward by the left hand. The position and size of the tendon are ascertained by careful palpation, and the knife is then inserted to its inner side, at about the level of the extremity of the internal malleolus. The flat surface of the blade is held parallel to the tendon, and it is passed beneath it until its point can be felt beneath the skin on the opposite side. The edge is then turned upward, and the tendon, being made tense, is divided by a sawing motion of the knife. When the division is complete, as indicated by the separation of the divided ends, the knife is withdrawn, and the minute opening in the skin, from which there is usually slight bleeding, is covered with a pledget of aseptic cotton. The foot is forced into dorsal flexion and is securely fixed by a plaster bandage. In applying the dressing one should take care that no pressure is brought upon the seat of operation, as this might interfere with the effusion of plastic material. As soon as the discomfort attending the operation has subsided the patient is encouraged to stand and to walk. Functional use, far from retarding repair, is, by stimulating the circulation, an important agent in assuring firm and rapid union.

Division of the *plantar fascia* is not infrequently necessary and should be performed subcutaneously. The tenotome is inserted beneath the skin at about the centre of the concavity to one or the other side of the central band of the fascia, which is divided by a sawing motion of the knife. The part is put upon the stretch, and other resisting bands to the outer and inner side are divided in the same manner; the cavus is then corrected by manual or instrumental force. The operation, like that upon the tendo Achillis, is practically free from danger.

Division of the *tibialis anticus* is not often necessary, as this tendon offers little resistance to the rectification of deformity.

The tendon of the *tibialis posticus* may be divided together with that of the tibialis anticus near the points of attachment. If the operation is required, it may be combined with simultaneous section of the *calcaneo-scaphoid ligament,* with which are blended the anterior part of the deltoid and fibres of the anterior ligament of the ankle.* According to Parker's directions, the foot should be strongly abducted to make the parts tense. The tenotome is entered directly in front of the anterior border of the internal malleolus, its cutting edge being turned forward between the skin and the ligament. It is then turned toward the ligament, and the tissues are divided to the bone. The blade is then made to enter the interval between the astragalus and the scaphoid, and is carried downward and forward to divide the inferior part of the ligament and at the same time the tendons of tibialis anticus and posticus.

The posterior ligament of the ankle joint may be divided or sufficiently weakened, so that it may be ruptured after section of the tendo Achillis by passing the knife directly downward in the middle line upon the upper border of the astragalus.

FIG. 2172.—Resistant Club-Foot in Adolescence.

Forcible Correction of Deformity by Means of Osteoclasts and Wrenches.—In place of manual correction of deformity greater force may be employed by means of osteoclasts or wrenches. There is this important difference between the two procedures: force may be applied by the hands for as long a time as is necessary with but little danger of injury, while force applied by a machine must be momentary because of the pressure and strain on the parts where the leverage is exerted. Manual force, continuously applied, may be supposed to stretch the resistant parts, and although much less power is exerted it is often more effective than the sudden and momentary force of the wrench or osteoclast.

Correction by means of the Thomas wrench is one of the simplest and most efficient of these procedures. The wrenching may or may not be preceded by tenotomy, a point to be decided by the resistance of the parts. As a rule division of the tendo Achillis is alone necessary. The instrument is a simple heavy monkey wrench, of which the jaws have been replaced by two strong pins slightly bulbous at the ends to keep the covers of rubber tubing from slipping off (Figs. 2163–2166).

* Parker: "The Astragalo-Scaphoid Capsule."

The wrench is applied to the inner side of the foot and screwed down, so that it may "bite" and hold its place firmly, for if it slips it is likely to abrade or tear the skin; then with considerable force the foot is twisted outward and upward. The "keynote" of the operation is so to wrench the foot that it loses its elasticity, and shows no tendency to recoil toward deformity. The foot is then placed in the best possible position and retained there by the Thomas foot splint or by a plaster bandage. In certain instances one may complete the rectification at one operation, but this is not usually attempted, the procedure being repeated at intervals of a few days until the deformity has been over-corrected. In very resistant cases eight or ten applications of force may be necessary. When the deformity has been rectified, the foot is held in the over-corrected position for several weeks by the splint or plaster bandage.

As a walking appliance, a simple upright of iron with a calf band is applied to the inner side of the leg from a point just below the knee to the heel of the shoe, into which it is inserted, as is the Thomas knock-knee brace. By bending the upright the foot may be kept in slight valgus, and this position is still further assured by making the outer side of the sole of the shoe thicker than the inner, so that the weight falls upon the inner border of the foot.

In many instances the walking brace may be dispensed with in the after-treatment, but a light brace is usually worn to hold the foot in the corrected position during the night, until the power of the abductors and dorsal flexors has been regained. Massage and manipulation are used in the after-treatment in the manner already described.

Properly applied the treatment is satisfactory and free from danger. Sloughing of the tissues caused by the pressure of the instrument or by the plaster bandages has been reported, but such accidents have not occurred in the extensive practice of Thomas and Jones.

Correction by Means of the Osteoclast.—The late Mr. Grattan, of Cork, used the osteoclast that goes by his name to crush and to over-correct resistant club foot. The operation may include, besides the correction of deformity of the foot itself, fracture of the leg above the malleolus to turn the foot toward valgus, and a second fracture half-way up the limb, to overcome the twist of the tibia.

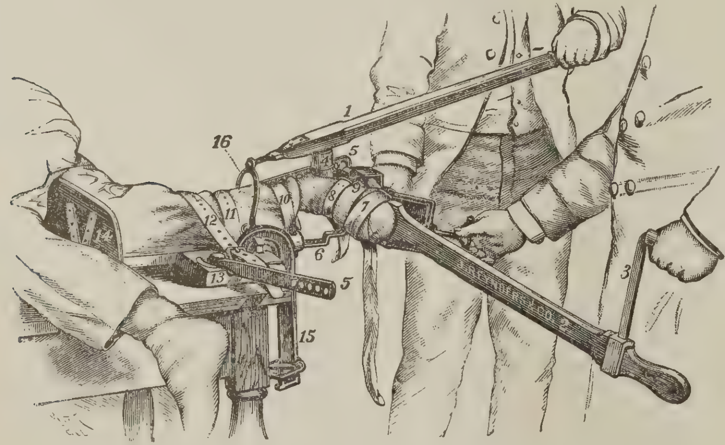

FIG. 2173.—Phelps' Machine in Use for the Correction of Club Foot in the Adult.

Other appliances constructed on somewhat similar principles may be employed. Of these the Lorenz osteoclast and the Bradford lever apparatus are the most effective.

The Open Incision Combined with Forcible Rectification of Deformity—Phelps' Operation.—When extensive division of soft parts is indicated, as in resistant cases, the open incision is to be preferred because of the opportunity thus offered for the recognition and for intelligent selection of structures that require division in the final correction of the deformity.

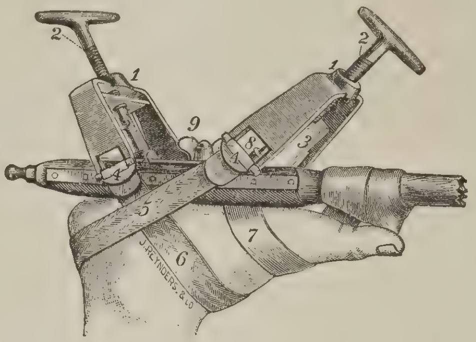

FIG. 2174.—Phelps' Machine Adjusted to the Foot.

Phelps' operation is in all essential respects simply the division of the contracted parts through an incision on the inner border of the foot, combined with the manual or instrumental force sufficient to over-correct the deformity. It is the most conservative of the more radical procedures, and by it even the most severe type of deformity in the adult can be corrected; that is to say, the deformity may be overcome and a serviceable foot may be assured to the patient. Perfect functional cure is not possible when deformity has become habitual after many years of neglect.

The steps of the Phelps operation are as follows: After proper surgical preparation the Esmarch bandage is applied. The tendo Achillis, and usually the posterior ligament of the ankle, are divided subcutaneously, and by manual or instrumental force the equinus is corrected as far as possible. An incision is then made on the inner border of the foot, just below and in front of the internal malleolus which is extended directly downward over the head of the astragalus to include the inner quarter of the sole. Through the incision all resistant parts are divided, according to Phelps, somewhat in the following order:

1. The tibialis posticus, and the anticus if it offers resistance.
2. The abductor pollicis.
3. The plantar fascia.
4. The flexor brevis digitorum.
5. The long flexor of the toes.
6. The deltoid ligament in all its branches.

During the successive division of the tissues repeated attempts are made to correct the foot, and only those structures are divided that present themselves as tense and resistant tissues when the foot is forcibly abducted.

In the adult type of club foot no attempt is made to recognize the different structures, but all the tissues on the inner side of the foot including blood-vessels and nerves, the deep ligaments, and occasionally the tendon of the peroneus longus muscle, are divided. Even then it is necessary to apply considerable force to correct the deformity (Figs. 2173 and 2174). In rare instances the rectification of deformity necessitates osteotomy of the neck of the astragalus, or the removal of a cuneiform section from the os calcis. The object of the Phelps operation is, by the use of force and by division of resistant tissues, to over-correct the deformed foot at one sitting, and as much force and as extensive division as are required should be employed by the operator.

When the foot can be held in the desired position without resistance, the wound is covered with Lister protective, the foot and leg are thickly covered with gauze and cotton, a plaster bandage is applied, and the limb is elevated. In younger subjects the patient may walk upon the corrected foot in a few days. The large gaping wound closes by granulation in from one to three months; in many instances healing is practically completed under the first dressing.

By this operation the foot, even in severe cases in adult life, may be made straight in appearance. It is evident, however, that in such cases the correction of the deformity of the bones is by no means always perfect, for the fore foot may be simply twisted outward and upward while the astragalus and os calcis may remain in an approximation to their original deformity. After thorough over-correction by the Phelps method the danger of recurrence of deformity in the adult and adolescent type of club foot is not great, and in many instances support other than that of the plaster bandage for several months after the operation may be unnecessary; but in childhood the ordinary precautions in after-treatment to prevent relapse will be necessary.

Operations on the Bones.—Osteotomy of the neck of the astragalus, as a supplementary part of the operation of forcible correction, has been mentioned. In certain instances, particularly in the adolescent or adult type of deformity, the displaced astragalus may offer such an obstacle to correction that its removal is indicated—an operation first performed by Mr. Lund of Manchester.

Astragalectomy.—The astragalus is usually removed by means of an incision passing over its most prominent part, in a direction forward and downward from the tip of the external malleolus, between the tendons of the peroneus brevis and peroneus tertius. The soft parts are drawn aside, the ankle and astragalo-scaphoid joint are opened, and the attachments to the scaphoid, and, as far as possible, those at the inner and outer border, are divided. The foot is next adducted so that the head of the bone may be seized with forceps and drawn upward; the interosseous ligament and the internal lateral ligament may then be divided with curved scissors and the bone may be removed. If after removal of the astragalus the deformity cannot be corrected, the anterior part of the os calcis or the external malleolus should be removed as well. A useful movable foot may be obtained by this operation, but it by no means assures the patient from recurrence of deformity. It is rarely indicated as a primary operation. The varus should be thoroughly corrected as a preliminary procedure; then the resistance that the astragalus offers to dorsal flexion can be estimated.

Cuneiform Osteotomy.—The removal of cuneiform sections of bone from the outer border of the foot is sometimes necessary, but the operation should be secondary to other methods of correction. The aim should be to lengthen contracted and shortened tissues on the inner border of the foot, to the extent required for reposition; not to remove bone to accommodate these shortened tissues. If this has been shown to be impossible by ordinary means, then removal of bone may be indicated, but this is practically never necessary in childhood or even in adolescence. If sufficient bone is removed from the adult foot to allow of perfect correction of the deformity, relapse is not usual; but in childhood, as has been stated, no operation will take the place of after-treatment.

The treatment by cuneiform osteotomy as it is ordinarily carried out is sufficiently simple. In severe cases, the astragalus is usually removed and a wedge-shaped section of bone is taken from the os calcis and the cuboid, and if necessary also from the scaphoid bone. The external malleolus may be removed if it interferes with reposition. Preliminary fasciotomies and tenotomies are usually performed, but those who favor this method of treatment rarely use force in reposition. In less advanced deformity the astragalus is not removed, but a part of its body and neck is included in the cuneiform resection. The foot is retained in proper position until the wounds are closed; then plaster bandages are employed for several months. Braces are seldom used in the after-treatment.

In certain cases of relapsed or ineffectively treated club foot, even in childhood, deformity of the os calcis either interferes with correction of the foot or favors relapse. In such instances the removal of a cuneiform section of bone from the anterior extremity, as a supplementary part of over-correction, may be of service.

Simple Mechanical Rectification of Deformity in Walking Children and in those of Older Growth.—It has been stated that simple mechanical rectification of deformity was possible even up to adolescence, but that the time required for such treatment, usually extending over several years, as a rule excluded it from consideration.

The simplest mechanical treatment is that by which the foot is slowly forced from equino-varus into equino-valgus by a brace on the lever principle, which is at first shaped to the deformity, and is then gradually straightened as the resistance diminishes. When the midpoint has been passed between varus and valgus the weight of the body aids in the correction of the remaining varus and equinus. The modification of the Taylor brace used by Judson, an advocate of pure mechanics in the treatment of club foot, will serve to illustrate the type of apparatus which, with slight change, may be employed to correct or to support the weakened or deformed foot.

The brace consists of an upright, a flat tapering bar of mild steel, a foot-plate of steel from 18 to 16 gauge, and a strong calf-band. The shape of the brace, the method of its attachment to the legs by straps of webbing, and its effect in gradually changing the attitude of the foot from varus to valgus are shown in the accompanying figures (Figs. 2174–2181).

The upright is firmly riveted to the foot plate in the angle of deformity, so that the patient walks upon his toes; as the equinus is decreased by the influence of the weight of the body, this angle is lessened.

The important points are, that the brace should be strong enough to hold its place under the strain of use, and that the foot shall be firmly secured to it, whether one or many straps of webbing are required, as may be seen in the figures. The use of massage and manipulation is of course combined with the mechanical treatment.

By persistent attention to the details of treatment satisfactory results can be obtained by this method in the less resistant cases, even in adolescence.

Recapitulation of the Principles of Treatment of Congenital Talipes Equino-Varus.—The object of treatment is to overcome and to over-correct the deformity at as early a period of life as is possible, and as quickly as possible. The object of over-correction is to overcome all the resistance of the tissues that may even in the slightest degree limit the normal range of motion in any direction. The foot must be supported in the over-corrected position until the recoil of the tissues toward deformity is no longer present.

It must be supported in the proper relation to the leg, and at a right angle with it, until the muscular balance has been re-established by stimulation of the weaker, and by limitation of the activity of the stronger, muscles, and until transformation of the internal structure has been completed.

If efficient mechanical treatment is applied at the proper time, that is to say, in earliest infancy, no operation, other than division of the tendo Achillis, will be required.

If the deformity is not corrected or is but partially corrected, when the child has begun to walk, some form of operation is as a rule indicated; but division of the resistant tissues must always be combined with the employment of sufficient force to accomplish the desired result, viz., over-correction of the deformity. Manual correction, applied in the manner described, is the most efficient means of attaining this object. No instrument can equal the hand, and the force that can be applied by the hand is sufficient in all the ordinary cases in early childhood, and in combination with subcutaneous division of the more resistant tendons and ligaments, even in later childhood and adolescence.

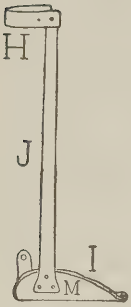

FIG. 2175.

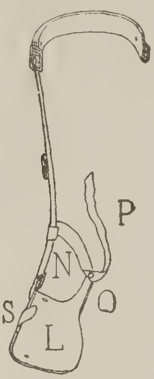

FIG. 2176.

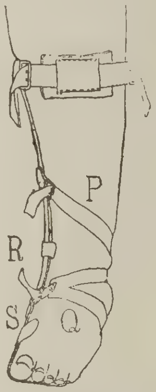

FIG. 2177.

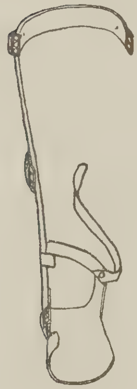

FIG. 2178.

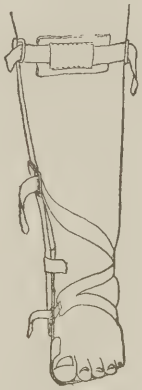

FIG. 2179.

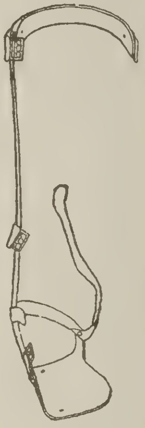

FIG. 2180.

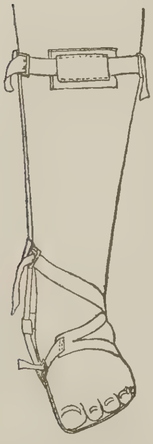

FIG. 2181.

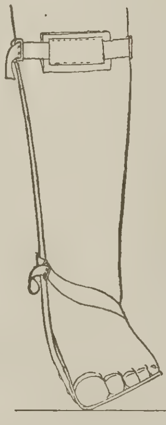

FIG. 2182.

Forcible correction by the Thomas wrench under the same conditions is an efficient treatment, but there is a manifest disadvantage in submitting a patient to a succession of operations, even of so slight a character, if immediate over-correction can be attained by other means.

The Phelps' operation, which combines thorough division of the resistant parts with the application of proper force to over-correct the foot, is the operation of selection for the more resistant cases in adolescence, in adult life, and in extremely resistant cases in childhood.

Astragalectomy and cuneiform resection are never indicated as primary operations, but one or the other may be necessary in the rectification of the deformity when other means have failed.

Complete cure of deformity, even in the later years of childhood, is possible by means of braces alone, but such treatment is very tedious. It requires not only the continuous supervision of the skilled surgeon, but the intelligent and persistent co-operation of the parents. The results are in no way superior to those attained by more rapid methods, while the disadvantages of long-continued use of braces are sufficiently obvious. To the popular faith in braces as a cure-all of deformity, and to the unintelligent use of braces, may be ascribed, now as in former times, the failure of treatment of this eminently curable deformity. This statement seems justified, even when balanced by the equally fallacious belief, so prevalent among physicians, that an operation, if not synonymous with cure, is, at least, the essential part of the treatment.

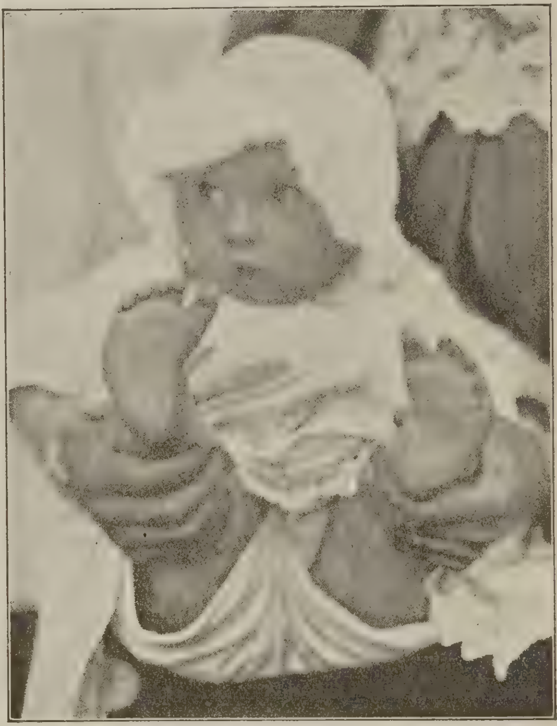

FIG. 2183.—Congenital Talipes Varus.

Rectification of deformity, by whatever means, simply completes the first stage of treatment. Perfect cure can be assured only by attention to the small details of after-treatment, by checking the slightest impulse toward deformity, and by guiding the unbalanced foot toward perfect functional use.

OTHER VARIETIES OF CONGENITAL TALIPES.—Forms of congenital distortion of the foot other than equino-varus are not uncommon, but as a rule these deformities are so slight, and, as compared to equino-varus, so easily remedied that they are relatively of little importance (Fig. 2183). This distinction does not apply, however, to acquired talipes, of which the various forms will be considered in other sections.

Congenital Talipes Varus.—This deformity often appears to be an incomplete form of equino-varus, but in some instances there is simply a slight inward twist of the foot without supination; in fact, the fore foot seems to be drawn inward by the active movement of the great toe, which in such cases seems almost prehensile (see Pigeon Toe). In the more marked form the foot is adducted and supinated, and the tissues are very resistant.

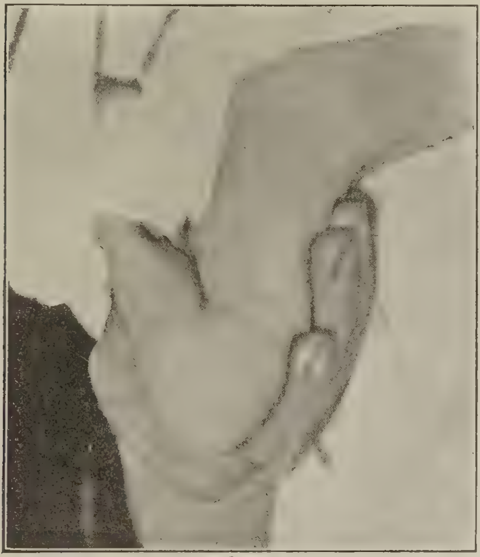

FIG. 2184.—Congenital Talipes Calcaneus.

The slight grades of deformity may be treated by simple manipulation, and if deformity remains after the first year, the shoe will, as a rule, correct it. The more marked varieties must be treated like the varus deformity of club foot, until the varus has been transformed into valgus. The after-treatment is the same as that for ordinary club foot.

Congenital Talipes Equinus.—This is a rare congenital deformity, about half as common, according to the statistics, as varus (40 cases in 1,660). The term equinus implies that dorsiflexion is limited, but that the foot is not deviated to one or the other side (toward valgus or varus). In congenital equinus the deformity is as a rule slight, and it may be overcome usually by simple manual force applied frequently. In the more resistant type, mechanical correction, or tenotomy, followed by over-correction and support, may be necessary.

Congenital Talipes Calcaneus.—Congenital calcaneus is comparatively rare (28 cases in 1,660). As a rule the heel is prominent, the foot is habitually dorsiflexed, and the dorsum can be brought into contact easily with the crest of the tibia (Fig. 2184). The exaggerated cavus that is usually present in acquired calcaneus is absent. Occasionally the deformity is accompanied by hyperextension of the knee, and if, as in many instances, there is a history of breech presentation, it may be inferred that the attitude before birth was one of extreme flexion of the thighs upon the abdomen, while the anterior surfaces of the extended legs were pressed closely to the ventral surface of the body, the feet being fixed in an attitude of dorsiflexion. As a rule the deformity is slight, and the resistance of the tissues on the anterior aspect of the leg can be overcome easily by massage and manipulation. The foot should be gently forced toward plantar flexion several times in the day, and the weak muscles of the calf should be stimulated by massage.

Cure may be hastened by the use of some simple form of retention splint to hold the foot in plantar flexion until the posterior group of muscles has recovered its power. Tenotomy or other operative treatment is not often necessary. In rare instances, the tibia may be bent slightly backward, thus increasing the deformity. In such cases the distortion of the bone may be overcome by manipulation and by apparatus.

Congenital Talipes Valgus.—Congenital valgus is somewhat more common than the preceding varieties (123 in 1,660). Not infrequently it is combined with a slight degree of calcaneus or equinus. The resistance of the contracted tissues is not great and the deformity may be overcome, in most cases, by persistent manipulation. If the muscular power is sufficiently unbalanced to warrant it, the foot should be held in the over-corrected position (varus) for some time.

Congenital valgus is one form of what is known as weak ankle, and it frequently passes unnoticed until the child begins to walk. If at that time, in spite of massage, the muscles appear weak or the foot inclines outward when weight is borne, it is well to make the sole of the shoe wedge-shaped, the thicker part (one-quarter of an inch) on the inner side. In more persistent cases, a brace may be necessary, as described in the treatment of the acquired variety (see the Weak Foot).

Talipes equino-valgus is less common. This must be treated as the other varieties by complete over-correction of deformity, manual or otherwise, by massage, and subsequently by support if necessary.

Calcaneo-valgus, calcaneo-varus, equino-cavus, valgo-cavus, valgo-cavus and cavus are extremely rare. If treated early by persistent forcible massage, these, as well as nearly all slighter grades of congenital deformity, may be corrected or cured even, before the child begins to walk.

CONGENITAL DEFORMITIES OF THE FOOT ASSOCIATED WITH DEFECTIVE DEVELOPMENT.—*Talipes Equino-Valgus Associated with Congenital Absence of Fibula.*—This is a rare deformity, but the most common of this class. The foot at birth is usually in an attitude of well-marked and resistant equino-valgus. The leg is somewhat shorter than its fellow, and the tibia is often bent sharply forward, sometimes to an acute angle, at a point somewhat below the centre, as if it had been broken in utero. At the most prominent point the skin may be adherent or it may present a dimpled appearance. In some instances the formation of the foot is perfect, but more often one or more of the outer toes, with the corresponding metatarsal bones, are absent.

The cause of deformity associated with absence of bone must be either an original defect in the germ or it may be due to interference with its development. In some instances amniotic adhesions may be one of the predisposing causes; the sharp bend in the tibia, so often present, may be due to lessened resistance of the defective part.

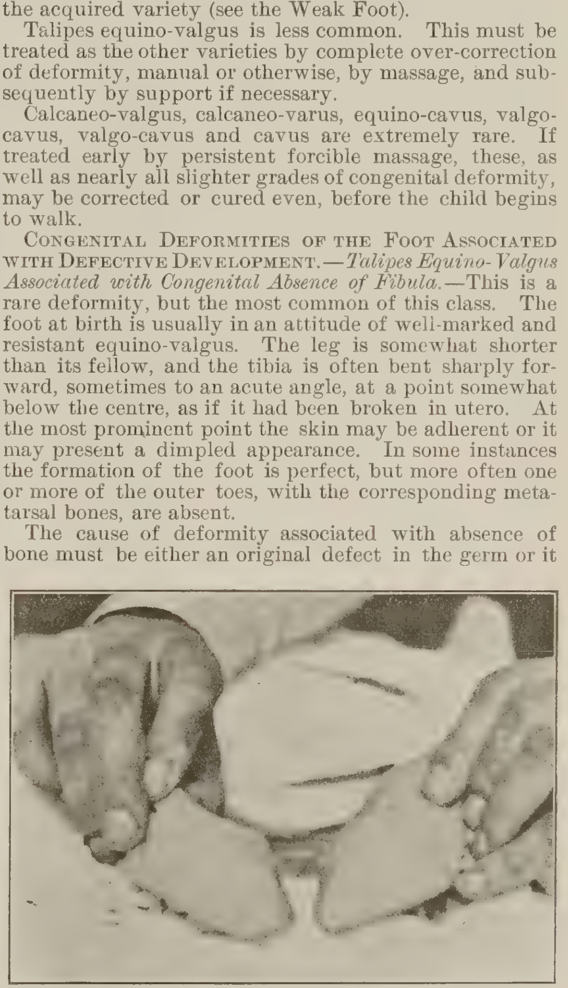

FIG. 2185.—Congenital Talipes Valgus—"Flat Foot."

Treatment.—The indications for treatment are to correct the deformity of the foot in the usual manner. The bend in the tibia may be straightened by manipulation and splinting, or by osteotomy if necessary. When the patient begins to walk the foot must be supported. A light steel upright on the outer side of the leg, provided with a T strap to hold the ankle against it, may be used to supply the place of the missing fibula. The growth of the tibia is retarded, and a final shortening of three or more inches may be expected, but with care a useful limb may be assured.

Talipes Varus or Equino-Varus Associated with Congenital Absence of the Tibia.—Defective formation of the tibia is much less common than that of the fibula. In most cases the femur is somewhat shortened and its lower extremity is imperfectly developed. The foot is practically always in an attitude of varus. The toes may be normal, but in a number of instances one is found to be lacking.

The prognosis, as regards a useful limb, is extremely bad. The growth of both the thigh and the lower leg is much retarded, and it is almost impossible to balance the foot upon the fibula by any form of brace.

The ordinary treatment, after the correction of the deformity of the foot, has been to resect the extremities of the femur and the fibula to produce ankylosis between the bones. No final results have been reported. A full account of the reported cases may be found in an article by Launois and Kuss, *Revue d'Orthopédie*, September, 1901.

Deformity of the Foot Associated with Absence of Bones.—The leg bones may be perfectly formed, but one or more bones of the foot itself may be absent. In these cases, after the reduction of the deformity, a support to hold the defective foot in its proper relation to the leg must be used.

The foot may be divided into two parts so that it resembles a lobster claw. Supernumerary toes, or deficiency of toes, or hypertrophy of one or more of the toes, with or without corresponding overgrowth of the foot or leg, are not extremely uncommon. These deformities must be treated on ordinary surgical principles.

Constricting Bands.—Tightly constricting bands of scar-like tissue, which cause deep indentations in the flesh of the foot or leg, are sometimes seen. These are supposed to be caused by amniotic adhesions. "Spontaneous amputations" of toes, or of the foot itself, are due to the same cause.

In ordinary cases the bands require no treatment, but they interfere with the nutrition of the foot. They may be removed.

Congenital Œdema of the Feet.—In rare instances, sometimes in combination with deformity, the tissues of the feet appear to be œdematous, although the circulation seems to be perfect. The condition is apparently due to obstruction of the lymphatic circulation. It should be treated by massage and compression.

Spina Bifida and Talipes.—Talipes coexisting with spina bifida should be treated as are other forms of club foot. If paralysis of the lower extremities be present, as is often the case, the corrected feet must be supported as in the ordinary forms of paralytic deformity.

ACQUIRED TALIPES.

It has been stated that equino-varus is by far the most common of the congenital deformities of the foot and that as compared with it the other forms of talipes are of slight importance.

In the acquired varieties of talipes, equino-varus is much less common (32.5 per cent. of the total number as contrasted with 77 per cent. of the congenital deformities). Acquired equinus comes next in frequency (26 per cent. as compared with 2.4 per cent. of the congenital deformities), and every variety and combination of distortion finds its representative in acquired talipes as may be seen in the table of statistics.

Etiology.—The cause of acquired talipes is almost always paralysis. In the table of statistics it may be noted that in 82.8 per cent. the paralysis was of spinal origin (anterior poliomyelitis); in 11.3 per cent. the lesion was of the brain, the talipes being a part of the deformity of hemiplegia or paraplegia. A few cases were caused by local disease of the nerves, and the remainder, 5.4 per cent., were of traumatic origin.

The distinction between congenital and acquired talipes is well marked. In the congenital form the disability is due simply to local deformity, and when this has been overcome a perfect cure may be expected. In paralytic talipes the rectification of deformity is but a part of the treatment, and perfect cure is impossible except in that small proportion of cases in which the spinal cord has sustained no permanent injury, or in which the deformity was the result of some slight or passing disability or disease.

Congenital deformity cannot be anticipated or prevented; acquired deformity is an evidence that protective treatment has been neglected. It is a result, therefore, that may be foreseen and prevented.

The characteristics of anterior poliomyelitis are described elsewhere. In its effect upon the foot the usual sequence is somewhat as follows: Immediately after its onset the paralysis is usually widespread, affecting the entire limb, for example. Then follows a period of partial recovery, after which the amount of damage that the spinal cord has sustained may be estimated. It is during the period of partial recovery, the six months or more following the attack, that contractions which lead to deformity occur. If, for example, the anterior group of leg muscles is paralyzed, the foot habitually hangs downward, a position due to the force of gravity and to the contraction of the unaffected posterior group. If this attitude is allowed to persist, the tissues accommodate themselves to the new position; the muscles that are never extended to their normal limit become structurally shortened, while the paralyzed group becomes correspondingly longer. Even within a few weeks after the onset of the paralysis the evidences of advancing deformity appear. The contracted tissues resist passive motion in the direction opposed to the habitual attitude, and the child shows evidence of pain if force is used to increase the limited range of motion. As has already been stated, paralytic talipes is an unnecessary deformity. It may be prevented by supporting the paralyzed part in a right-angled relation to the limb, and by systematic passive exercise throughout the entire range of normal motion.

Anterior poliomyelitis is most common during and after the second year of life or when the child has already begun to walk. When the first and more general effect of the disease has passed away, the child again uses the disabled limb as best it may; thus the distortion of the foot is increased and confirmed by the weight of the body and by functional use in the abnormal attitude.

The final deformity in a particular case may be predicted from the knowledge of the function of the muscle or muscles which has been lost. For example, paralysis of the tibialis anticus, the most powerful dorsiflexor and adductor of the anterior group, must result in equino-valgus; paralysis of the tibialis posticus induces valgus. If the peroneus brevis and tertius are affected varus will follow. Paralysis of the calf muscle will cause calcaneus. Paresis or paralysis of the entire anterior group will cause equinus. If all the muscles are paralyzed, what is called a "dangle foot" is the result. The cold atrophied member dangles from the attenuated leg with but little tendency to deformity unless the limb is used, when it is usually forced into an attitude of equino-varus or valgus.

A slight degree of paralysis may cause so little disability that it may be entirely overlooked, and its later effect in causing disability or deformity may not attract attention for many years. This fact has been mentioned in the etiology of the contracted foot.

Differential Diagnosis between Congenital and Acquired Deformity.—The history itself is usually sufficient, for deformity of the foot at birth is never overlooked by the mother. Acquired talipes is practically always preceded by a history of disease, or weakness, or injury which was soon followed by slight and afterward by increasing and confirmed deformity.

In paralytic talipes (anterior poliomyelitis), there is evidence of paralysis in loss of function of certain muscles, as shown by electrical stimulation or by pricking the foot with a pin; later, in the atrophy of the muscles, and the evident change in the nutrition and diminished growth of the limb.

Only in extreme and untreated cases of congenital deformity of long standing could there be difficulty in distinguishing between the acquired and the congenital deformity. In rare instances, it is true, paralysis may be present at birth, due to intra-uterine disease or to defect in the nervous apparatus. In such cases the cause of the paralysis is usually apparent (spina bifida, or spastic paralysis associated with defective cerebral development), and the treatment does not differ from that of the acquired form.

ACQUIRED TALIPES EQUINUS.

In well-marked cases, the foot is plantar-flexed to its full limit, and it is held in this attitude by the shortened structures on the posterior aspect of the leg. The patient walks upon the heads of the metatarsal bones, the toes being dorsiflexed to accommodate the attitude. The arch of the foot is increased and the tissues of the sole, particularly the plantar fascia, are contracted. The entire foot is broadened and shortened, the breadth being especially increased across the metatarsal region. On the dorsal surface the cuneiform bones are prominent, and the head and body of the projecting astragalus may be felt beneath the skin. Occasionally, in cases of extreme deformity, in which all the anterior muscles are paralyzed, the toes may be plantar-flexed so that the patient walks upon their dorsal surface.

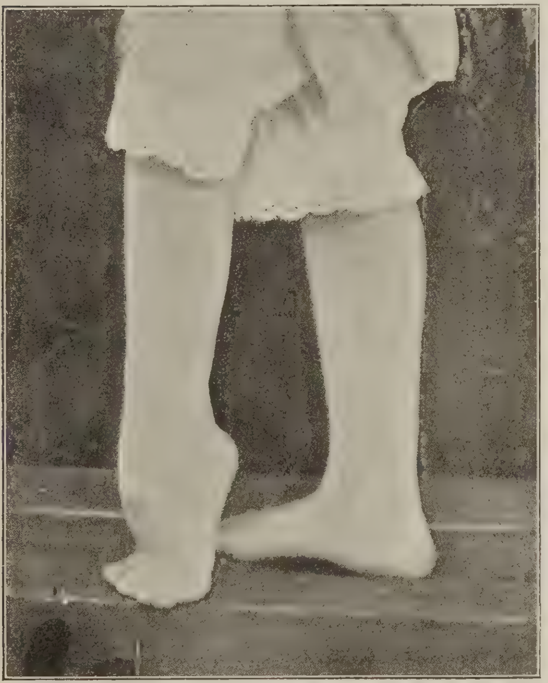

FIG. 2186.—Acquired Talipes Equinus.

The cavus or exaggerated arch is due primarily to the plantar flexion of the fore foot at the medio-tarsal joint, and in many instances this dropping of the fore foot is largely responsible for the equinus, for the os calcis is rarely plantar-flexed to the degree commonly found in the ordinary congenital equinus.

In the slighter degrees of the deformity the toes are usually dorsiflexed, an attitude due apparently to the over-action of the extensor longus digitorum and proprius pollicis, an aid in dorsiflexion.

Etiology.—Equinus in the slighter degrees is perhaps the most common of the forms of acquired talipes, and it is not at all infrequent as a result of other affections than anterior poliomyelitis, although this is by far the most important cause. The nerve supply of the anterior muscles of the foot seems especially susceptible, and toe-drop from neuritis of various types is not at all uncommon. As a sequel of infectious diseases it has been mentioned as an explanation of the slight forms of equinus first noticed after recovery from such affections.

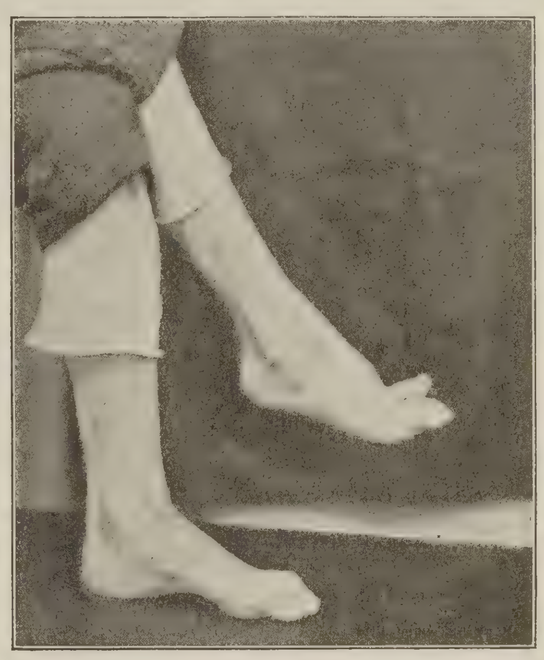

FIG. 2187.—Slight Equinus Caused by Paralysis of the Tibialis Anticus Muscle. The distortion of the toe due to the over-use of the extensor proprius pollicis is characteristic.

Equinus may be a result of cerebral disease, or even, in rare instances, of pseudo-hypertrophic muscular paralysis or of locomotor ataxia. It is sometimes induced by habitual posture, as after long confinement to the bed for the treatment of fracture, or during the treatment of hip disease by apparatus. The contraction may be an effect also of voluntary posture as when the patient habitually walks upon the toes because of a short leg. It is a very common result of neglected disease at the ankle joint, and it may be due to direct injury; but as of paralysis, so of these less frequent causes it may be said that equinus need never follow, if the foot is protected.

The changes in the internal structure of the foot are secondary to the deformity and are more marked in the cases of long standing originating in early life than in those that follow other forms of deformity; the tissues on the long side are lengthened and attenuated while those on the short side become contracted. The bones themselves are but little changed in gross appearance, but the articulating surfaces are in different relation to one another; for example, only the posterior aspect of the astragalus is in relation to the tibia, while only the lower part of its anterior surface articulates with the scaphoid bone.

In all cases of equinus there is a strong tendency toward lateral deviation to varus or valgus, particularly in cases of paralytic origin.

Symptoms.—If the limb is actually shorter than its fellow, and if the foot is firmly fixed in the deformed position, surprisingly little discomfort or disability may be experienced other than from corns or calluses beneath the metatarsal bones. If the limb is not shorter, the additional length caused by the equinus must be compensated by an upward tilting of the pelvis, which may induce symptoms of discomfort in the lumbar region. The gait is always awkward, giving the impression as of stepping over an obstacle. If the foot is not fixed but simply hangs downward when it is lifted, the gait is very awkward because of the insecurity and because of the exaggerated flexion of the knee at each step, necessary in order that the pendent foot may not drag upon the ground.

If the equinus is extreme, the limb is usually flexed at the knee when in use; if the equinus is slight, the strain resulting from the limitation of dorsal flexion is felt at the knee, and in childhood at least there is often a well-marked tendency to over-extension, or recurvation, caused by the effort to place the sole flat on the ground.

In the slight forms of equinus, discomfort about the calf is experienced; the limitation of dorsal flexion causes a rather shortened stride and awkward gait, while an unguarded step that throws a sudden strain upon the rigid heel cord is felt as a shock and strain through the leg and body. Very often the patient complains of pain about the metatarsal bones (anterior metatarsalgia), and if the equinus is accompanied by a slight degree of valgus, symptoms of the weak foot may be present.

The *Prognosis* depends of course upon the cause of the deformity. If it is simply the result of posture, or if it is secondary to neuritis, permanent cure may be expected. In many cases caused by anterior poliomyelitis recovery of function, complete or partial, has taken place; yet although voluntary control of the muscles has been regained it cannot be exercised because the foot is held in the distorted position by the contracted tissues.

In such instances practical cure may be predicted if, after the over-correction of deformity, sufficient time is allowed for the lengthened and atrophied muscles to regain their proper length and volume.

Treatment.—In the somewhat uncommon cases of fixed equinus combined with a short leg and not attended by discomfort, no treatment is required other than a shoe so built that the heel may support a part of the weight. In the more extreme cases in which the leg is short and the foot is atrophied, an extension foot attached after the manner of an artificial leg may be worn with comfort and with but little evidence of deformity.

In the ordinary cases, whether permanent cure is expected or not, the rule holds good that the heel should bear the weight of the body and that the range of dorsal flexion should not be limited when the calf muscle retains its power. If the nervous apparatus has received permanent injury, the foot must be supported after the deformity has been rectified; but even in this class the gait may be improved and the discomfort relieved by removing the restrictions to normal motion. The slighter degrees of equinus, such as those that are seen soon after the onset of anterior poliomyelitis, may be rectified by simple manipulation and retention in a splint or in plaster of Paris.

The Shaffer extension shoe is also a useful appliance, and is especially so in that it may be employed to reduce the accompanying cavus at the same time.

The weight of the body may be utilized as a means of overcoming slight equinus, when the foot is held in its proper relation to the leg by a brace which extends above the knee; but this tedious method has but little to recommend it in ordinary cases. The elastic tension of straps and bands attached to a brace or to the foot itself by means of adhesive plaster is of some service in slight cases, but by far the most effective method is the immediate reduction of the deformity by a simple forcible manipulation under anæsthesia, or by tenotomy combined with forcible manipulation, or by wrenching.

Immediate Correction of Deformity.—Attention has been called to the cavus as an accompaniment of confirmed equinus, and whenever one attempts to correct the deformity by force, the exaggerated arch should be reduced to its normal depth, otherwise the foot will appear stunted and deformed.

One of the most effective procedures for overcoming the cavus is the use of the Thomas wrench. The contracted bands of the plantar fascia are first divided subcutaneously, the wrench is then fixed to the foot, and, with sudden force exerted against the resistant tendo Achillis, the foot may be straightened, the deep ligaments being ruptured or stretched to the proper degree. The tendo Achillis is then divided, and the foot having been dorsiflexed is fixed by a plaster-of-Paris bandage. As the patient is encouraged to walk upon the foot as soon as possible, the weight of the body forcing the relaxed tissues against the unyielding sole, completes the flattening of the arch. In many of these cases the knee has been over-extended by use in the deformed attitude, so that the habitual flexion necessary to bring the dorsiflexed foot upon the ground during the two months allowed for the complete union of the divided tendon is of benefit as it serves to correct this secondary weakness and deformity.

The importance of the immediate relief of the strain of the deformed position upon the weak anterior group of muscles, together with the complete relaxation of the over-stretched tissues which allows the "slack to be taken in" during the long rest in the over-corrected position, is not generally appreciated. Whenever the weakened muscles after paralysis show by tests, electrical or otherwise, that they have recovered their power in part, this treatment should be that of selection. The application of electricity or other form of stimulation to muscles that are unable to exercise their function because of contraction of opposing tissues is useless. Nor is any form of artificial stimulation equal to that of the functional use, which is made possible by the removal of the deformity and by the employment of proper support.

In many instances after the equinus, which more often than any other deformity is the result of slight or temporary disability of the anterior group of muscles, has been corrected in the manner described perfect cure seems to have been attained when the plaster bandage is finally removed. But even in such cases the application of a simple support to hold the foot at a right angle with the leg for several months is an advantage. The after-treatment by massage, muscle-beating, electricity, and the like, combined with methodical passive movements to the limit of dorsal flexion to guard against recontraction of the calf muscle, should be continued for a long time, or until the muscular balance has been regained.

The same form of support is necessary in cases of hopeless paralysis, to hold the foot at a right angle with the leg. The common form is a simple steel sole plate of sufficient size to support the foot and the toes, if their muscles are paralyzed, attached to a light upright provided with a calf band. The upright is usually applied on the inner side of the leg where it is least noticeable. At the ankle there is a "stop joint," which allows dorsiflexion but prevents the toe-drop. This, when properly fitted, can be placed inside the ordinary shoe, as the paralyzed foot is usually somewhat smaller than its fellow. If the toes do not need support, the upright can be attached to the outside of the shoe and the foot plate may be dispensed with; or the upright may be concealed by introducing it inside the shoe to a joint sunk in the heel; the toe-drop being prevented by straps passing from the front of the upper leather of the shoe to the calf band.

Equinus due to posture or disease may be cured by simple correction of the deformity. That due to fracture, when the deformity is caused by displacement of the bones, may be treated by direct operation or by the removal of a cuneiform section from the anterior surface of the tibia above the ankle.

ACQUIRED TALIPES CALCANEUS.

Acquired talipes calcaneus is much less frequent than equinus and it is almost always of paralytic origin (anterior poliomyelitis).

There are several varieties or grades of the deformity. In the early stage, and especially if all the muscles of the posterior group have been paralyzed, the foot assumes an attitude of slight dorsiflexion and the range of plantar flexion is gradually lessened by secondary contractions. This variety resembles closely the congenital form. In the ordinary and typical form of calcaneus, when fully developed the patient walks, as the name implies, on an elongated heel. The arch of the foot is much increased in depth, and the fore foot is atrophied and useless.

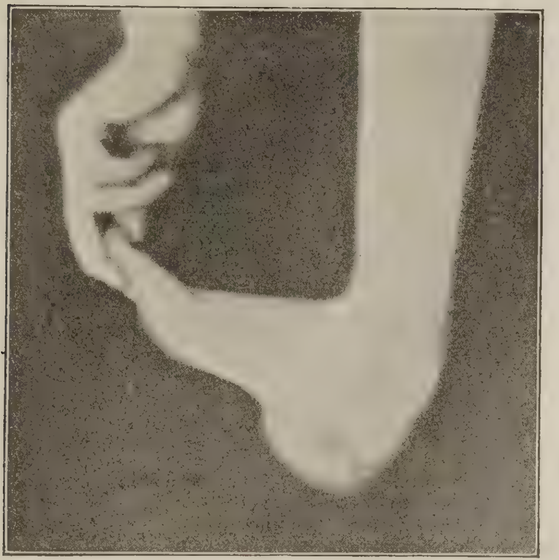

FIG. 2188.—Acquired Talipes Calcaneus.

The development of the deformity is somewhat as follows: The support of the calf muscle being removed, the os calcis, in the foot that is used, gradually assumes an attitude of dorsiflexion. It stands on end so that its posterior surface becomes inferior. The posterior projection of the heel is lost and it lies in the plane of the atrophied calf. The change in the position of the os calcis increases the distance from the malleoli to the ground; thus calcaneus, though in less degree than equinus, makes the leg longer. The turning of the os calcis on end shortens the foot and increases the arch; thus cavus in more marked degree than with equinus accompanies calcaneus. The cavus is a later complication of nearly all cases of paralytic calcaneus. In many instances there is no permanent dorsiflexion or elevation of the forefoot, although in all the range of plantar flexion is limited. In this class the power in the remaining muscles of the posterior group is probably sufficient to counteract the contraction of the dorsiflexors. Cavus is thus a direct effect of the displacement of the os calcis. If the entire posterior group of muscles is paralyzed, while the anterior muscles are unaffected, the foot will be somewhat dorsiflexed and the cavus will be less marked. If the calf muscle only (gastrocnemius and soleus) is paralyzed, the remaining muscles of the posterior group will counterbalance the dorsiflexors and at the same time increase the cavus. In some instances the calf muscle is alone affected, in others one or more of the anterior muscles may be paralyzed also, in which case the foot is usually turned toward varus or valgus. The changes primarily caused by the paralysis and by unopposed muscular action become fixed by habitual use and by secondary adaptation of the tissues. The heel only is used in walking, and the area of callus which marks the weight-bearing surface becomes much enlarged, while the fore foot and toes, which have but little functional use, become atrophied, a mere appendage to the enlarged heel.

Symptoms.—The gait is awkward and inelastic; the patient, who is, as it were, "ham-strung," stamps along upon the insecure support of the heel in a manner which is easily recognizable by one familiar with the disability. The changes in the internal structure of the foot, the inevitable adaptations to the deformity, do not call for especial description; the disused bones atrophy together with the other tissues and new articulating surfaces form to accommodate the necessities of functional use.

Treatment.—When the diagnosis of paralysis of the calf muscle is made one may predict, unless recovery takes place, a deformity such as has been described. This deformity may be prevented by proper support, by massage, and by methodical stretching of the tissues that have a tendency to contract. The form of brace used for walking and for support should be provided with a sole plate, upright, and calf band, as already described in the treatment of paralytic equinus. If motion is allowed at the ankle it should be in plantar flexion only, the stop being the reverse of that used in equinus, or as this form of check entails much strain upon the brace, the joint may be omitted as in that form used by Judson. Thus the strain removed from the weakened tissues is borne by the anterior surface of the leg. Other forms of braces provided with elastic bands to supply the place of the calf muscle are sometimes used, but as a rule the improvement in gait hardly compensates for the trouble in adjustment or the conspicuousness of the appliance.

The most important part of the actual deformity of calcaneus is the cavus due to the changed position of the os calcis; and in confirmed cases it is practically impossible to reduce this completely because the absence of the tendo Achillis takes away the point of resistance that makes the corrective force efficient. If the deformity is not marked operative treatment is not required. The foot may be drawn as far as possible toward equinus and fixed in a plaster bandage. Upon this the patient may walk, the heel being built up with cork wedges to make the sole level. When the contraction of the anterior tissues has been overcome, the brace is applied and the usual treatment of manipulation and massage is continued.

The method of prolonged fixation in the attitude of equinus by means of the plaster bandage is often very efficacious in childhood and cures of apparently hopeless cases by this means have been reported.

Operative Treatment.—In more extreme cases immediate reduction of the deformity under anæsthesia may be attempted. The plantar tissues, more particularly the plantar fascia, may be divided and by forcible manipulation or wrenching the foot may be somewhat lengthened and the heel pushed somewhat upward and backward, so that the foot may be fixed in a plaster bandage in slight plantar flexion. The tissues on the front of the leg that require elongation are those directly in front of the ankle. It must be borne in mind that in correcting the deformity one must not force the forefoot downward, as this would simply increase the cavus, but whatever overcorrection is gained should be by means of elevation of the os calcis and elongation of the plantar tissues.

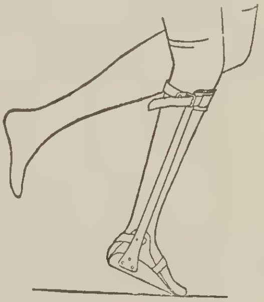

FIG. 2189.—Judson's Brace Applied for Talipes Calcaneus.

In some instances the improved position of the os calcis may be confirmed by shortening the tendo Achillis, as first performed by Willett, of London (St. Bartholomew's Hospital Reports, vol. xvi., 1880, p. 309).

Willett's Operation for Calcaneus.—A Y-shaped incision about two inches in length is made through the tissues down to the tendon. At the lower or vertical part of the incision, which is continued down to the tuberosity of the os calcis, the tendon is dissected free from the surrounding parts. It is then divided in an oblique direction from within outward and downward, and the heel having been pushed upward as far as possible, the divided ends are overlapped and sutured; the flap of skin is drawn downward at the same time, so that the Y incision is converted into the shape of a V. According to Mr. Willett's original directions, deep sutures are passed through the skin flaps and through the tendon on either side, so that all the tissues are united. The foot is then fixed in a plaster bandage, in the attitude of equinus, and the patient is allowed to walk about wearing a high heel to compensate for the elevation of the sole.

The operation is of especial value in those cases in which some power remains in the calf muscle, which is thus made serviceable. In cases of complete paralysis the position of the foot may be temporarily improved, but unless proper support is used afterward, the tissues will stretch under the strain of use; thus the treatment should always be supplemented by a brace of the character already described.

Astragalectomy and Backward Displacement of the Foot.—In cases of confirmed calcaneus, or calcaneus especially if combined with lateral deformity, removal of the astragalus may be indicated. This operation permits the malleoli to be brought into direct contact with the os calcis, thus improving the security of the foot.

The astragalus may be removed by a long curved external incision passing from the tendo Achillis just below the outer malleolus to the front of the joint. The peronei tendons are divided, the foot is displaced inward, and the astragalus is removed. The articulating surfaces of the leg bones and of the os calcis are denuded of cartilage; the tendo Achillis is shortened and to its insertion the peronei tendons are attached, if the muscles are active. The entire foot is then displaced backward so that the denuded malleoli overlap the anterior extremity of the os calcis. The object of this procedure is to throw the weight of the body upon the centre of the tarsus; thus the deformity is reduced and the stability of the foot is increased.

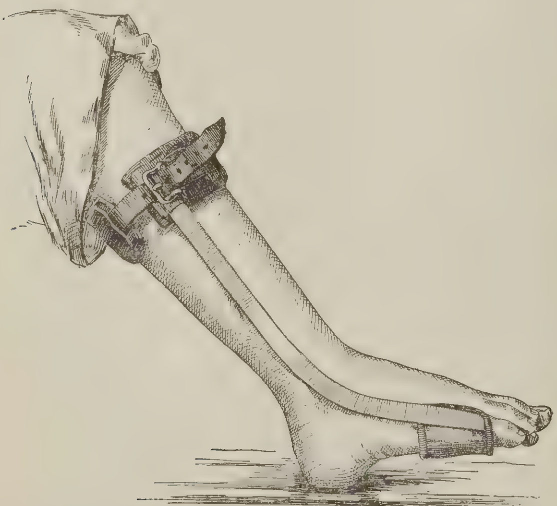

FIG. 2190.—Whitman's Brace for Talipes Calcaneus. Two lateral bars of thin steel connected by a foot plate and anterior leg band. The brace is supported by the shoe which should be elevated sufficiently at the heel to hold the foot in slight equinus.

The wound is closed and the foot is fixed in plaster of Paris. As soon as possible the patient uses the foot in standing and walking. Ultimately apparatus may be dispensed with, but a brace may be used for a time with advantage. This operation has been performed in many instances by the writer, for whom it is now the treatment of choice in this type of cases. By it the usefulness of the foot is greatly increased and its appearance very much improved.

ACQUIRED CALCANEO-VALGUS AND CALCANEO-VARUS.

In many cases the foot deformed as a result of paralysis of the calf muscle is in addition turned in a lateral direction, so that the weight of the body falls to the inner or outer side of its centre.

Calcaneo-valgus, in which the foot is turned outward and upward so that the patient walks on the inner side of the heel, or even on the inner ankle, is not uncommon; the opposite deformity is far less so. Calcaneo-valgus is usually a result of more extensive paralysis than simple calcaneus. For example, all the muscles about the foot may be disabled except the peronei, or in cases of a milder type the tibialis anticus may be the only muscle of the front of the foot that is paralyzed.

Treatment.—When the foot inclines toward calcaneo-valgus it is difficult to hold it in proper position. The usual method is to apply the brace used for ordinary calcaneus, with the upright on the outer side of the foot; the ankle and arch are then held against it by means of the valgus strap. Another form of brace is provided with an upright on either side of the leg, the outer being slightly longer than the inner so that the sole plate is tilted inward, or as it were supinated; thus the weight is guided toward and balanced on the outer side of the foot. It must be borne in mind that other muscles of the limb are often paralyzed, so that the deformity of the foot may be but a part of more general distortion; hence the foot brace is often combined with apparatus for the support of the leg.

In these cases the deformity may be reduced and the stability of the foot may be increased by the removal of the astragalus in the manner described.

Calcaneo-varus is a much less serious affection, since the foot may be more easily supported. A brace such as is used in the treatment of ordinary varus, without motion at the ankle or provided with a reverse stop, is ordinarily employed.

ACQUIRED TALIPES EQUINO-VARUS.

Talipes equino-varus is, as in the congenital form, the most common of the paralytic deformities of the foot.

The tendency of simple equinus is usually toward varus, because in plantar flexion the foot is slightly adducted, and because the outer side of the foot is shorter than the inner side, so that in walking with the foot extended the tendency of the foot is to turn somewhat inward.

Equino-varus is usually preceded by equinus and the etiology of the one will serve for the other.

In certain cases the varus is more marked than the equinus, as, for example, when the abductors of the foot are paralyzed while the adductors retain their power; or in cases of direct injury as in fracture at the ankle; or when the growth of the tibia has been arrested as the result of injury or disease.

The appearance and effect of the deformity are sufficiently indicated in the description of the congenital form.

Treatment.—If the distortion is recent and therefore non-resistant, the treatment consists in supporting the part in proper position by a brace, of which the Taylor club-foot apparatus is the type. During the night the over-corrected attitude may be assured by a strap running from the upright to the sole plate. Massage, electrical stimulation, and the like may be applied as in the routine treatment of anterior poliomyelitis.

If the deformity is fixed it should be reduced and over-corrected by forcible manipulation under anæsthesia. Division of the resistant parts is less often necessary than in the congenital form, but should be performed in suitable cases. The over-corrected position should be retained until time has been allowed for the recontraction of the lengthened tissues, preferably for several months; such rest in the over-corrected position is by far the most effective treatment that can be applied to a weak or paralyzed part.

Astragalectomy and cuneiform osteotomy are rarely indicated, but the latter operation is sometimes of service in checking the tendency toward recurrence of deformity which is more marked after over-correction in the paralytic than in the congenital talipes.

Acquired Talipes Equino-Valgus.

Simple equino-valgus is usually the result of primary paralysis of the tibialis anticus, the most powerful of the dorsal flexors; thus the foot is drawn somewhat outward in dorsal flexion, while the metatarsal bone of the great toe, having lost the support of the tibialis anticus muscles, falls downward and is drawn outward by the peroneus longus. In this type one's attention is often attracted by the peculiar appearance of the great toe which is deformed somewhat like a hammer toe by the over-action of the flexor longus pollicis in its attempt to take the place of the tibialis anticus. The equinus is usually slight and is secondary to the valgus. If the tibialis posticus is paralyzed in addition, the lateral displacement of the foot is more marked.

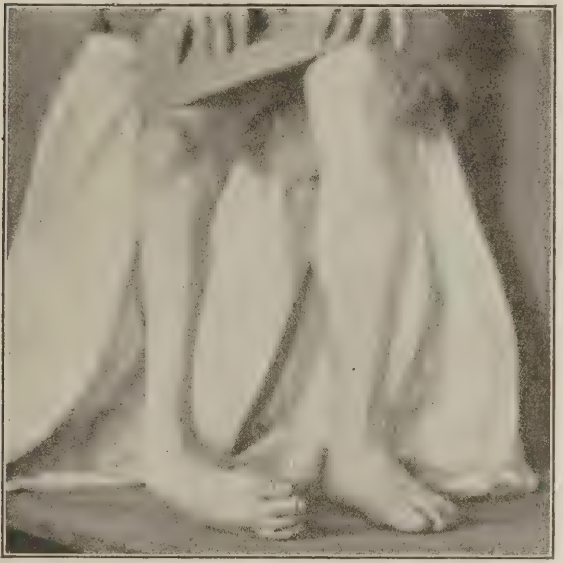

Fig. 2191.—Paralytic Deformity of the Foot, of the Varus Type. The atrophy and shortening of the limb are evident.

Treatment may be begun by placing the foot in a plaster bandage in an attitude of varus and allowing the patient to walk upon it until the tendency toward deformity has been overcome. A support with the catch, as for toe-drop, is applied to the shoe while the tendency toward valgus is checked by raising the inner border of the sole or by the use of a sole plate, as in the treatment of the simple weak foot.

Acquired simple talipes valgus, from paralysis of the tibialis anticus and posticus, is rare. Talipes valgus, as when the foot is dislocated outward, in cases of complete paralysis of all its muscles, may be regarded as a variety of dangle foot.

Talipes valgus, sometimes called spurious valgus, the simple weak or flat foot, has been described.

Traumatic valgus and equino-valgus, due to fracture at the ankle (Pott's fracture), may be treated by osteotomy of the tibia above the ankle in order that the proper relation of the leg to the foot may be restored. Equino-valgus of slight degree is not uncommon after tuberculous or rheumatic disease at the ankle or at the astragalo-scaphoid joints. This is practically one variety of the weak foot.

Talipes from Other Causes.—Talipes caused by cerebral disease or injury, whether of the paraplegic or hemiplegic type, is almost always in the form of equino-varus. The hemiplegic form of talipes is usually more unyielding and rigid than the paraplegic type.

The deformity must be corrected by the ordinary methods. In many instances, when the contractions are not marked, the after-treatment by a brace is not necessary.

Hysterical equino-varus or other forms of deformity are not especially uncommon. The diagnosis can be made by the other symptoms of hysteria, from the history of the onset and duration of the distortion, and from the appearance of the deformity which is evidently merely an assumed posture.

Tendon Transplantation for the Relief of Paralytic Talipes.—When one or more of the muscles are paralyzed the unbalanced action of those that remain tends to distort the foot. The object of tendon grafting or muscle transplantation is to utilize the power that remains by giving an active muscle a new point of attachment where it may be of service instead of an agent of deformity.

Tendon grafting is, as the name implies, the operation of attaching the tendon of a living to that of a paralyzed muscle. The first operation was performed by Nicoladoni in 1882 for the relief of paralytic calcaneus (*Archiv f. klin. Chir.*, 3, 27, S. 660, 1882). The tendons of the peroneus longus and brevis were divided behind the external malleolus, and the proximal ends united to the distal extremity of the divided tendo Achillis. The result was said to be satisfactory.

The first operation on the front of the foot was performed by Parish of New York (New York *Med. Jour.*, October 8th, 1892) for the relief of paralytic valgus, by attaching the tendon of the extensor proprius pollicis to that of the paralyzed tibialis anticus, without division of either tendon. In more recent years the field of the operation has been extended to include almost every possible combination of tendons and muscles.

Tendon grafting is most effective as a curative operation when but one muscle, for example an adductor or an abductor, is paralyzed. The most common form of this milder type is paralysis of the tibialis anticus, resulting in secondary equino-valgus. In Parish's operation the tendon of the adjoining extensor proprius pollicis was simply attached to that of the tibialis anticus, but as the extensor of the great toe is a very weak muscle, its power is hardly sufficient for the double task.

A more efficient procedure is to split the tendon of the paralyzed muscle. The outer half is then separated from its muscular attachment and the distal extremity is carried across the foot and is sutured to all the other tendons. The proprius pollicis is then attached to the inner half. In cases of longer standing and more marked deformity it is well to reduce the power of the abductors by cutting the tendon of the peroneus tertius from its insertion. This is then drawn beneath the other tendons and is attached to that of the tibialis anticus. All of the tendons may be sutured to one another, so that all may act as direct dorsal flexors.

If varus has resulted from paralysis of the peroneus tertius or brevis, or if there is weakness of the extensors of the toes, while the tendon of the tibialis anticus retains its power, it may be split, and the outer half, having been separated at the distal end, may be passed beneath the other tendons to be attached to the peroneus tertius, or a new attachment to the tissues on the outer border of the foot may be made.

Every variety of combination has been employed. The tendon of the peroneus longus has been brought across the foot and attached to the tibialis anticus for the relief of valgus, and a portion of the inner part of the tendo Achillis has been utilized for the same purpose, a procedure, however, that can hardly offer much prospect of success. Operations for the relief of calcaneus have been practically that of Nicoladoni, the transplantation of the two peronei muscles into the tendo Achillis; or, as modified by Goldthwait, the tendon of the peroneus longus was inserted into the tendo Achillis and the brevis was transplanted into that of the flexor longus pollicis. If the tibialis posticus is paralyzed with resulting valgus, the peroneus brevis may be carried beneath the tendo Achillis and attached to its distal extremity.

The operation of tendon transplantation should not be performed until the recovery from the paralysis is considered impossible. The incision should be sufficiently long to expose the tendon and the muscular substance. The paralyzed muscle is quite different in color from the normal, being dull reddish-yellow, and the tendon is usually dull white in place of the silvery glistening color of the normal tendon. The splitting of the tendon should be begun high up, including, in some instances, muscle substance, and in joining the splices as much surface as possible of each splice should be apposed because the tendons do not readily unite. In certain instances it may be advisable to attach the transplanted tendon directly to the periosteum at the point at which its force may be exerted to best advantage. This as a routine measure is advocated by Lange (*Münch. med. Wochen.*, November 15th, 1900).

Fine silk is usually employed for suturing. The tendon sheaths are, as far as possible, closed by fine catgut and the skin incision by the same material. Before the operation is performed, all resistance to normal motion should be overcome by force, and by division of the contracted parts, if necessary. The attachment of the muscles or tendons should be made while the foot is held in proper position, and in many instances it is well to cut and overlap the paralyzed tendons to aid in retaining the foot in the improved attitude.

After the operation is completed, the foot should be fixed in a plaster bandage in the over-corrected position for several weeks or months. As a rule the foot should be supported by a brace until it is evident that the union of the parts is firm, and a good functional result is assured.

The prognosis will depend entirely upon the character of the paralysis. If the tibialis anticus is alone affected, it may be hoped that sufficient power may be borrowed from the other muscles to lift the foot at least enough to prevent awkwardness of gait, and to restrain deformity. Even more favorable is the prospect for the relief of varus caused by weakness of the abductors; but it is impossible for weak muscles like the peronei to supply the place of the great calf muscle. The power obtained from the peronei, however, which has become useless and even harmful because it draws the foot into deformity, may be sufficient to hold the heel in proper position and at least to aid the brace in retaining the foot in a normal attitude.

The relative strength of the muscles should be considered in selecting grafts, as well as in making a prognosis. According to Fick it is as follows, in kilogrameters:

BACK OF THE LEG.

The calf muscle—gastrocnemius and soleus	8.21
Tibialis posticus	.40
Peroneus longus	.44
Flexor com. digitorum	.37
Flexor longus pollicis	.82
Total	10.24

FRONT OF THE LEG.

Tibialis anticus	1.61
Extensor proprius pollicis	.39
Extensor longus digitorum	.72
Peroneus brevis	.31
Peroneus tertius	.20
Total	3.23

The importance of the calf muscle on the back, and of the tibialis anticus on the front of the leg, is apparent. The former is nearly four times as strong as the other muscles of the combined posterior group, the latter being nearly equal to all the others on the front of the leg. (Rudolph Fick, "Ueber die Arbeitsleistung der auf die Fussgelenke wirkenden Muskeln," Leipsic, 1892.)

It has been claimed that the transplanted muscle may become hypertrophied sufficiently to carry out its new function, but this is somewhat doubtful. Direct transplantation of muscles on the same principle as tendon grafting has also been performed by Drobnik, Goldthwait, and others; for example, the sartorius, the gracilis, or the tensor vaginæ femoris may be transplanted into the substance of the quadriceps extensor muscle. Drobnik has suggested the possibility of regenerating the paralyzed muscle by thus engrafting a portion of one that is still active, but this is, of course, a possible rather than a probable outcome.

The principle of the operation applies, of course, to other parts of the body as well, but the opportunities for its application are far less frequent than in the lower extremities.

TENDON SPLICING.—Division and overlapping of the tendons of paralyzed muscles may be employed with advantage in certain instances. For example, in complete paralysis of all the dorsal flexors of the foot, each tendon may be shortened and attached to the anterior ligament; thus the toe-drop may be remedied or reduced to such an extent that the deformity may interfere but slightly with locomotion. In most instances, however, unless support is used the shortened part will relax subsequently.

ARTHRODESIS.—Arthrodesis, for the purpose of producing ankylosis of a joint, was first performed by Albert of Vienna, in 1878. Its field is practically limited to those cases in which no muscular power remains, the so-called dangle foot. It may be of service also in cases of partial paralysis, as in equinus or calcaneus, when the patient is unable to provide himself with apparatus.

The operation consists in opening the joint and removing the cartilage from the opposing surfaces of the bones, then sewing or nailing them to one another, or simply fixing the parts in a plaster bandage until union has taken place. If the case is one of simple calcaneus or equinus, without lateral deviation, the operation may be limited to the ankle joint, which may be opened from the back or front or side, as seems preferable. The cartilage is usually removed with a sharp spoon and at the same time relaxed tissue may be shortened after the Willett method, if the deformity be calcaneus; or the tendons on the front of the foot may be similarly shortened with the aim of lifting the toes to the proper level, if they are depressed. The operation, to be effective in cases of complete paralysis and dangle foot, must include all the larger joints of the foot. Even when ankylosis has been attained, there is a marked tendency to subsequent deformity. In cases of calcaneus, the removal of the astragalus in the manner described is the preferable operation.

Arthrodesis is also performed at the knee and at other joints for the purpose of fixing the part in a useful attitude. In certain instances the operation is indicated. It is, of course, limited to cases of hopeless paralysis and is more suitable to the older than to the younger class of patients.

The improvement in the gait obtained by the removal of deformity and fixation of the foot is often very marked, and support may often be discarded, but in early childhood, at least, cases should if possible be kept under observation in order that support may be applied if the deformity shows a tendency to recur.

Royal Whitman.

FOREARM, THE.—The forearm is that portion of the pectoral girdle or upper extremity lying between the elbow and wrist joints. Its bony framework comprises two bones, the radius and the ulna.

The *skin* of the forearm is soft and is usually well supplied with hairs, especially along the postero-external surface. Along the anterior surface the hairs are fewer and finer. The skin is freely movable throughout the forearm upon the deep fascial sheath. The bursa over the olecranon gives it free mobility at that point. Lying within the layers of the superficial fascia are the superficial veins and the cutaneous nerves.

The SUPERFICIAL VEINS rise in two plexuses: the large *plexus of the dorsum of the hand* which is derived from the digital veins, and the smaller *plexus of the front of the wrist,* from the palm and thumb. These veins are larger than those of the deep set, have fewer valves and return most of the blood. At points of communication between these sets of veins, valves are regularly found.

The veins arising from these two plexuses are irregular in their distribution and are seldom symmetrical upon the two sides in the same body. For convenience four principal vein trunks are distinguished upon the outer, anterior and inner surfaces of the forearm: the *radial,* the *median,* the *anterior* and the *posterior ulnar* veins respectively. The *median* vein as it reaches a point opposite the insertion of the biceps receives a communication from the deep set which perforates the deep fascia. This trunk is short and is known as the *profunda.* The median at once divides into branches that diverge in V-form, the median-cephalic to the outer side and the median-basilic to the inner side of the biceps. The *median-cephalic* ascends to a point a little above the elbow, is joined by the *radial* vein, and this trunk, called the *cephalic,* lies in the furrow to the outer side of the biceps in the arm. The median cephalic vein overlies the cutaneous branches of the musculo-cutaneous nerve as they pass the elbow. The *median-basilic* vein passes upward and inward and is usually joined at a point about in front of the internal condyle by both the *ulnar* veins. The trunk so formed is called the *basilic* and lies to the inner side of the biceps in the arm. The median basilic is usually larger and shorter than the median cephalic; the basilic is usually a considerably larger trunk than the cephalic. The median basilic vein overlies from without inward the bicipital fascial aponeurosis, the brachial artery, a part of the anterior division and the whole of the posterior division of the terminals of the internal cutaneous nerve.

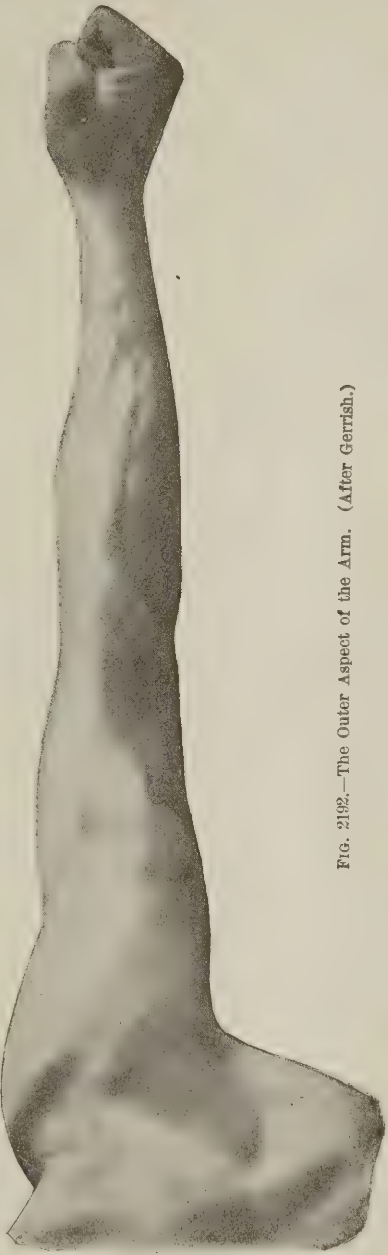

FIG. 2192.—The Outer Aspect of the Arm. (After Gerrish.)

SUPERFICIAL NERVES.—The cutaneous nerves are the musculo-cutaneous, with a few fibres from the musculo-spiral near the elbow, for supplying the outer side of the forearm, front and back; the internal cutaneous, for supplying the inner side of the forearm, front and back. Lying between the two on the back of the forearm is the distribution of the lower (larger) cutaneous branch of the musculo-spiral. All these nerves pass the elbow. Behind, over a small area, limited to the olecranon, is the nerve of Wrisberg.

Piercing the fascia at the lower third of the forearm, the following nerves become superficial or cutaneous: the palmar branches of the ulnar median and radial nerves on the front, and the dorsal branch of the ulnar nerve and the radial nerve on the back.

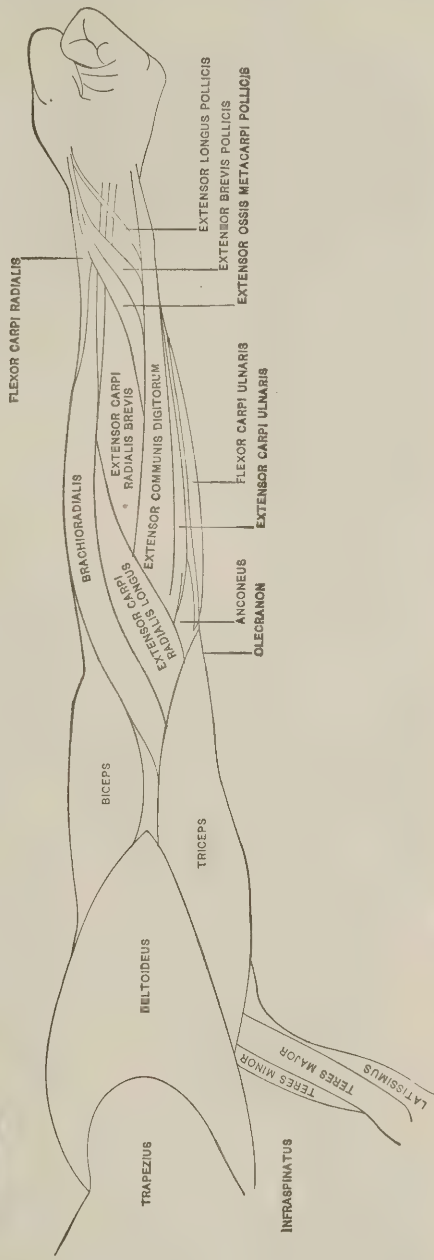

FIG. 2193.—The Outer Arm. Distribution of the Different Muscles. (After Gerrish.)

The *brachial* (deep) *fascia* at the elbow is firmly fixed to the bony prominences, and is strengthened in front by the bicipital fascia. This slip is given off from the tendon of insertion of the biceps, which bridges over the brachial artery, and is lost over the pronator teres and its sheath at the inner side of the forearm. Some fascial fibres are also often received from the tendon of the triceps. Together in the upper third of the forearm this deep fascia

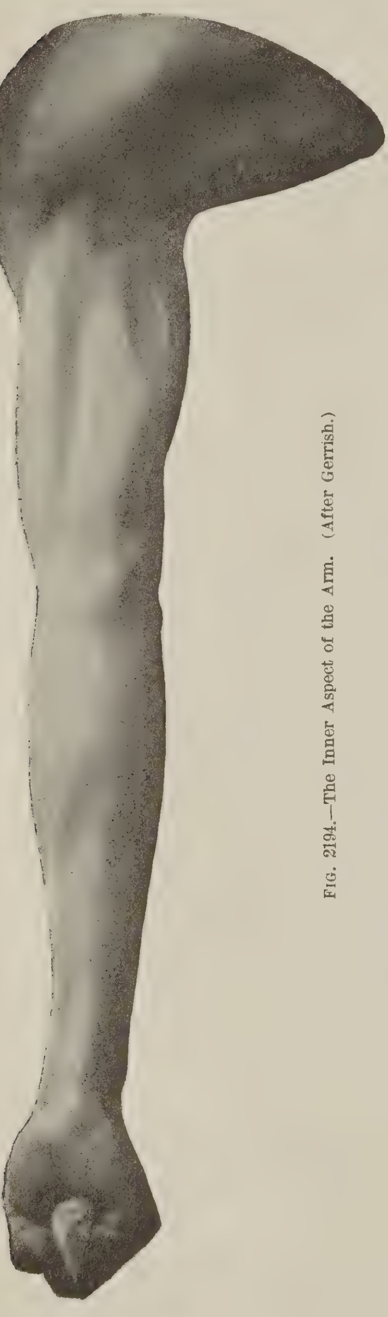

FIG. 2194.—The Inner Aspect of the Arm. (After Gerrish.)

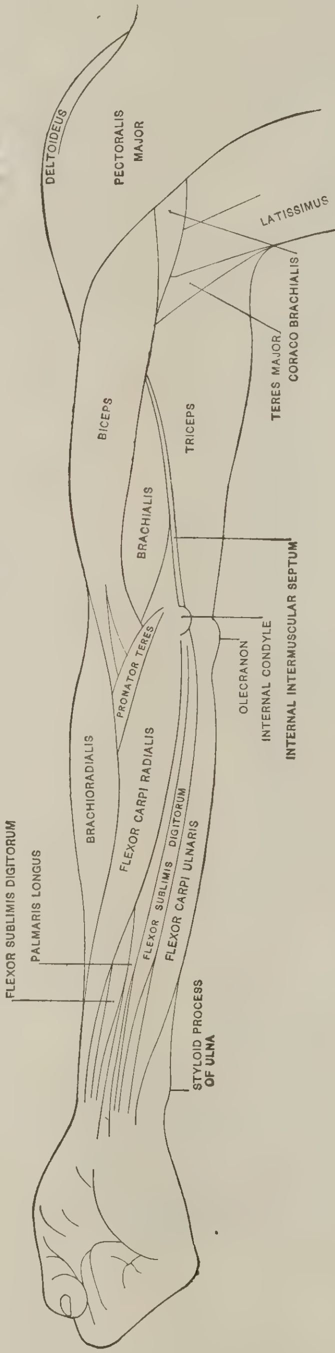

FIG. 2195.—The Inner Arm. Distribution of the Different Muscles. (After Gerrish.)

forms a strong enveloping sheath. Near the elbow at the internal condyle it serves in part as the origin of several muscles which spring from the condyle. Lower down in the forearm septa are given off from its deep surface to dip down between the various muscle bellies. In the lower third the fascia is continuous with the various muscle tendons and at the wrist forms the anterior and posterior annular ligaments. It ends in the fascia of the hand. It is attached to the posterior triangular area of the olecranon and to the whole of the posterior ridge of the ulna, and is much thicker behind. Between the superficial and deep layers of muscles, front and back, is a thin membranous layer of fascia. Below and behind the fascia is strengthened by transverse fibres to form the posterior annular ligament of the wrist which passes from the anterior border of the radius above the styloid process backward and inward, over the series of ridges forming grooves for tendons, over the ulna serving as an orbicular ligament, to attach itself to the inner aspect of the wrist, especially over the pisiform and cuneiform bones.

MUSCLES.—The muscles of the forearm, for convenience, can be divided into groups: those of the front, those of the back, and those of the outer side of the forearm. Those of the *front* (anterior radio-carpal) consist of a superficial set, five in number: the pronator teres, flexor carpi radialis, flexor carpi ulnaris, flexor digitorum sublimis, and (flexor) palmaris longus; and a deep set, three in number: flexor digitorum profundus, flexor pollicis longus, and pronator quadratus. The muscles of the *outer side* (radial), three in number, are: brachio-radialis, extensor carpi radialis longus, and extensor carpi radialis brevis. Those of the *back* (posterior radio-carpal) comprise a superficial set, four in number: extensor digitorum communis, extensor digiti minimi, extensor carpi ulnaris, and anconæus; and a deep set, five in number: supinator (brevis), extensor ossis metacarpi pollicis, extensor pollicis longus, extensor pollicis brevis, and extensor indicis.

The five muscles of the *superficial flexor* group are intimately associated at their origin from the internal condyle. Rising from it is a tendon common to them all, which gives fibres to each and sends septa between every two contiguous muscles. The muscles, from without inward, are the following:

The *pronator teres*, the most external, crosses obliquely the upper half of the forearm. It rises by two heads: one, large and superficial, from the inner condyle of the humerus, by a tendon common to both heads, and from the supracondylar ridge, fascia, and intermuscular septa; the other, a thin and deep band, coming from the inner side of the coronoid process and soon joining the deep surface of the large head. This slip separates the median nerve from the ulnar artery. The muscle thus formed passes outward and ends in a flattened tendon which turns over the radius and is inserted into a rough impression on the outer surface of the shaft of the radius about at its middle. Near the insertion the muscle is crossed by the radial artery and is covered by the brachio-radialis.

The *flexor carpi radialis* rises from the flexor tendon, from fascia, intermuscular septa, and adjacent muscles. At about the middle of the forearm its fleshy belly merges into a long flattened tendon, passes in a special compartment of the anterior annular ligament, grooves the trapezium, and inserts itself into the base of the second and frequently into the third metacarpal bone.

The (*flexor*) *palmaris longus* is a long slender muscle, the smallest of the group. It rises from the flexor tendon, fascia, and septa, to form soon a small round belly. It soon ends in a long slender tendon which inserts itself into the lower border of the annular ligament and the palmar fascia. This muscle is very variable and is often absent.

The *flexor carpi ulnaris*, the innermost muscle of the group, rises by two heads: the one from the back part of the flexor tendon, the other from the inner side of the olecranon and, by an aponeurosis, from the upper two-thirds of the posterior border of the ulna. The two heads bridge the space between the internal condyle and the olecranon, and between and beneath them the ulnar nerve is transmitted. The muscle converges into a tendon which is placed along its front surface and inserts itself into the pisiform bone.

The *flexor digitorum sublimis* (flexor perforatus) is a broad flat muscle placed behind the preceding. It rises by a strong head from the flexor tendon, from the internal lateral ligament of the elbow joint, from the inner border of the coronoid process, and from the overlying muscles and septa; and by a second head, a thin flat band, from the anterior oblique line of the radius and its anterior border. It merges from a broad muscle into four separate tendons which first pass through the middle compartment of the anterior annular ligament, then diverge, and continue their course, each one separately, in company with a corresponding tendon from the profundus (behind), to each of the last four fingers. At the wrist the tendons pass in pairs, those for the third and fourth fingers being in front, those for the second and fifth lying behind the first pair. The tendons opposite the first phalanx divide, allow the profundus tendon to pass between, then unite behind to insert themselves into the second phalanx.

The *deep-seated flexor* group comprises the following muscles:

The *flexor digitorum profundus* (flexor perforans), a large thick muscle, rises from the upper three-fourths of the front and inner side of the ulna, from the ulnar half of the interosseous membrane, and from the aponeurosis of the flexor carpi ulnaris. It divides finally into four tendons for the inner four fingers, but the tendon for the index finger becomes distinct in the forearm. It passes behind the sublimis at the wrist, behind the sublimis tendons in the palm, and after perforating the sublimis inserts itself at the bases of the last phalanges of the inner four fingers. The lumbricales take origin from the tendons in the palm.

The *flexor pollicis longus*, to the outer side of the profundus, rises from the front of the radius between the oblique line and the pronator quadratus, and the adjacent interosseous membrane. From a fleshy belly, a round tendon passes under the annular ligament and thenar eminence to its insertion at the base of the second (last) phalanx of the thumb. Occasionally a second head rises from the coronoid process or internal condyle in common with the sublimis.

The *pronator quadratus* rises from the pronator ridge and from the front of the ulna at its lower fourth, passes close to the bones, and inserts itself into the front of the lower end of the radius.

The muscles of the *outer* (radial) *extensor* group are:

The *brachio-radialis* (supinator longus) rises from the upper two-thirds of the external supracondylar ridge and from the front of the external intermuscular septum. It forms a long slender muscle which, near the middle of the forearm, merges into a flat tendon; and this, in turn, inserts itself into the outer side of the radius near the base of the styloid process.

The *extensor carpi radialis longus* rises just below the preceding muscle fom the ridge and septum, a few fibres being derived from the common extensor tendon. From this origin a long tendon passes under the posterior annular ligament in its second compartment and passes to its insertion into the base of the second metacarpal. In its course it lies upon the following muscle.

The *extensor carpi radialis brevis* rises by the common extensor tendon from the external condyle of the humerus, from the intermuscular septa, and from the external lateral ligament of the elbow. Its tendon passes with the longus in the same compartment at the wrist and is finally inserted into the base of the third metacarpal.

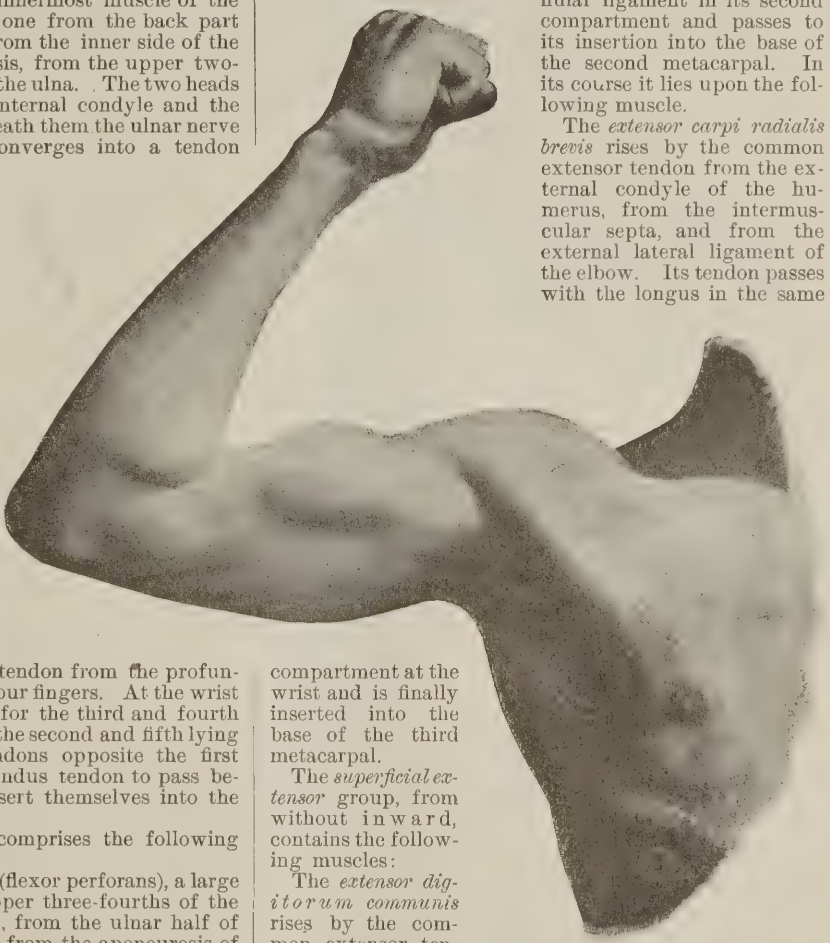

Fig. 2196.—The Inner Arm. Muscles contracted. (After Gerrish.)

The *superficial extensor* group, from without inward, contains the following muscles:

The *extensor digitorum communis* rises by the common extensor tendon, fascia, and septa. From a fleshy belly four tendons are ultimately given off, and these pass through the fourth compartment of the posterior annular ligament on their way to the hand. Here they diverge and then pass on to the points where they are inserted at the bases of the second and the third phalanges of the inner four fingers.

The *extensor digiti minimi* lies at the inner side of the preceding muscle. It rises in the same manner as does the latter and passes through the fifth compartment at the wrist (between radius and ulna); its points of insertion are the same as those of the corresponding tendon of the preceding muscle.

The *extensor carpi ulnaris* rises in the same manner as the preceding, and also by an ulnar aponeurosis common to it, the flexor carpi ulnaris, and the flexor profundus. The tendon emerges near the wrist, passes in the sixth compartment, and is inserted into the base of the fifth metacarpal near its ulnar border.

The *anconæus* rises from the lower part of the back of the external condyle and from the adjacent posterior ligament of the elbow and is inserted into the outer surface of the olecranon and the upper third of the back of the ulna. This muscle is sometimes continuous with the triceps and is usually described in connection with it, as a fourth head.

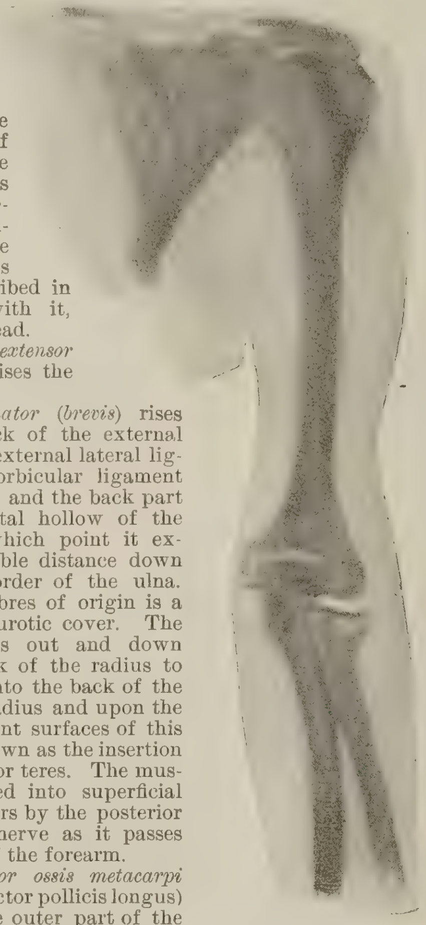

FIG. 2197.—Skiagraph Showing Relations of Bony Framework of the Shoulder, Arm, and Elbow to the Soft Parts which Surround Them. (After Gerrish.)

The *deep extensor* group comprises the following:

The *supinator* (*brevis*) rises from the back of the external condyle, the external lateral ligament, the orbicular ligament of the radius, and the back part of the bicipital hollow of the ulna, from which point it extends a variable distance down the outer border of the ulna. Over these fibres of origin is a strong aponeurotic cover. The muscle passes out and down over the back of the radius to insert itself into the back of the neck of the radius and upon the outer and front surfaces of this bone as far down as the insertion of the pronator teres. The muscle is divided into superficial and deep layers by the posterior interosseous nerve as it passes to the back of the forearm.

The *extensor ossis metacarpi pollicis* (abductor pollicis longus) rises from the outer part of the back surface of the ulna at the junction of the upper and middle thirds, from the corresponding portion of the interosseous membrane, from a small part of the back of the radius near its middle, and from intermuscular septa. The muscle extends down and out, emerges between the extensor digitorum communis and the extensor carpi radialis brevis, and in company with the extensor pollicis brevis it crosses the two radial extensors. At about this point it merges into its tendon, follows down the outer side of the base of the radius, and enters the first compartment of the posterior annular ligament. It is inserted into the outer side of the base of the first metacarpal bone and by its aponeurosis into neighboring structures, notably the back of the trapezium, and also into the palmar fascia, especially that part which covers the thumb.

The *extensor pollicis brevis* (extensor primi internodii pollicis) rises from the middle of the back of the interosseous membrane just below the preceding, from the back of the radius extending obliquely outward and downward, and from the intermuscular septa of this group of muscles. It extends obliquely down and out and forms its tendon at the lower third of the forearm. From this point it accompanies the tendon of the preceding muscle, lying behind it, to be inserted into the base of the first phalanx of the thumb.

The *extensor pollicis longus* (extensor secundi internodii pollicis) rises from the outer part of the back of the ulna at its middle third, close to the outer border, from the interosseous membrane, and from the septum between it and the extensor indicis. This muscle, somewhat stronger than the preceding, passes down and out to merge into a tendon placed along its back. The tendon becomes free just above the posterior annular ligament, passes through its third compartment, then over the radial extensors, lies close to the inner side of the tendon of the preceding, and is inserted into the base of the second phalanx of the thumb.

The *extensor indicis* rises from the back of the ulna (from a point just below the preceding muscle to one situated nearly at the lower end of the bone), from the adjacent interosseous membrane, and from the septum between it and the preceding. It merges into a tendon which is placed along its radial border. This becomes free at the lower third of the forearm, passes through the fourth compartment beneath the tendons of the extensor digitorum communis, and after it emerges from this it is inserted into the inner border of the tendon of the common extensor of the index finger at about the metacarpophalangeal joint.

ARTERIES.—The *brachial artery* ends just below the bend of the elbow where it divides opposite the neck of the radius into its two terminals, the radial and the ulnar.

The *radial artery*, the smaller of the two, extends downward, in direct continuation of the brachial artery, along the outer side of the front of the forearm to the lower end of the radius. Here it turns around the outer side of the radius to the back of the wrist, over the external lateral ligament, and under the extensors of the thumb.

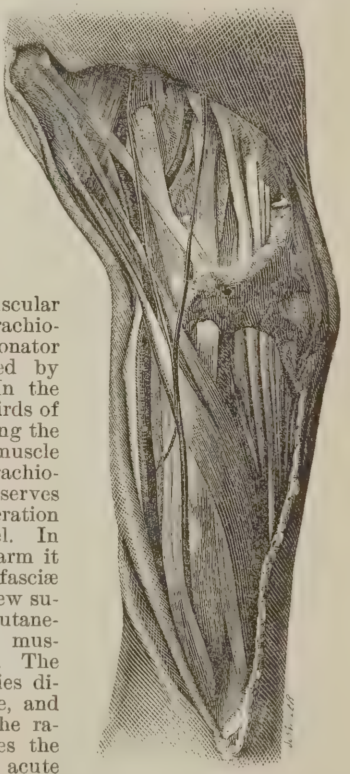

FIG. 2198.—External and Posterior Region of Wrist, showing Arrangement of Tendons, Artery, Nerve, etc. The skin and fasciæ have been removed. (Reduced in size.) (After M. H. Richardson.)

In the upper forearm it lies in the outermost intermuscular space between the brachioradialis and the pronator teres, and is covered by fasciæ and skin. In the middle and lower thirds of the forearm it lies along the inner border of the muscle and tendon of the brachioradialis, which latter serves as a guide in the operation for ligating this vessel. In this part of the forearm it is covered only by fasciæ and skin, and by a few superficial veins and cutaneous branches of the musculo-cutaneous nerve. The radial at the wrist lies directly upon the bone, and forms the pulse. The radial nerve approaches the artery above at an acute angle; in the middle and lower thirds it lies along its outer side. The venæ comites accompany the artery on either side.

The radial artery in the forearm, besides the irregular and numerous muscular branches, gives off the radial recurrent, the anterior radio-carpal, and the superficial volar.

The *radial recurrent*, a branch of considerable size, is usually given off from the outer side of the radial just below its origin from the brachial. It runs outward between the brachio-radialis and the supinator (brevis), divides into several branches and anastomoses with the interosseous recurrent and superior profunda, and gives off a branch to supply the elbow joint.

The superficial volar and the anterior radio-carpal are branches given off just above the wrist.

The *ulnar artery*, the larger of the terminals of the brachial, from the inner side of the neck of the radius passes down and inward to the front of the inner (ulnar) side of the forearm, thence directly to the wrist, and over the anterior annular ligament to the palm.

In the upper half of its course the artery lies deeply beneath the pronator teres and the superficial flexors; in the lower half of the forearm it is overlapped only by the flexor carpi ulnaris muscle and tendon which lie to its inner side and serve as a guide in operations for ligating the vessel. Only in the last inch or so is the artery superficial. As the artery lies beneath the pronator teres it is crossed from within outward by the median nerve, the deep head of the muscle usually separating the two. The ulnar nerve approaches the artery from behind the inner condyle at an acute angle, being separated from it by the flexor sublimis, and in the lower two-thirds it lies close to the inner side of the artery. The latter is covered by superficial ulnar veins, in addition to fasciæ and skin, and is crossed by branches of the internal cutaneous nerve. The artery is accompanied by two venæ comites.

The ulnar artery, besides numerous and irregular muscular branches, gives off the anterior and posterior recurrent ulnar, the anterior and posterior interosseous, the anterior and posterior ulnar carpal, and usually the nutrient of the ulna.

The *anterior recurrent ulnar*, the smaller of the two recurrent branches, runs up in front of the inner condyle of the humerus, between the pronator teres and the brachialis, and anastomoses with the anterior branch of the anastomotica magna and a branch of the inferior profunda.

The *posterior recurrent ulnar*, the larger, passes inward between the flexor sublimis and the flexor profundus, then up and back of the inner condyle of the humerus, and comes to lie, with the ulnar nerve, between the two heads of the flexor carpi ulnaris. It anastomoses with the posterior branch of the anastomotica magna, with the inferior profunda, and with the interosseous recurrent to form the olecranal rete.

The *interossei* rise from the ulnar by a common trunk about half an inch in length, and the latter, in turn, rises from the outer and back part of the ulnar just before the median nerve crosses the main vessel. It rises about an inch below the origin of the ulnar, and proceeds backward to the interosseous membrane, where it divides into its two terminals.

The *anterior interosseous*, the smaller, follows the front of the membrane in company with two veins and the deep branch of the median nerve which lies to its outer side. It usually supplies nutrients to both bones.

The *posterior interosseous*, the larger, passes back between the interosseous membrane and the oblique ligament above, descends between the superficial and deep muscles, and, crossing the extensors of the thumb and index finger, anastomoses below the latter muscle with the anterior interosseous.

The anterior and posterior ulnar carpals are small carpals which, in company with the anterior radial carpal, anastomose and form the carpal arch.

NERVE TRUNKS.—The nerve trunks of the forearm are the radial, posterior interosseous, median, and ulnar.

The *musculo-spiral* nerve, a short distance above the elbow, lying upon the brachialis and covered by the brachio-radialis, divides into its terminals, the posterior interosseous and the radial nerves.

The *posterior interosseous* nerve passes back, out, and down between the brachialis and extensor carpi radialis longus, through the supinator (brevis), to the deep layer of the forearm extensors. It approaches the posterior interosseous artery at an angle, and is in relation with it as far as to a point below the origin of the extensor pollicis longus where it approaches and is in relation with the posterior branch of the anterior interosseous artery. Lower down, it passes through the fourth compartment of the wrist, with the extensors communis and indicis, to the back of the wrist where it becomes ganglionic.

The *radial* nerve passes directly downward under cover of the brachio-radialis. At the middle third of the arm it lies along the outer side of the radial artery, then winds around the outer side of the radius under cover of the brachio-radialis tendon, and pierces the deep fascia in the lower forearm, breaking up into its terminal branches on the back of the wrist.

The *median* nerve, from the bend of the elbow, where it lies to the inner side of the tendon of the biceps, the brachial, and the beginning of the ulnar artery, passes down the centre of the front of the forearm beneath the condylar head of the pronator teres and over the ulnar artery, being separated from the latter by the deep head of the same muscle. Beyond this point it passes beneath the radial head of the flexor digitorum sublimis, and later still it lies deep beneath the flexor sublimis and on the flexor profundus. At the wrist the nerve becomes superficial and lies between the tendons of the flexor sublimis to the inner side, and of the flexor carpi radialis on the outer side. It passes superficially through the large flexor compartment of the anterior annular ligament and soon divides into an inner and an outer terminal. Besides muscular branches in the forearm, the median gives off the anterior interosseous and small branches to the elbow joint.

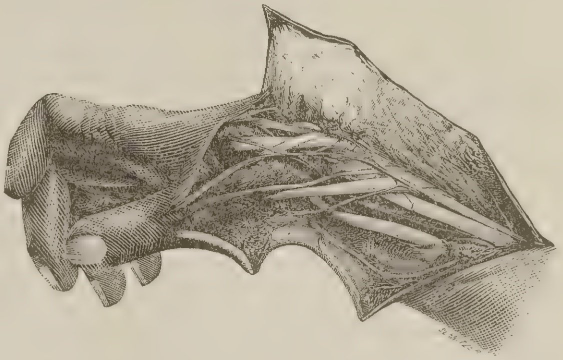

FIG. 2199.—Dissection of the External Region of the Right Wrist. The radial artery is seen between the relaxed tendon of the flexor carpi radialis below, and the brachio-radialis on the outer (upper) side. It then passes beneath the first two extensors of the thumb and a small branch of the radial nerve, crosses the base of the thumb obliquely, and disappears under the tendon of the extensor pollicis longus. (Thin subject, female, one-half normal size.) (After M. H. Richardson.)

The *anterior interosseous* nerve is given off from the median opposite the insertion of the biceps, runs down the front of the membrane in company with the anterior interosseous artery, and supplies the medullary arteries, the periosteum of the radius and ulna, and the wrist joint.

The *ulnar* nerve, from the angle between the olecranon and the internal condyle, passes between the inner and outer heads of the flexor carpi ulnaris to the front of the forearm. It passes down upon the flexor profundus under cover of the flexor carpi ulnaris and overlapped by it upon the inner side. It passes nearly to the wrist along the outer side of this muscle and its tendon, when it becomes superficial and enters the hand anteriorly to the annular ligament. In the lower two-thirds of the forearm the ulnar artery lies to its outer side, separating it from the flexor sublimis. It also, besides giving off muscular branches, supplies the elbow joint.

The *interosseous membrane* bridges across between the interosseous borders of the radius and ulna, from a point a little below the bicipital tubercle of the radius to the wrist joint. Its fibres pass mainly in an oblique direction from the radius to the ulna. The posterior interosseous vessels pass back over its upper border and are in relation with its back surface low down in the forearm. The anterior interosseous vessels and nerve are in relation with the front surface throughout. Except in supination of the forearm and in full pronation this membrane is usually tense. It serves also to carry strains from the radius to the ulna and to bind the bones together.

The forearm is subconical, so that the lateral flap operation is a necessity, since the skin cannot be pushed far upward in the lower forearm. The skin is, also, quite adherent to the underlying aponeurosis. Roughly speaking, the intermuscular septa, the bones, and the interosseous membrane form a front and a back compartment. The *ulna* is subcutaneous from olecranon to styloid process, so that any injury or fracture is readily manifest. The *radius* lies deeply lodged among the upper forearm muscles and it is only occasionally that its head can be felt. In the lower forearm the radius becomes gradually subcutaneous and can be examined. The *interosseous membrane* is relaxed in the semi-prone position of the forearm, which indicates the best position, in fracture of the radius or ulna, for splinting. Care should be exercised not to permit the fractured ends of the radius to rest upon the ulna, thereby causing injury to interosseous vessels and nerves and favoring an eventual ankylosis. Antero-posterior splints may press too much upon radial and ulnar vessels and nerves and injure them.

The *muscles* of the forearm, in extremely muscular subjects after too long and severe use, may cause pressure upon arteries and nerves, and resultant pains and neuralgias. Muscular spasm may effect the same results. Muscles become greatly hypertrophied under special exercises (as occurs, for example, in the pronator teres muscle of the "tennis arm"). A spasm of the same muscle may take place, as in the "glass arm" of baseball pitchers. Hypertrophy of both of the pronators, the result of "feathering," may take place in the case of oarsmen. The inner edge of the brachio-radialis is the guide to the *radial artery* and nerve; the inner edge of the palmaris tendon is that for the *median nerve;* and the outer border of the flexor carpi ulnaris indicates where the *ulnar artery* and nerve are to be sought for. Both arteries may be ligated at any point above the annular ligament for severe hemorrhage of the palm. Above the anterior annular ligament the two synovial tendon sheaths of the flexor pollicis longus and that common to the sublimis and profundus extend for a distance of an inch and a half, and often carry infection from the palm to the tendon spaces of the forearm.

Through the posterior annular ligament extend upward six such sheaths, all of which save the last extend well above the ligament. They are: one for the two outer thumb extensors, one for the two radio-carpal extensors, one for the long thumb extensor, one for the common extensor, one for the little finger extensor, and lastly one for the ulno-carpal extensor.

Injuries of the *nerve* trunks may cause varying symptoms. (Compare *Arm.*) The *posterior interosseous nerve* may be injured in resection of the head of the radius or in fracture of the radial neck, and thus may cause paralysis of the extensors. The posterior interosseous nerve may suffer loss of function from fracture of the humerus at some point near its middle. Pressure upon the *median nerve* in muscular spasm and in compression from long and severe muscular exercise, may cause increased cramps and pain or even a prolonged neuralgia. The *ulnar nerve* may be injured in fracture of the olecranon and may cause loss of sensation, or numbing; or it may be caught in the callus of fracture, either there or along the shaft of the ulna, and cause pain; and, finally, the conditions may be such as to necessitate excision of the nerve from the callus. The numbness from a sudden blow upon the ulnar nerve at the elbow —commonly spoken of as "striking the funny bone"— is a familiar instance; and if severe, this numbing and tingling may be persistent and may be accompanied by loss of function of the flexor muscles. In plumbism the ulnar nerve is regularly involved, causing the "claw hand." The ulnar and median nerves are both involved in alcoholic neuritis. The *radial nerve* may be painful at its points of distribution if the trunk is injured in Colles' fracture. Neuromata along the nerve trunks, due to injury, may demand excision.

Luzerne Coville.

FORMALDEHYDE, formic aldehyde, methyl aldehyde or oxymethylene (HCOH), is a gas whose saturated aqueous solution is known as *formalin* or *formol.* The method of manufacture used now on a large scale is a modification of that used by A. W. Hoffmann, who introduced formaldehyde in 1867. By means of superheated steam passing through a copper coil, methyl alcohol is vaporized under pressure in a steel chamber, from which it issues with great force and mixed with a definite quantity of air, and then passes through a double tube converter. The inner tube of this is perforated with very fine holes and separated from the outer tube by broken coke, and the whole is kept at a dull red heat. As it passes through this heated coke, the vapor is oxidized to formaldehyde, and this is either condensed by extreme cold to a liquid, or cooled and dissolved in water by agitation. Copper filings, spongy platinum, or any porous material may be substituted for coke. The gas is usually generated on a small scale by heating paraformaldehyde, though methyl alcohol can be employed by heating in a tin vessel so that the vapor will pass through a perforated red-hot copper plate. The reaction is: $CH_3OH + O = CHOH + H_2O$. The yield is said to be only twenty per cent. from commercial wood alcohol. Other methods of manufacture are by the complete oxidation of ethyl nitrate; by heating a mixture of ethylene and oxygen to 400° C.; by the dry distillation of calcium formate, etc.

Formaldehyde is a colorless gas of pungent, penetrating odor, and very irritating to the eyes and nose. Its saturated cold aqueous solution (formalin) contains from thirty-five to forty per cent. of the gas by weight, is colorless, has a sharp taste, and mixes freely with water, alcohol, and glycerin. The gas is more soluble in methyl alcohol than in water. Its chemical affinities are extensive. It is rendered inert by alkalies, deodorizes hydrogen sulphide, and is the basis of many aniline colors and new synthetic remedies, such as urotropin, bismal, tannoform, etc. It reduces Fehling's solution, produces a black precipitate with ammoniacal silver-nitrate solution, and white precipitates with dilute aqueous solution of aniline and with ammonia and bromine water. Henner's test, sensitive 1 in 200,000, consists in superposing a mixture of very weak carbolic acid with the suspected liquid upon concentrated sulphuric acid; a rose-violet ring at the line of contact indicates formaldehyde. A modification of this is to dissolve 0.1 gm. morphine hydrochlorate in 1 c.c. of sulphuric acid and add to this the suspected liquid. In milk and such fluids, however, these tests may be obscured by the charring of the organic substances by the acid; hence, in such a case, the formaldehyde should be distilled off and passed into water, and then tested for. Jorrissen's test was designed for milk: shake together 25 c.c. of milk and 10 c.c. of 0.1 per cent aqueous phloroglucin, add 5 to 10 c.c. of one-third strength potash lye, and a transient salmon-red color indicates formaldehyde.

When formalin is heated, part of it is converted into paraformaldehyde (paraform, triformol, or trioxymethylene), which separates as a white insoluble flocculent mass, capable of again yielding HCOH gas. Formaldehyde renders gelatin insoluble, forming elastic translucent masses, so it has been used to replace tannin in making leather and to harden gelatin films in photography. Formaldehyd-gelatin is employed as an absorbable antiseptic. When added to serum albumin, formalin prevents coagulation by heat; added to calcium carbide, it retards the evolution of acetylene gas. It neutralizes alkalies by forming with them complex substances, that with ammonia being hexamethylene-tetramine.

It is said not in any way to affect the textile character of wool, cotton, fur, silk, or leather; and it does not change their colors except in the case of iron-containing dyes or a few of the aniline colors such as fuchsin (aniline red). Its aqueous solution attacks metals; consequently the dry gas only should be used for sterilizing instruments. In 1886 its powerful bactericidal properties were reported by Loew, and it has now become an almost universal disinfectant (see *Disinfectants* and *Disinfection*). Rubber goods, catheters, etc., may be kept sterile in a weak solution for a long time without harm. Hoffmeister, Hirst, and others have used it for sterilizing catgut.

It is also used largely as a hardening and fixing agent, and as a preservative for anatomical and biological specimens. These, especially plants, tend to retain some of their brilliant colors, and do not shrink as they would in alcohol. Plants slowly discolor the solution by giving up their tannin. As formaldehyde has little penetrating power, openings should be made so that it may permeate the interiors of specimens; otherwise they may rot, even in strong solution. Moulds have been found growing on tissues apparently saturated with solutions of five to ten per cent. strength. Orth's hardening and fixing formula is: Müller's fluid, 100 parts; formalin, 10 parts. To be mixed just before use. Kaiserling keeps the specimen for twenty-four hours in formalin 75, potassium nitrate 1, potassium acetate 3, distilled water 100, then transfers to 80-per-cent. alcohol for twelve hours, then to 95-per-cent. alcohol for two hours. The specimen may then be mounted for sectioning, or kept in equal parts of water and glycerin containing 3 per cent. of potassium acetate. Before putting through alcohol, Carter leaves the tissues for from six to twelve hours in 20-per-cent. formaldehyde solution with 5 per cent. acetic acid. Blood smears exposed to the vapor are firmly fixed, and may be stained as by any other method of fixing. Blood on the hands becomes hardened and difficult to wash off.

Being difficult of detection in small quantities, it is used as a preservative of foods and medicines, vigorous prohibitive laws not preventing its widespread use by dairymen, canners, etc. In the strength of 1 to 20,000 it is said to preserve milk for several days, yet even this minute quantity has been shown by Annett and others to be harmful. It has been employed by pharmacists for the preservation of ointments, syrups, fruit juices, infusions, and various other articles which readily spoil. Mucilage of acacia, lard, cider, etc., remained sweet after a year, yet the odor of formaldehyde could not be detected at any time. Once added to an article, a portion of it remains persistently and cannot be driven off by heat. The best means of neutralizing it in vapor or in solution is by ammonia.

Physiological Action and Toxicology.—Formaldehyde vapor is a powerful irritant to the eyes and the mucous membranes of the respiratory tract. Applied in solution to the skin it smarts, but usually for a short time only. Severe urticaria is reported to have followed its application. The solution in glycerin is said to be less irritant. Taken by mouth it retards digestion even in small dosage, especially the pancreatic digestion of albumin. In strong solution it may cause vomiting. It weakens pulse and respiration and is depressing to the vital functions. The ingestion of several ounces of formalin by an adult was followed by unconsciousness, marked pallor, cold clammy perspiration, increased respiration, and râles over both lungs. The urine contained formic acid. In a few hours anuria developed, and the next morning the coma disappeared, and the patient acted as if drunk, complaining of headache, conjunctivitis, and a sore mouth. He recovered in twenty-four hours (Klueber). In England, the drinking of two ounces of a four-per-cent. solution resulted in death from heart failure twenty-nine hours later. The autopsy showed corrosive action on the œsophagus and stomach. Fischer (1901) reported to the Chicago Pathological Society an experimental study of the action of formaldehyde on animals. Inhalation resulted in marked inflammation throughout the respiratory tract. Dosage by stomach produced vomiting, subnormal temperature, rapid weak pulse, and death. Sometimes the death was sudden. Necropsy revealed intense gastritis, with congestion, necrosis, and leucocyte infiltration. Intraperitoneal injections were followed by a fibrino-hemorrhagic peritonitis of an intensity referable to the strength of the solution. Small repeated intraperitoneal injections of dilute solutions stimulated great connective-tissue proliferation. Eye instillations caused iritis. Every case showed early eosinophilia followed by general leucocytosis, and degenerative changes with focal necroses in liver and kidneys. Experiments in France show that fleas easily succumb to the vapor, but that to kill rats and mice requires as much as 8 or 10 gm. to the cubic metre of air space.

The best local antidote is ammonia, though other alkalies are of some avail. Ammonia gas quickly neutralizes the irritating vapors in a room. For the stomach it may be given as the aromatic spirit of ammonia or the liquor ammonii acetatis. When formalin is swallowed, vomiting should be promoted, or the stomach emptied by lavage. Stimulants, especially aromatic spirit of ammonia and caffeine, and hypodermics of strychnine should be administered, external heat applied, and absolute recumbency enjoined. Demulcent drinks may be given to allay irritation.

Therapeutics.—As a general disinfectant and deodorizer this drug is undoubtedly without a peer, though its penetrating power is not great (see *Disinfection*). In the respiratory passages it is of pronounced value as a prophylactic and curative in *influenza* and *pertussis*, and in allaying the cough and sweetening the sputum in *tuberculosis*. It is also used in *chronic pharyngitis*, in *atrophic rhinitis* (principally as a deodorizer), and as a *mouth wash*. It is said to be of less use in *diphtheria*, as it does not penetrate the dense membrane. A few drops of ℞ Aq. chloroformi ʒ iij. (12 c.c.), ether ℥ ss. (15 c.c.), formaldehyde solution (6 per cent.) ad ℥ iv. (120 c.c.) may be sprinkled on the sponge of a zinc respirator, and inhaled for fifteen minutes. Or one can use as a mouth wash or spray a mixture of 40-per-cent. formaldehyde solution ʒ i. (4 c.c.), glycerin ʒ iv. (15 c.c.), and water to make ℥ iv.–vi. (120 to 180 c.c.). The method of treating *tuberculosis* by cataphoresis or the electrical transmission of formaldehyde directly into the human body, the writer saw tested scientifically with negative results.

For *suppurative otitis media* Reik recommends irrigation twice a day with ʒ i. (4 c.c.) of formalin in O i. (500 c.c.) of water. Ward uses five to ten drops of a one-per-cent. solution, and in *acute otitis* three drops at a time.

In the mycotic skin diseases, such as *sycosis*, *ringworm*, and *favus*, the strong solution may be applied every other day. Cures resulted from one to four applications (Salter, Daniel). For *seborrhœa* Ravogli advises rubbing with ℞ Formalin, ʒ i.–ij. (4–8 c.c); glycerin, ʒ ij. (8 c.c.); aq. coloniensis, alcohol, āā ℥ iij. (90 c.c.).

Hyperidrosis pedis may be checked for a week or two (Hahn, Hirschfeld) by momentarily immersing the feet in pure formalin, or by applying it with a brush. Unna applies adeps lanæ 20, vaseline 10, formalin 10–20. The application of formalin to eczema or intertrigo Unna found to be very painful. He then tried a gelatin mask hardened with formalin for lupus, erythema centrifugum, lepra, and obstinate chronic eczema, but was obliged to discard it. Next he employed formalin as a corrosive for carcinoma, lupus, condylomata, and ulcers. The diseased tissues were cleanly destroyed, the necrotic surface being dry and odorless, but the development of a line of demarcation took so long a time that other means were deemed preferable. He found formalin of value, however, in *inoperable carcinoma*, as it deodorizes and mummifies the part. For *condylomata* and other soft skin protuberances he uses paraform collodion, which possesses the advantage of keeping the growths dry. Daniel rubs formalin into *warts* with a stick, and these shrink and come off without leaving a scar.

As a vaginal douche Crawford recommends formalin in *obstetrics*, and Van Winckel uses ʒ i. (4 c.c.) to a quart (1 litre) for *endometritis* or for *vaginitis*, especially gonorrhœal. It may be used in full strength in the treatment of *chancroids*.

Surgically it is an antiseptic of great power (see *Disinfectants* and *Disinfection*), and is used for sterilizing the hands, dressings, sutures, and instruments. Hoffmeister, Hirst, and others recommend it highly for catgut. Hoffmeister's method is to harden the catgut on glass spools in four per cent. formaldehyde for twenty-four hours, then boil in water for ten minutes and keep in alcohol containing five per cent. of glycerin and 0.1 per cent. of corrosive sublimate. Vandermarker states that it should not be used directly in wounds, as one-per-cent. solutions will destroy fresh granulations, and two-per-cent. will produce sloughs. Its combination with gelatin (glutol), however, is used thus by Schleich and others. Inoperable epitheliomata and sarcomata have been treated with injections of one-half-per-cent. solution (about twenty minims) followed by curetting of the hardened tissue. The bleeding has been slight, and the growths have practically disappeared after a few treatments (Mitchell, Thompson). Ravogli claims to obtain the same results from the application of a paste of rice powder, oxide of zinc, and formalin. In chronic tuberculous joints, tuberculous abscesses, and empyema, Hahn considers a one-per-cent. glycerin solution to be more efficient than the much used iodoform-glycerin.

In dentistry, paraformaldehyde is preferred, as, being in solid form, it can be placed in cavities, disinfecting them by slowly evolving formaldehyde gas.

The more common preparations and compounds of formaldehyde are:

Aminoform, Ammonio-formaldehyde—synonyms for hexamethylene-tetramine.

Amyloform—starch and formaldehyde (see Vol. I.).

Bismal—the bismuth salt of methylene digallic acid, formed by the action of gallic acid on formaldehyde. Used as intestinal antiseptic and astringent.

Creoform, Creosoform, Kreoform—a non-toxic, tasteless, and odorless compound of creosote and formaldehyde. A strong antiseptic.

Cystamine, Cystogen—synonyms for hexamethylene-tetramine.

Dextroform—formaldehyde and dextrin (see *Amyloform*, Vol. I.).

Eka-iodoform—iodoform and paraformaldehyde (see Vol. III.).

Euformol is a mixture of oil of eucalyptus, formaldehyde, thymol, menthol, etc.

Formacoll—synonym for glutol.

Formaldehyd-bisulphite (HCOH, $Na_2S_2O_5$) is a crystalline mixture resulting from the action of formaldehyde on sodium bisulphite in solution. It is claimed to possess the antiseptic properties of both constituents.

Formaldehyde-casein (Formalbumin) is an odorless, tasteless, coarse yellow powder, used in surgery as an antiseptic.

Formaldehyde-gelatin—used in photography and in surgery (see *Glutol*).

Formaldehyde-sulpho-carbolic acid $[(CH_2OH)_2.C_6H_3.OH]$ is used as an antiseptic dressing for wounds.

Formaldehyde tannalbuminate—tannalbumin subjected to the action of formaldehyde to render it more resistant to the action of the gastric juice. The compound passes unchanged through the stomach, and as it is split up but slowly in the intestines, it gets well down in the bowel before it separates into its components. Used as an intestinal antiseptic and astringent.

Formaldehyde-urea is an amorphous, white condensation product of urea and formaldehyde in alkaline solution. It is insoluble in water. Used as disinfectant.

Formalin, Formol—a saturated aqueous solution of formaldehyde.

Formatol is a proprietary dusting powder containing formaldehyde.

Formin—synonym for hexamethylene-tetramine.

Formo-chloral is an oily compound formed by the action of formaldehyde on chloral in the presence of concentrated sulphuric acid. It is used as an antiseptic.

Another compound of this name, used by Trillat as a deodorizer, is made by acting with calcium chloride on formaldehyde in solution in methyl alcohol.

Formoforin consists of formaldehyde 0.18, thymol 0.10, zinc oxide 34.44, and starch 65.28 per cent., and is used for sweating of the feet.

Formopyrin occurs in white crystals formed by the action of formalin on a solution of antipyrin. It is insoluble in cold water or ether, but fairly soluble in boiling water, alcohol, chloroform, and acids, with the latter forming stable salts.

Fortoin—cotoin acted upon by formaldehyde (see *Fortoin*).

Galloformin is prepared by acting on hexamethylene tetramine with gallic acid (see *Galloformin*).

Geoform—guaiacol and formaldehyde (see *Geoform*).

Glyco-formol is a mixture of formalin, water, and glycerin.

Glycero-formol is said to be formed by the prolonged action of formaldehyde on glycerin. It is claimed to be more toxic than formaldehyde, but the writer could find no evidence for this statement.

Hexamethylene-tetramine—the chemical name for aminoform, cystamine, cystogen, formin, and urotropin (see Urotropin).

Holzin is a sixty-per-cent. solution of formaldehyde in methyl alcohol used by Oppermann as a deodorizer.

Holzinol is a mixture containing formaldehyde and menthol.

Krameroform is prepared like tannoform, but from rhatany-tannin.

Lanoform is lanolin containing one per cent. of formaldehyde.

Lysoform is a soapy disinfectant containing formaldehyde (see *Lysoform*).

Naphthoformin is made from paraformaldehyde and the alpha and beta compounds of naphthol. It is used both externally and internally as an antiseptic.

Paraform is paraformaldehyde.

Polyformin Soluble and Insoluble—used in skin diseases (see *Polyformin*).

Preservalin—a mixture used by dairymen.

Protogen is an albuminous food obtained by acting on serum or egg albumen with formaldehyde. It is not coagulated by heat.

Quebrachoform, Quinoform, Querciform are prepared like tannoform (which see), but from the tannins of quebracho, cinchona, and oak.

Saligenin, also yielded by salicin, may be obtained by the interaction of phenol and formaldehyde.

Steriform Chloride and *Iodide*—formaldehyde 5, pepsin 20, lactose 65, and ammonium chloride or iodide 10.

Tannoform—an antiseptic in skin diseases (see *Tannoform*).

Tannopin or *Tannon* consists of tannin and hexamethylene-tetramine, and is used in diarrhœa (see *Tannopin*).

Thymoform is thymol-formaldehyde (see *Thymoform*).

Triformol, Trioxymethylene—synonyms for paraformaldehyde.

Urotropin—hexamethylene-tetramine (see *Urotropin*).

W. A. Bastedo.

FORMANILID ($C_6H_5NH.COH$) occurs in long, colorless prismatic needles obtained by digesting aniline with formic acid, or by rapidly heating aniline and oxalic acid together. It melts at 46° C. (115° F.), and is soluble in water, alcohol, glycerin, and oils. In dose of 0.13–0.3 gm. (gr. ij.–v.) it is antipyretic and analgesic, but is said to depress the heart and produce cyanosis. Its chief employment is as a local anæsthetic in two-per-cent.

solution, as in genito-urinary inflammation, or subcutaneously, or in powder form, mixed with chalk, starch, or talcum, or as a snuff in nasal troubles. *W. A. Bastedo.*

FORMIC ACID.—$HCHO_2$. Formic acid is a heavy, colorless fluid of a sharp, sour odor and taste, soluble in all proportions in water, alcohol, and glycerin. It is exceedingly irritating, producing, when applied to the skin, redness, blistering, and even sloughing, and, taken internally, gastro-enteritis and bloody urine. It has been used occasionally, locally, as a counter-irritant, applied diluted with an equal measure of water.

Edward Curtis.

FORT CRAWFORD MINERAL WELL.—Crawford County, Wisconsin.

Post-Office.—Prairie Du Chien. Hotel.

Access.—Viâ Chicago, Burlington and Quincy, and Chicago, Milwaukee and St. Paul Railroads. Prairie du Chien contains about 4,000 inhabitants, and is one of the oldest towns in the State. The well from which the mineral water is obtained was bored in 1876. At a depth of 960 feet a strong flow of water was encountered, and ever since there has been a continuous stream, six inches in diameter and having a pressure of twenty pounds to the square inch. The well yields about 40,000 gallons per hour. By means of mains and hydrants it furnishes the city fire department, and affords an abundance of water for domestic purposes. It was soon learned that the water possessed medicinal qualities. An analysis by Professor Bode, of Milwaukee, showed the following results:

One United States Gallon Contains:

Solids.	Grains.
Calcium bicarbonate	0.62
Magnesium bicarbonate	10.97
Sodium chloride	90.20
Potassium chloride	3.80
Sodium bromide	.13
Sodium sulphate	12.80
Calcium sulphate	15.38
Iron bicarbonate	.23
Sodium phosphate	Trace.
Sodium bicarbonate	Trace.
Alumina	.66
Silica	3.84
Organic matter	None.
Total	138.63

This is a valuable member of the widely useful alkaline-saline class of waters. It closely resembles some of the Saratoga waters in its mineral constituents, being, however, somewhat milder than those waters. Its chief effects are antacid, laxative, diuretic, and tonic. It is well adapted for the class of diseases to which such waters are applicable. It is also an excellent table water. A well-equipped sanitarium with ample bathing facilities is conducted in connection with the well. The water is used commercially. *James K. Crook.*

FORTOIN, or methylene-dicotoin [$CH_2(C_{14}H_{11}O_4)_2$] is obtained by allowing formaldehyde to act on cotoin, and occurs in yellow, tasteless crystals or powder having a cinnamon-like odor. It melts at 211°–213° C. (412°–415° F.), is insoluble in water, soluble with difficulty in alcohol, ether, and benzol, and readily soluble in chloroform, acetone, glacial acetic acid, and alkalies. Overlach reports thirty cases of diarrhœa in which it was used in dose of 0.25 gm. (gr. iv.) three times a day as an intestinal astringent. He believes it preferable in cases with sloughs of the mucous membrane of the intestine, as, unlike the tannin preparations, it stimulates tissue growth and causes regeneration of the mucous membrane. Its advantages over cotoin are that it is free from pungent taste and is a more powerful bactericide. *W. A. Bastedo.*

FOUNTAIN PARK MAGNETIC SPRINGS.—Champaign County, Ohio.

Post-Office.—Fountain Park. Hotel and cottages.

Access.—Viâ Pennsylvania Railroad (P., C., C. and St. L., Indianapolis Division). The hotel is within five minutes' drive of the Fountain Park Station. The location is 34 miles west of Columbus and 12 miles east of Urbana. Fountain Park village was laid out in 1882 soon after the discovery of the springs. The resort came under the present management in 1894. The site of the village is one of great natural attractiveness. The elevation is 1,200 feet above the sea-level and the surrounding country is gently undulating. The hotel and cottages are located in a beautiful tract of 43 acres in which are numerous hills surmounted by groves of deciduous trees. New acme stone walks and driveways have recently been laid around the hotel grounds, and an artificial lake of sufficient size for boating constructed. The large lawn is adapted for all kinds of outdoor sports and games. Brush Lake, one mile east of the Park, affords rare attractions to the piscatorially inclined visitor. The waters at Fountain Park proceed from five flowing wells. The largest is 2,200 feet in depth and fills a ten-inch pipe at about twenty-one pounds' pressure. Following is an analysis of this spring, made in 1892 by Prof. E. S. Wayne, of Cincinnati:

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	13.64
Calcium chloride	4.22
Magnesium chloride	2.12
Potassium sulphate	2.61
Calcium carbonate	26.24
Magnesium carbonate	11.41
Iron carbonate	.16
Silica	.24
Organic matter	.39
Total	61.03

This is an excellent water of the alkaline-saline-calcic variety. The presence of a small quantity of carbonate of iron will prevent debilitating effects on continuous use. The water has been found valuable in acute and chronic rheumatism, gout, dyspepsia, and diabetes. Two of the remaining four wells were analyzed in 1895 by Prof. H. A. Weber of the Ohio State University. They show the same general characteristics as Spring No. 1 (above). There is an excellent modern hotel in the Park. It contains twenty well-equipped bath-rooms, under the charge of an experienced physician. *James K. Crook.*

FOXGLOVE. See *Digitalis.*

FRACTURES.—A fracture is the breaking of a bone or of a cartilage. The sudden forcible destruction of the continuity of a bone in whole or in part, except when done with a cutting instrument, is called a fracture (Stimson). The gradual undermining of the strength of a bone, whether by tumor or by inflammation, does not produce a fracture until a trauma, however slight, snaps the diseased bone. The so-called *pathological* fractures are of this class. The trauma may be so slight as to pass unrecognized, but, nevertheless, this "sudden, forcible destruction of continuity" constitutes the fracture. The only etiological difference between pathological and traumatic fractures is that in the former the disease of the bone predisposes it to fracture and the violence required to produce the fracture is comparatively insignificant.

Varieties.—Fractures are commonly classified as complete and incomplete.

A Complete Fracture is a break traversing the whole thickness of a bone. In a long bone, this implies that the extremities of the bone are separated by the line of fracture. In a flat bone a complete fracture may simply break off a fragment.

Incomplete Fractures may be: (1) Fissured; (2) "Greenstick"; (3) Depressed; (4) Separation of a splinter or of an apophysis.

By a "depressed" fracture is here meant a depression of only part of the thickness of a flat or long bone. It is not an uncommon fracture of the cranial bones.

The commonest of all incomplete fractures is the *green-*

stick fracture (infraction). It usually occurs in the forearm or clavicle, and is rarely seen in adults. The condition of the bone is exactly that of a green stick broken over the knee (Fig. 2200). The bone is bent and on its convexity broken, the line of fracture running inward, transversely or obliquely, and then longitudinally in either or both directions.

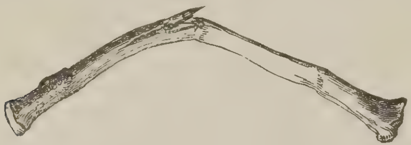

Fig. 2200.—Green-stick Fracture.

Fractures are usually described according to—

(*a*) Their direction, as tranverse, oblique, longitudinal, toothed (dentate), etc. (Figs. 2201, 2202, 2203).

(*b*) The seat of fracture—of the shaft, neck, epiphysis, condyle, epiphyseal separation, etc.

(*c*) Special features—simple, compound, comminuted, impacted, multiple, gunshot, pathological, intra-articular, etc.

A *simple* fracture is one neither compound nor comminuted. A *compound* fracture is one in which the external wound runs down to the seat of fracture. A *comminuted* (Fig. 2204) fracture is one in which the bone is splintered into a number of small fragments. By *multiple* fracture is meant the fracture of several bones or of the same bone in several distinct places. Simple fracture of both bones of the forearm or leg, however, is not spoken of as a multiple fracture. An *impacted* fracture is one in which the broken bone ends are crushed into each other and thus fixed more or less firmly.

Etiology.—*Frequency.*—Men are more subject to fractures than women (three to one), by the nature of their occupations, and their habits of life. Stimson disagrees with the accepted belief that fractures are most frequent during the winter months on account of the ice and snow, the increased frequency of fracture of the lower extremity in winter (seventy-six to fifty-three) being more than offset by the increased frequency of fractures of the upper extremity in summer (one hundred and seven to sixty-seven.)

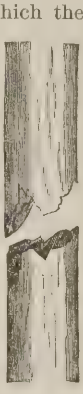

Fig. 2201.—Toothed Fracture of the Femur.

Fractures are relatively more frequent in the aged than in the adolescent (Malgaigne, Gurlt), and this in spite of the greater exposure of the latter class to various injuries. This increasing liability to fracture with age is due to a progressive decrease in agility and strength of muscle with which to ward off or minimize an injury, and also to certain changes that take place in the bones themselves.

Predisposing Causes.—In infancy the structure of the bones is in great part cartilaginous, the bones are elastic, and fracture is rare. In adult life the cartilage is replaced by bone; hence a loss in elasticity and an increase in strength; fractures are more frequent. Later still, when senile changes occur in the body, the bones become thinned by an actual diminution in the amount of bone tissue and a corresponding increase in the contained fatty and connective tissue. The bone becomes weak and brittle, and in spite of the lessened exposure to injury, fractures are most frequent. The luxations of elbow and hip, for example, are in great part replaced by fracture of the humerus, and neck of the femur, the latter being, *par excellence*, the fracture of old age.

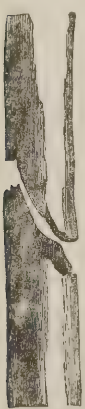

Fig. 2202.—Oblique Fracture.

Pathological predisposing causes of fracture are disease of the bone, such as gumma, sarcoma, osteomyelitis, and necrosis. The condition known as osteoporosis is a rare cause of fracture. In this disease the bones appear to have undergone in early life the rarefying process natural in old age. Diabetes, paralysis, locomotor ataxia, osteomalacia, and pregnancy have been noted as causes of this condition. The resulting brittleness of bone is often so marked that many fractures occur almost simultaneously. Such fractures usually heal perfectly well. Prolonged disuse may apparently cause osteoporosis, and some cases are congenital.

Immediate Causes.—A fracture is always caused by some force, external or internal. (1) Fracture by external violence. (2) Fracture by muscular action.

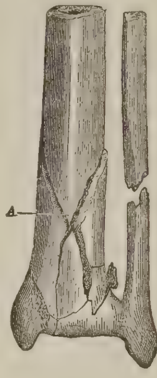

Fig. 2203.—V-shaped Fracture.

The mechanism of fracture by external violence is usually simple enough. The bone is crushed, broken or twisted, or a fragment is torn away from it. The fracture may be *direct* or *indirect*. A direct fracture occurs at the point of impact, an indirect one by transmission of the force to some more or less distant point. Thus a fall upon the outstretched hand may result in a direct fracture of the carpus, metacarpus, or phalanges, or an indirect fracture of radius, ulna, humerus, or clavicle. This distinction is most important only in compound fractures.

Muscular action is concerned in almost every fracture. Indeed the drunken man who uses his muscles little or not at all is notoriously shielded by a special Providence in this matter. But by "fracture by muscular action" is meant those fractures caused solely by muscular action. The commonest of these is fracture of the patella.

Spontaneous and *pathological* fractures have already been considered.

Pathology.—When a bone is broken the condition is a laceration of the bone itself, the periosteum, and, to a greater or less degree, of the surrounding tissues.

The bone is broken more or less completely, splintered or comminuted (see Varieties). The periosteum is usually torn in one or more places, and is elsewhere stripped up from one or both fragments, while remaining attached to each and forming a bridge between them. This *periosteal bridge* is of great service in the process of repair.

The damage to the soft parts, if caused by the broken ends of the bone ploughing through them, constitutes a complication of the fracture, while if the fracture is simply one of a number of lesions due to a trauma, the condition of the bone is relatively unimportant. This distinction has no weight in fractures of the extremities where bone lesions are always of primary importance; but in injuries of the skull and thorax an undue prominence is often ascribed to the bone lesion and injuries of the contained viscera are classed as complications of fracture; whereas the presence or absence of fracture has often little or nothing to do with the etiology, prognosis, or treatment of the visceral injury.

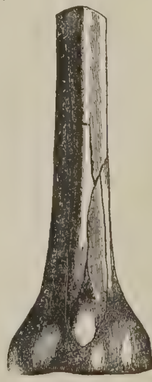

Fig. 2204.—Comminuted Fracture.

The laceration of the skin may, like that of other soft parts, be caused directly by the trauma or indirectly by the protrusion of a fragment of bone either by laceration or sloughing. Here, again, the distinction is of importance. If the fracture is compounded at the seat of injury the wound is usually large and plentifully befouled, while if indirectly compounded by puncture or sloughing over a sharp point of bone, the skin wound is comparatively small and clean; the probability is that it will escape infection, and as a compound fracture it is comparatively unimportant.

Process of Repair.—Within the first few hours after a fracture has been received the contusion and laceration of the various tissues produce a hæmatoma and then œdema. This œdema increases for twenty-four or forty-eight hours and then gradually subsides. The application of moist heat and pressure to the limb minimizes the œdematous reaction and hastens its resorption. During this period, the periosteum like the other tissues is boggy and thickened, and the bone ends lie in a cavity of greater or less size, full of semi-coagulated blood. As the œdema disappears, granulations spring from the periosteum, the surrounding soft parts, the marrow, and the bone itself. At the same time the blood collection disappears, partly by absorption and partly by making its way along the various fascial planes whence it may finally reach the surface, forming an ecchymosis some days after the injury and thus constituting one of the signs of fracture.

Thus the process of repair begins by simple granulation of all the lacerated structures, and it may be said to have completed its *first stage* when these granulations, spreading along the periosteal bridge or simply filling the cavity between the bone ends, completely envelop the region of fracture in a mass of granulation tissue. This mass is called the provisional callus. Its shape and size, as well as its relation to the bone ends, depend on the amount and nature of the displacement. If this is slight the callus is small; if considerable, it is large and irregular. This callus is formed chiefly by granulations springing from the periosteum (Fig. 2206), and in a less degree from the marrow, and also by a thickening of the periosteum and by granulations from the soft parts and the bone ends. The greater part of the callus, that arising from the periosteum, first changes to cartilaginous tissue and then to bone; the callus formed from the marrow goes through no cartilaginous formation, but becomes bone directly, the osseous formation beginning around the inner surface of the bony shell and extending inward until it entirely occludes the medullary canal (medullary plug), and outward to meet the periosteal callus and the medullary plug of the other fragment.

By this time, toward the end of the third or fourth week, the healing of the soft parts is complete, the ecchymoses are disappearing, and the callus, composed of bone within and cartilage and bone without, is quite firm everywhere except over the broken edges of the fragments. The delay here is due to the very slow progress of bone granulation, partly because of the comparatively poor circulation of that tissue and partly because a thin shell along the surface of the bone is cut off from the circulation and has to be absorbed, as have also the splinters which must inevitably be torn away at the time of fracture, before the callus can unite firmly to the bone itself. This concludes the *second stage* of the process of repair.

The osseous callus now unites the bone ends very much as a mass of solder connects two ends of pipe, with this important difference, however, that the callus is a solid mass obstructing the lumen of the "pipe" as well as extending beyond its circumference. In the *third and final stage* of repair the superabundant callus is gradually absorbed. The lumen of the bone is cleared, the callus between the bone ends becomes firmer and more compact, approaching in structure very nearly to that of the bone ends which it connects, and the external callus is absorbed until in some cases, when the bone has been accurately "set," there remains no trace of the fracture. Thus the reparative process is completed months after the receipt of injury. In most cases, however, the reduction of the fracture is not and cannot be absolutely accurate, and in these cases the displaced bone is fortified by a permanent exuberance of callus which persists during the life of the subject. At the same time projecting edges of displaced bone are rounded off in the process of callus absorption. If the exuberant callus invades a joint cavity or surrounds a nerve, ligament, or tendon, the chisel may be required to reduce it.

The fate of completely detached fragments of bone is interesting. Small splinters are probably always absorbed, but, judging from the appearance of old fractures, it is probable that fairly large fragments may become embedded in the granulations, derive new circulation from them, and end by forming an important element in the reconstructive process. On the other hand, fragments may remain embedded but unattached to the callus for years, and their presence be first suspected when, on account of debility or inflammation elsewhere in the organism, they become centres of suppuration which go on to abscess and fistulization and persist until the offending fragment is removed.

In fractures of the skull the repair is chiefly effected by the diploë which is not capable of producing exuberant callus or of closing in large defects, such as those left by a trephine opening.

Fracture of spongy bones or of the spongy ends of long bones is repaired chiefly by the bone itself. Fracture of cartilage is slow to heal and the union is chiefly fibrous. Hence old fractures crossing a joint surface are usually marked by a line of fibrous tissue or bare bone where the cartilage has been lacerated, though in exceptional instances the callus is exuberant.

The histological processes of callus and bone formation and resorption are quite the same as take place in the normal growth of a bone.

The repair of a compound fracture differs in several ways from that of a simple fracture. In the first place the primitive œdema and hæmatoma are less on account of the free escape allowed to the blood and serum. A more important difference, however, lies in the result of infection. If the wound suppurates, healing is delayed by the casting off of all fragments, by the death of a layer of some thickness along the broken edge, and especially by the destruction of the periosteum. The bone is reformed entirely by the medullary plug which grows slowly (and does not undergo immediate cartilaginous formation). The callus is large and irregular and fragments of dead bone caught within it may prolong the suppuration indefinitely.

Symptoms and Diagnosis.—The symptoms of fracture are subjective and objective. The subjective symptoms are the history, pain, tenderness, and loss of function. The objective signs are deformity, abnormal mobility, crepitus. It is usually one or more of the subjective symptoms that lead to the suspicion of fracture, while it is upon the objective signs that the diagnosis is based.

Subjective Signs.—The *history* of the patient may relate to previous fractures which have left a deformity that might otherwise be misleading. A history of active syphilis affects the prognosis and treatment. In old fractures the history may be of valuable assistance, though in recent cases it is usually indefinite and unreliable.

Pain and tenderness are constant symptoms of fracture unless the patient is intoxicated, comatose, or suffering from some grave lesion of the central nervous system. Spontaneous pain is usually diffuse and referred rather to the point of greatest contusion than to the point of fracture. Thus in Pott's fracture, the pain is often greatest over the inner side of the joint, though the chief lesion of the bone is in the other side. Tenderness is, however, a more definite symptom. It is usually localized over the point of fracture and may be a great aid in establishing this point accurately. This is especially the case in fracture of the ribs and fibula (*q. v.*). It is a universal rule that *when pressure applied laterally or in the long axis of a bone evokes pain at a distance from the point where the pressure is applied there is a fracture at the painful point.*

Loss of function may be considerable or slight. When the shaft of a long bone is broken function is lost in most instances. Yet the loss of function is in part due to pain and fright, and hence varies with the nervous quality of the patient.

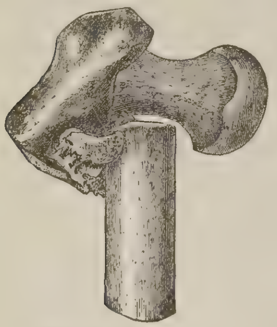

FIG. 2205.—Fracture of the Shaft of the Femur. Overriding and angular displacement; faulty union.

OBJECTIVE SIGNS.—Without the objective signs the diagnosis of fracture is never certain. They are essential. The objective signs of contusion or laceration of the soft parts, always present in greater or less degree, sometimes (*e.g.*, compound fractures) facilitate the diagnosis, but more often only obscure the objective signs of the fracture itself.

Deformity.—The deformity caused by fracture is the result of injury to the soft parts as well as of displacement of the broken bone. In some fractures the bone deformity is characteristic and unmistakable, but it is too often obscured by the effusion of blood and consecutive œdema to be a symptom readily determined by simple inspection. Hence the four methods of determining the existence of deformity, *viz.*, inspection, palpation, mensuration, and the *x*-rays.

The deformity is caused by displacements of the broken ends of the bone. The displacement may be slight or great, characteristic or obscure; hence the variety of means adopted to recognize it. Malgaigne has classified displacements as transverse, angular, rotary, overriding, impaction or crushing, and rarest of all, direct longitudinal separation. Clinically the displacement may come under two or more of these classes (*e.g.*, overriding and angular) (Figs. 2205, 2206).

Inspection may suffice to determine the existence of displacement. *Palpation* may determine the angular deformity of a bone or the protrusion of sharp fragments close under the skin; but abnormal motility and crepitus (*q. v.*) are *par excellence* the data sought by palpation.

Mensuration, on the other hand, is often of great service in the estimation of deformity, for whether impacted or overriding, the broken bone is usually shortened by muscular tension and swelling, the increase in circumference of the member being compensated for partly by shortening and partly by the elasticity of the integument. However obscured the deformity at the point of fracture, the shortening of the bone may be estimated by comparing its length with that of its fellow of the opposite side. In applying mensuration, however, two most important facts must be borne in mind:

1. There may be a previous difference in length, either congenital or acquired, of the two bones.
2. In comparing the length of the long bones of a limb it is often necessary to measure from bony points not on the same bone. In this case the bones to be compared must be in the same relative position.

In other words, if the injured limb is measured in the abducted or flexed position, the measurements of the uninjured member must be taken with it *at the same angle* of abduction or flexion. Neglect of this simple precaution is often a grave source of error in estimating shortening from fracture of the neck of the femur. The measurements are usually taken from the anterior superior spine of the ilium to the external malleolus, and the injured limb, whether fractured or not, usually lies slightly abducted and flexed, while the patient instinctively protects it by adduction of the sound limb. The relative positions of the limbs cannot be appreciated unless the patient is laid flat on his back and stripped so that the two anterior superior spines can be distinctly felt. A string drawn tightly from one to the other marks the horizontal plane of the body, and a perpendicular dropped from the centre of this marks the sagittal plane with which the abducted thighs should make equal angles.

Measurements of the diameter or the perimeter of the limb are entirely fallacious.

Abnormal Mobility and Crepitus.—These two symptoms might be termed the accessory symptoms of fracture. When obtainable there is nothing more characteristic of fracture than abnormal mobility along what should be the firm shaft of a bone, especially if accompanied by a grating sensation of crepitus imparted to the fingers rather than to the ear of the surgeon as the rough bone ends are made to rub against each other. But while these two signs are more frequently sought for than any other of the signs of fracture, they may be misleading and non-essential to a complete diagnosis, and the search for them is often the occasion of rough and painful manipulations injurious both to the patient's tissues and to his mental attitude toward the surgeon. In this matter gentleness is far more successful than force, for force assures the resistance of the patient's muscles at the same time as it blunts the sensitiveness of the surgeon's fingers. The methods of eliciting abnormal mobility and crepitus are two; (1) pressure; (2) passive motion.

Pressure is usually applied transversely to one or alternately to each of the fragments with the intent of making them slip by each other. Passive motion, angular or rotary, is employed for the purpose of demonstrating that one fragment (or some bony prominence upon it) is unaffected by motion communicated to the other.

The commoner causes of error are impaction which prevents both abnormal mobility and crepitus, the interposition of soft parts which prevents crepitus or the existence of that form of fracture known as epiphyseal separation, in which crepitus is cartilaginous. Moreover, in injuries about a joint abnormal mobility may indicate either fracture or dislocation, perhaps both, and the rule that "in fracture there is mobility where before there was none, while in dislocations abnormal mobility in one direction is compensated by restricted mobility in other directions," may not be practically applicable.

X-Rays.—The report of the committee of the American Surgical Association defines very accurately the present status of the *x*-rays in the diagnosis of fractures. Among their conclusions are the following:

1. The routine employment of the *x*-ray in cases of fracture is not at present of sufficient definite advantage to justify the teaching that it should be used in every case. If the surgeon is in doubt as to his diagnosis, he should make use of this as of every other available means to add to his knowledge of the case, but even then he should not forget the grave possibilities of misinterpretation. There is evidence that in competent hands plates may be made that will fail to reveal the presence of existing fractures or will appear to show a fracture that does not exist.

2. In the regions of the base of the skull, the spine, the pelvis, and the hips, the *x*-ray results have not as yet been thoroughly satisfactory, although good skiagraphs have been made of lesions in the last three localities. On account of the rarity of such skiagraphs of these parts special caution should be observed, when they are affected, in basing upon *x*-ray testimony any important diagnosis or line of treatment.

3. As to questions of deformity, skiagraphs alone, without expert surgical interpretation, are generally useless and frequently misleading. The appearance of deformity may be produced in any normal bone, and existing deformity may be grossly exaggerated.

4. It is not possible to distinguish after recent fractures between cases in which perfectly satisfactory callus has formed and cases which will go on to non-union. Neither can fibrous union be distinguished from union by callus

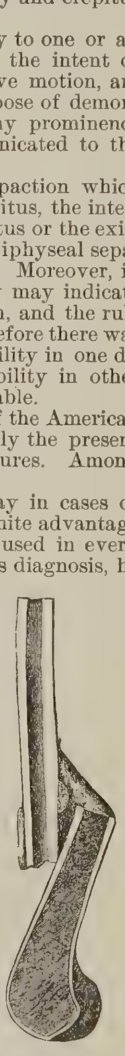

FIG. 2206.—Malunion after Fracture of the Shaft of the Femur. Shows callus formation under periosteal bridge.

in which lime salts have not yet been deposited. There is abundant evidence to show that the use of the *x*-ray in these cases should be regarded as merely the adjunct to other surgical methods, and that its testimony is especially fallible.

DIAGNOSIS.—In general the diagnosis of fracture is made by inspection and gentle palpation, aided perhaps by mensuration. Most of the commoner fractures are marked by a characteristic deformity, or by some other pathognomonic sign.

In compound fractures the diagnosis should be made with as little probing as possible. If the wound is small and clean it should be drained or sealed after it has been thoroughly irrigated, and the diagnosis made as in simple fracture. If, however, the wound is wide and befouled, the diagnosis of the exact nature of the fracture is readily determined in the course of the preliminary antiseptic toilet.

Young persons up to the age of twenty-five present two special points of diagnosis. In the first place, when they receive a fracture through the extremity of a long bone, it is very likely to follow the line of least resistance along the unossified cartilage between the diaphysis and epiphysis, thus forming an *epiphyseal separation.* The diagnosis of this condition is made on three data: first, the correspondence of the line of fracture either wholly or in greater part with the line of the epiphyseal cartilage; second, the "muffled" cartilaginous crepitus obtained when the bone ends are drawn across each other; and third, the subsequent atrophy of the torn cartilage often resulting, unless the bone has attained its full growth, in a shortened deformed limb. The most important epiphyseal separations are those of the upper extremity of the humerus and the lower extremity of the radius, since these injuries are comparatively common and these epiphyses together are responsible for two-thirds of the growth of the upper extremity. The second point of importance in the diagnosis of fracture in young persons is the frequency of incomplete fractures. The *green-stick* fracture, practically unknown in the adult, occurs with comparative frequency in the young as a result sometimes of a slight trauma. If the break is insignificant the only clinical evidence of it is an abnormal protuberance of the shaft of the bone. This may pass for a mere contusion, especially if the superficial tissues are considerably bruised. Such fractures are unimportant since they require no attention and have no more consequence than an outgrowth of callus which is absorbed in the ensuing months. More severe "green-stick" fractures produce a curving or angular deformity of the bone and a considerable protuberance of the split fragment, so that the diagnosis is not difficult.

DIFFERENTIAL DIAGNOSIS.—A fracture must be differentiated on the one hand from a dislocation, and on the other from a sprain or bruise. In either case the confusion is likely to arise only in the region of a joint, where, from the slight deformity, the difficulty in eliciting crepitus and abnormal mobility, and the unimportant interference with function (*e.g.*, many Colles' and some Pott's fractures), the injury may be mistaken for a sprain; or because of the great swelling of the soft parts all landmarks may be obscured. In such a contingency, if an accurate diagnosis cannot be reached by the aid of the ordinary data, an examination should be made with the patient anæsthetized, or, better still, if the apparatus is at hand, the *x*-rays may be employed.

PROGNOSIS.—If a fracture is properly reduced and immobilized, the primary inflammatory reaction may be expected to subside in from three to ten days. During this period there is more or less discomfort; but later physiological rest and a comfortable splint may be depended upon to relieve the patient of almost all his pain. The amount of rest required depends upon the nature of the injury and the individuality of the patient. The laboring man who insists upon walking off on an ambulatory splint two days after he has received a Pott's fracture is not to be classed with the neurasthenic woman whom the same injury confines to her room until long after the bones have united. Immobilization is almost as unimportant in the treatment of Colles' fracture as it is essential in fracture of the patella.

Age affects the prognosis in that metabolism is less rapid in the aged; their bones heal more slowly and their confinement to bed may result in bed sores and permanent debility; while if they escape this, a permanent stiffening and neuralgic condition of the affected limb may result. In the young the prognosis of simple fracture is entirely good, unless there is epiphyseal separation.

Habits and *disease,* such as alcoholism, syphilis, and general debility, affect the prognosis in proportion to their severity. The shock of fracture will often bring on delirium tremens in an alcoholic subject. Such an attack may sometimes be averted by getting the patient up and about immediately, in addition to the usual therapeutic measures. Syphilis in an active stage may delay or prevent union in a broken bone, and any chronic debilitating disease may have a similar effect.

Certain qualities of the fracture itself must be considered in the prognosis. For example, the prognosis in *compound fractures* is far graver both as to life and limb than that of simple fracture. Indeed, what with the dangers of suppuration, septicæmia, delayed and malunion, it is almost impossible to give an accurate prognosis for a compound fracture until healing is well advanced. Again, *fractures of spongy bone* heal far more rapidly than fractures of the shaft. But, on the other hand, the spongy bones lie chiefly in the region of joints, and if these are invaded by the callus, or even if merely immobilized during the process of repair, the stiffness resulting from prolonged inaction may indefinitely delay complete recovery. Indeed, the union of the bone is only the skeleton of the cure as far as the patient is concerned. When the bones are sound he is "set upon his feet," but it may be weeks before he is "limbered up" enough to accomplish anything but the lightest labor. In this connection Loew's figures are instructive and represent a most successful series. Of 167 simple fractures of the leg, one was permanently disabled, and the others were able to return to work in an average of one hundred and one days (seventy per cent. of them in ninety-one days), more than twice the classical limit assigned to the healing of a fracture of the leg. In this matter of regaining function, age is of prime importance. The young and vigorous regain both strength and agility in a few weeks, while the aged and rheumatic remain stiffened and more or less completely decrepit. The joint implicated also makes a difference. The fingers and toes are especially liable to stiffening when extended. Other elements in the prognosis are afforded by the complications.

COMPLICATIONS.—The pain, œdema, and contusion of the soft parts during the first days, and the later stiffening of the joints, occur as complications to almost every fracture, however normal the process of repair, and they have therefore been described above. The remaining complications may be early or late, local or general.

Among the *early local complications* the most important are the laceration of the soft parts producing a compound fracture, penetration of a joint by the line of fracture, and fracture dislocation.

A *compound fracture* may be direct or indirect. Direct compound fracture occurs when the trauma causing the fracture tears open the soft parts surrounding the bone. Indirect compound fracture is caused by the protrusion through the skin of one of the fragments, perhaps at some distance from the point of injury. This may be due to displacement at the time of fracture or during the subsequent manipulation or transportation; or it may occur later by sloughing of the tissues over a sharp fragment on account of faulty splints. The distinction between direct and indirect compound fractures has an important bearing on the prognosis and treatment. In the former class the wound is often gaping, irregular, and befouled; wherefore the prognosis is bad and the primary antisepsis must be thorough. In the latter the small, clean wound may often be cleansed by superficial antisepsis, without disturbing the deeper tissues.

Fractures implicating joints, *intra-articular fractures,* imperil the integrity of the joint both by displacing the articular surfaces and by the production of callus which may invade the joint cavity and impede its motion or even unite the opposing articular surfaces by fibrous or bony union, thus altogether preventing motion.

Fracture dislocation is often a very serious condition. The various fracture dislocations will receive special mention.

Other early local complications are laceration of a nerve, gangrene from rupture, thrombosis or occlusion of vessels, profuse, even fatal hemorrhage through laceration of a large vessel, and traumatic or arterio-venous aneurism from the same cause. Gangrene and muscular contracture from improper splinting are complications of the treatment rather than of the fracture itself.

Suppuration and septicæmia, so common in direct compound fractures, are rare otherwise. *Fat embolism* is most exceptional. In the first days after fracture, fat globules may sometimes be found in the urine. Of exceptional occurrence are the cases in which within twenty-four or forty-eight hours of the injury the patient is suddenly overcome with dyspnœa and dies sometimes with symptoms of pulmonary embolism, sometimes with œdema of the lungs, sometimes with predominence of symptoms from the central nervous system, unconsciousness, paralysis, convulsions. On autopsy the pulmonary or cerebral capillaries are found occluded by minute globules of fat, derived, it is presumed, from the bone marrow. Opinions differ as to how much influence fat embolism has in the production of "delayed" shock, and irregular "delirium tremens" occurring within the first few days after fracture. *Delirium tremens* and *pneumonia* are not infrequent complications of fractures in alcoholic subjects, both on account of the shock and the confinement to bed. Either condition is a very grave one coming on during the first week and often terminating fatally.

The *late complications* of fracture are all local. Persistent pain of a rheumatic, gouty, or neuralgic character, atrophy of the muscles from disuse, arrest of development in the bone after epiphyseal injury, and stiffness of the joints from prolonged immobilization have already been alluded to. Permanent atrophy and paralysis may result from rupture of a nerve, and permanent neuralgia from the inclusion of a nerve within the callus. There is always some œdema when the limb is first allowed to hang down. This is transitory, however, unless maintained by other causes.

The callus may be painful, excessive, or weak. Pain localized in the callus is rare and suggestive of threatening suppuration, inclusion of a nerve, or hysteria. That the callus should be excessive at first is not abnormal nor is it to be expected that a small callus will suffice to weld two widely separated or widely displaced fragments. Indeed, except from an æsthetic point of view, excessive callus is not a complication unless it produces pressure on some vital structure or impedes the action of a joint or muscles. In such a case recourse must be had to the chisel, but only after several months of massage and motion have proven that resorption is not to be expected. Pathological weakness in the callus—weakness, namely, after the time necessary for consolidation has elapsed—is unusual except from considerable displacement, from compound fracture in which suppuration has occurred, or from systemic debility or disease. Primary sarcoma and secondary carcinomatous deposits have very rarely been observed after fracture. Weakness of the callus produces the condition known as delayed union.

Delayed union (failure of union, pseudoarthrosis) is that condition in which the callus uniting a fracture fails either wholly or partially to ossify, so that the fragments are connected by a mass or band of fibrous tissue, or rarely by a distinct joint.

From this definition must be excepted certain fractures, such as those of the patella, the olecranon, and other apophyses, in which bony union is unusual and unessential. A theoretical distinction may be made between delayed union, in which union is still possible, and failure of union in which it is not. But it is never certain in any given case that union is impossible unless years have passed from the time of the injury, and hence the more hopeful term is preferable.

The causes of delayed union have been briefly enumerated above. Although every form of lowered vitality has been incriminated, local conditions are to blame in the great majority of cases. Either the fracture is a "pathological" one, in which case the "pathological" factor must be removed before union can be expected, or the bone ends have not been kept in apposition, on account of faulty immobilization, the interposition of the soft tissues between the fragments, or the interposition of a considerable amount of comminuted bone detached from its periosteum. A common cause of delayed union is suppuration, notably in compound fractures. Even a slight inflammatory reaction destroys the osteogenetic power of the periosteum and leaves to the marrow the burden of ossification. Hence this process is always slow and often fails entirely. Loss of periosteum is the usual cause of delayed union after operations on bone.

Especially common is the delayed union after a comminuted or compound fracture of both bones of the leg. The fibula unites speedily, and thus holds the fragments of the tibia at such a distance from each other that the bony callus is inadequate to bridge the gap. The same thing may occur in the forearm.

Finally there are certain fractures which do not unite, although apposition, immobilization, and all the other factors are apparently perfect. Such failures are not explained.

The morbid anatomy of delayed union depends on many factors. The bones are united either by a band of fibrous tissue or by a distinct joint. In the former case there may be but little change in the shape of the fragments. Their edges may be slightly rounded off; but except for this, they remain as they were at the time of the fracture, united simply by a fibrous band in which no ossification has taken place. Or, on the other hand, there may have been some attempt at ossification, manifesting itself in exuberant callus, or in partial ossification of the fibrous band. Or, finally, there may be a progressive rarefying ostitis rendering the fragments soft and pointed and gradually absorbing them, thus constantly enlarging the gap.

Where there is a distinct joint (nearthrosis) the bone ends enlarge and become eburnated—they are said even to become covered with cartilage—and lie in a cavity containing a pseudo-synovial fluid, and surrounded by a dense fibrous capsule.

The prognosis depends on the amount of abnormal mobility, the time which has elapsed since the receipt of injury, the general health of the patient, and the treatment he has already undergone for the purpose of remedying the defect. In general, the prognosis should be guarded; for while union may be obtained by persistent efforts in apparently desperate cases, and after the lapse of many months, all efforts may fail even though the defect be small and the condition of the patient excellent.

Faulty union, by which term a union with deformity that might have been avoided is understood, is rather a complication of the treatment than of the fracture itself. In certain cases, on account of the nature of the fracture or the condition of the individual, any union, with however much deformity, is a proud achievement rather than a failure. Indeed,

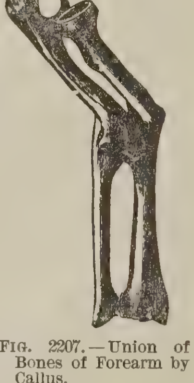

FIG. 2207.—Union of Bones of Forearm by Callus.

after no fracture is it possible to predict with certainty that every trace of the injury will disappear in time, while in many cases a greater or less amount of deformity will surely persist for all time. A common form of mal-union is union of the two bones of the forearm to each other (Fig. 2207), a condition which effectively limits pronation and supination.

Treatment.—The treatment of fractures in general will be considered according to the following scheme:

I. Prophylaxis.
II. Treatment of simple fractures.
General measures.
Reduction.
Immobilization, temporary and permanent.
Accessory measures.
The management of joints.
Massage.
Hot air.
Direct fixation.
III. Treatment of compound and gunshot fractures.
IV. Treatment of articular fractures.
V. Treatment of complications.
Early—
Gangrene.
Nerve injury.
Suppuration and sepsis.
Late—
Pain.
Joint stiffness.
Exuberant callus.
Delayed union.
Mal-union.

I. *Prophylaxis.*—The prophylaxis of fracture is more a matter of common sense than of surgery. No especial precautions need be suggested except to the surgeon. Fracture of the arm or leg of a fœtus during instrumental delivery is unfortunately not the most uncommon thing in the world, and the same may be said of fracture during operations on diseased bones. To avoid fracture in the latter class of cases it is not sufficient to leave a firm bridge of bone untouched. Besides that precaution the surgeon must be gentle in the use of heavy chisels and large forceps, lest the jar caused by the avulsion of a fragment be sufficient to split the entire shell.

II. *Treatment of Simple Fractures.—General Measures:* The first thought that arises after the diagnosis of fracture has been made concerns the *setting* of the broken bone. Yet many impediments may arise to make the setting or reduction of the fracture a matter of secondary importance. The patient's condition may be such as to demand immediate removal to home or hospital. It may be impossible to make a definite diagnosis or immediately to effect reduction on account of local swelling or spasm. In such cases transportation is the immediate question, and whether the fracture has been set or not, it is of the greatest importance that the injury already inflicted be not increased by the jolts and jars of travelling. To this end the fractured limb must either be confided to the care of an intelligent attendant who shall support it in his hands, or it must be bound firmly but not tightly to a board or a barrel stave, care being taken to immobilize the adjacent joints as well as the fragments themselves. And since the greatest danger is that the fragments may be driven through the skin and a simple fracture thus rendered compound, the dressing is to be applied with sufficient pressure near bulging fragments to secure safety in this regard. It is scarcely necessary to recommend gentleness and despatch in transportation as well as in the local manipulations.

If the patient is to remain long in bed, the quality of the bed demands consideration. If impending bed sores are foreseen, the patient will ultimately have to lie on a water bed, and he should be placed there from the beginning. If one of the long bones of the lower extremity is broken, a flat couch is necessary, such as can be produced by sliding several boards between the springs and the mattress of an ordinary bedstead. Fancy fracture beds are unessential.

The patient, once in bed with his fracture reduced and immobilized, as a rule has to pass long weeks of waiting before the member can be of use again, and it is the surgeon's part to attend during this season more to the general condition of the patient than to his fracture. The fight may be a life-and-death one, or it may be a mere question of when to get the patient about. But in any case, however insignificant, the surgeon who wishes to do full justice to his patient will not be satisfied with mere union of the broken bone, but will, by the aid of those measures grouped as "accessory," endeavor to leave his patient in the best possible condition at the time he throws off his splints and is "discharged cured."

Reduction: Many fractures cause no displacement and therefore require no reduction. Such are fractures of the ribs, pelvis, shaft of the fibula, etc. Many others are complicated by some impediment to reduction. Such an impediment may be temporary or permanent.

The local swelling caused by hemorrhage or œdema may, by obscuring the diagnosis and preventing immobilization, make it advisable to postpone reduction. Elevation of the limb and a temporary dressing applied as firmly as the patient permits will speedily reduce the swelling. Muscular spasm occasionally impedes reduction in the same way and may be overcome by similar measures or by the administration of chloroform or opium. The danger of gangrene may also discourage reduction during the first few days, although reduction often lessens this danger. In any such case reduction may usually be postponed for two or three days with perfect propriety and with no subsequent effect on union or function; but longer delay is inadvisable lest the bones acquire relations with the surrounding tissues so firm as to impede reduction.

Reduction is never literally impossible in a recent fracture, though it may well be inadvisable if the operation for the removal of the impediment to reduction involves too great a risk or puts the patient in a worse condition than before. Thus certain impacted fractures, notably fracture of the neck of the femur, are irreducible, since reduction, which could be accomplished only imperfectly and with great difficulty, would separate the ends of the bone, so that in place of a slightly deformed and shortened member a false joint would result, with considerable or complete loss of function. Another form of permanent obstruction occurs when reduction is mechanically impossible because of interposed soft parts, or fragments of bone, or interlocking of the bone ends. The associated contusion may make the diagnosis as doubtful as the treatment.

In face of such complications the surgeon may well hesitate. The choice lies between immediate operation and expectant treatment in the hope that the patient may yet have a fairly useful limb which may in any case be improved by a later operation. As a rule, immediate operation is to be preferred, and irreducible fractures involving a joint especially demand the knife, for if let alone they will almost inevitably heal with excessive callus, impaired function, and with little prospect of relief by secondary operation.

Elements which should weigh against operation are the unfamiliarity of the surgeon with such treatment, and the impossibility of obtaining asepsis. The best results will be obtained if operation is performed within twenty-four hours of the time of fracture. Later, the union is delayed by œdema and contusion. The operative method is described below.

Unless some of the above complications are present, the sooner the fracture is reduced the better. This is not only that union may progress favorably but also for the comfort of the patient; his pains are immediately lessened and the œdematous reaction is diminished.

The general principles upon which reduction is usually performed are:

1. To place the lower fragment in the same plane as the upper one, and
2. To draw it into place by relaxing the muscles as much as possible, and by traction and counter-traction.

These rules hold good because the upper fragment (the one nearest the body) is usually more or less fixed by the muscles attached to it, and the lower fragment must be manipulated with a knowledge of this position, obtained often rather from anatomy and pathology than from inspection and palpation of the broken limb.

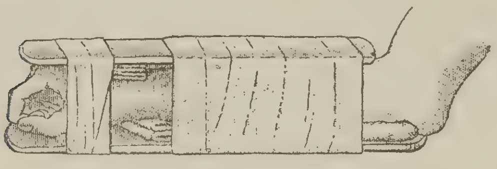

FIG. 2208.—Board Splints Applied.

Evidently no generalization is possible in this matter. Each fracture must be discussed individually. But few fractures are reduced directly by apposing the fragments, although local manipulations are often employed to aid traction as well as to ascertain its results.

The reduction of green-stick fractures is accomplished by forcibly bending the bone back until it is straightened. It may be necessary to break it entirely across before it will remain straight.

Small fragments, if they interfere with reduction or threaten to slough through the skin, should be removed with due antiseptic precautions.

If one of the fragments pierce a muscle, relaxation of the muscle by flexion or extension of the neighboring joints may aid materially in its extraction.

Immobilization: The apparatus employed to retain a fracture in place is called a splint. Before describing the different varieties of splints, temporary and permanent, a few rules governing their use may be laid down.

1. The splint must immobilize the broken bone. To do this it must usually immobilize the joints at each end of the bone.
2. It must not be allowed to interfere with the circulation, hence
3. Temporary splints to be used during the first few days after fracture, while the circulation of the limb is impaired, should never consist of a snug encasement.
4. Splints made of metal or board should be wide enough to prevent the circular retention dressing from encircling the limb snugly, and
5. The toes and fingers must always remain exposed as indices of the circulation in the extremity.
6. When a dressing is applied to the upper part of a limb, light compression by bandage should be carried to the toes or fingers to prevent œdema and pain.
7. Every patient wearing a splint should be inspected once a week, and the splint removed for that purpose, if necessary.

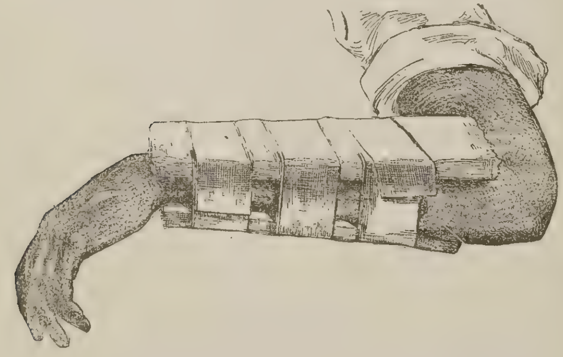

FIG. 2209.—Mode of Using Adhesive Plaster for Retaining Splints.

8. After the first two weeks (or even sooner) the splints should be so arranged as to allow the greatest possible freedom to adjoining joints as far as compatible with the union of the bone.

Once the fragments are in place they must be kept so. Yet in many instances during the first few days there is so much swelling about the seat of fracture that the retentive apparatus must be applied as much for pressure as for immobilization, and after the swelling has been thus reduced this primary dressing is no longer suitable. Other reasons for the use of a temporary dressing are transportation and the treatment of compound fractures. In many varieties of fracture the temporary apparatus may be entirely dispensed with, permanent dressings being applied at once.

Temporary Immobilization: The important requirements of a temporary splint are that it may be (1) everywhere obtainable, and (2) universally and readily applicable. Hence wide side splints of board, cardboard, or metal are usually employed for this purpose (Fig. 2208). Such articles are obtainable everywhere and may be bound to the limb with any cloth, though adhesive plaster makes the best binder (Fig. 2209). The board need only be wide enough to prevent the bandage from compressing the limb laterally and long enough to immobilize the adjacent joints. It should be roughly padded with cotton, heaped up to fill the space left by the natural depressions of the limb and thickened around the bony prominences (but not on them) so as to prevent pressure upon them.

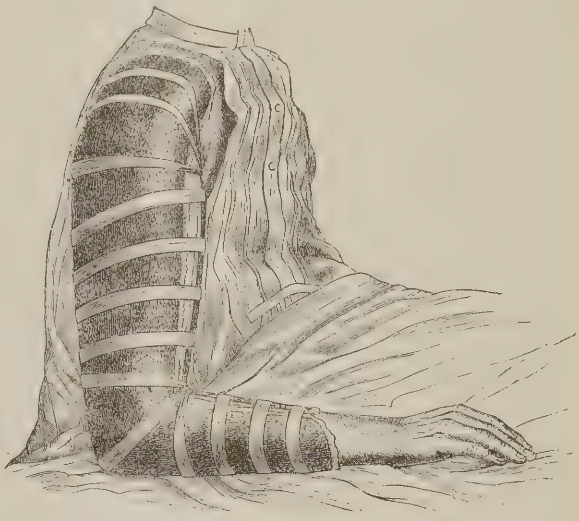

FIG. 2210.—Moulded Splint for Fracture of the Humerus.

When the material is at hand, *moulded splints* of gutta percha (Fig. 2210), leather, felt, or wire mesh make more elegant and lighter splints. But these have been discarded by most surgeons in favor of moulded splints of *plaster of Paris.* This substance is easily obtained and can readily be moulded into a splint which, for durability, stoutness, and lightness, leaves nothing to be desired. Unfortunately the plaster adheres firmly to the surgeon's hands, and although this may be prevented in some degree by anointing the hands with vaselin, and its removal assisted by glycerin and hot water, yet it is an annoyance that cannot be completely overcome.

To make a *plaster-of-Paris splint,* previously prepared bandages may be employed or the plaster may be applied to the bandage at the making of the splint. The former method is by far the simpler; but unless the bandages are hermetically sealed in tins they soon absorb enough moisture from the atmosphere to render them absolutely useless, and unfortunately their condition cannot always be determined until they are being applied.

If prepared bandages are to be used to make a moulded splint, they are immersed in hot water to which a little salt or zinc sulphate is added. The length of splint required is measured off with a muslin bandage, which is then laid upon a towel or oilcloth. By this time the plaster bandage will be soaked through, and may be taken from the water, squeezed gently and applied back and forth until the muslin bandage (which had best be a double thickness) is covered by six or eight lengths of plaster bandage. A little of the hot water sprinkled here and there adds smoothness, and the whole is strengthened and polished with a handful of dry plaster rubbed in and moistened. This band is then applied lengthwise to the limb with the muslin bandage next to the skin. A snug roller bandage binds it in place, and the limb being laid or propped in a suitable position, there results in about six hours a light, strong splint, perfectly moulded to the limb and removable at will.

If there are no prepared bandages at hand, the plaster is poured into an agate basin, enough hot water is added to bring it to the consistence of a rather thin paste, and it is then applied to the muslin bandage between the folds of a gauze bandage, a layer of plaster being spread quite thick between every two layers of bandage. Six or eight layers of the gauze bandage are used and the dressing is finished and applied as directed above. When using the prepared bandages the tendency is not to wet them enough; when using the fresh plaster to wet it too much. Hence the latter usually sets more slowly.

Such devices as waterproofing the exterior of a splint with varnish, protecting it with rubber tissue, or strengthening it with additional plaster at its angles or with iron bands or bass wood slivers, will suggest themselves to the surgeon. Such splints should last two or three weeks.

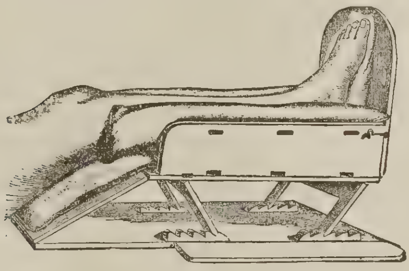

FIG. 2211.—Petit's Fracture Box.

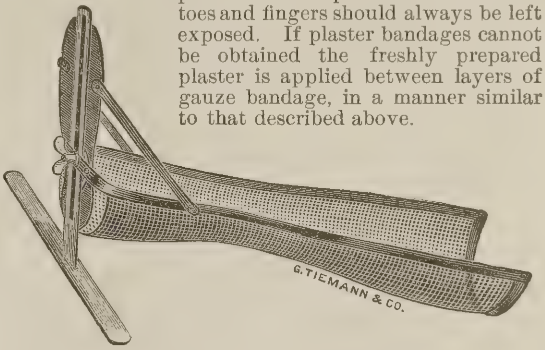
For fractures of the leg or ankle the *fracture box* (Fig. 2211), or better the *Volkmann splint* (Fig. 2212) is often applied during the first few days. Unless care is taken to prevent it, the pressure of the heel upon the splint causes excruciating pain and later ulceration. To avoid this the foot is suspended by a strip of adhesive plaster passing from the ankle under the heel and along the sole of the foot and over the top of the foot-piece to which it is attached by a reversed strip. This splint, moreover, must be well padded, especially on each side of the tendo Achilis. If pain is felt in spite of these precautions it may be relieved by pushing the cotton from under the heel up on each side of the ankle. When using these appliances a snug bandage should be previously applied to the limb in order to hasten the subsidence of swelling.

Permanent Immobilization.—The various splints described in the preceding paragraph, except the moulded splints, are too clumsy and do not produce sufficient immobilization to be useful after the first œdematous reaction has subsided. As for the moulded splints, the more one uses them the more satisfactory they seem, especially for fractures about the upper arm and leg; but when the primary reaction subsides the primary splint no longer fits and must be exchanged for a tighter one.

For strictly permanent dressings, to be changed not oftener than every week or two, a complete *encasement* of the limb in *plaster of Paris* forms a very efficient splint (Fig. 2213). The limb is first encased in a thin layer of cotton or muslin bandage (or it may be simply greased thickly with vaselin) and held in proper position while the wetted (*v. s.*) plaster bandage is applied from below upward. In applying a plaster encasement the bandage is run as for a reverse, but the "reverse" is not made, the bandage being simply turned sharply downward. Two or three thicknesses of bandage and a liberal polish of plaster are ample allowance. The toes and fingers should always be left exposed. If plaster bandages cannot be obtained the freshly prepared plaster is applied between layers of gauze bandage, in a manner similar to that described above.



G. TIEMANN & CO.

FIG. 2212.—Volkmann's T Splint.

Silicate of soda ("liquid glass") may be employed in a similar manner. This substance makes a far more elegant and somewhat lighter splint, than the plaster of Paris, but it sets slowly and is neither so strong nor so enduring as the other

Various forms of *mechanical splints* are employed in certain cases. Except where traction is necessary in order to maintain reduction, mechanical devices are rarely necessary. A past and fanciful age was rich in such appliances which were more notable for their ingenuity of construction and general clumsiness than for any aptness to their special purposes. These have been swept away by the neatness and cleanliness of modern surgery; but the ever-increasing ingenuity of the orthopedist to relieve the pain and deformity of disease promises a revival of mechanical apparatus for the treatment of fracture (for those who can afford the luxury). As yet the only notable examples of mechanical splints are employed for fractures of the thigh and spine and will be considered under those headings.

Accessory Measures: The Management of Joints.—Since stiffness of the joints adjacent to a fractured bone is of such frequent occurrence as to be the universal complication of fracture, and since this more than any other thing is likely to retard convalescence, it is not far to conclude that the joints should be exercised at the earliest possible moment, and in the manner best calculated to procure satisfactory results.

Stimson lays down two rules on this point:

1. "So long as the joint is swollen and hot, so long as its use is followed by an increase of swelling and heat and by persistent pain, so long must it be kept at rest; and so long must active treatment be limited to massage or elastic compression; and, as a rule, this attitude of non-interference may be maintained until after union of the fracture has become complete. Then . . . passive motion or . . . gradually increasing use of the limb will rapidly restore the function of the joint.

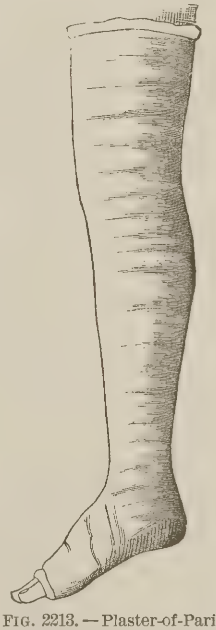


FIG. 2213.—Plaster-of-Paris Encasement for Fracture of the Leg.

2. "Forcible passive motion, with or without anæsthesia, is always harmful before the second month, and even after that time it is far more likely to do harm than good. . . . The proceeding should, I think, be almost wholly abandoned, and in its place we should resort to massage, constant use within existing limits, and possibly to the recently introduced method of prolonged exposure to high, dry temperatures; and these failing, I should prefer to expose the joint by incision in order to remove such intra-articular obstacles as might exist and be removable rather than blindly to seek to break and tear them without knowing what and where they are."

Since the fingers are peculiarly liable to stiffening, especially if kept extended, they should always be immobilized in the position of flexion, and passive or active motion should be begun on them within the first two weeks.

Massage.—Massage at the hands of any one but an expert should never be employed until after union has taken place. Lucas Championnière is the ardent advocate of massage and passive motion in the early days. When employed with the utmost gentleness and skill these measures eliminate joint stiffness and hasten the resorption of the primary exudate and perhaps the union of the bone. But the treatment is expensive and therefore beyond the reach of most patients. Moreover, the benefit derived from it is in many cases a negligible quantity, while any mishap or excess of zeal on the part of the operator is not unlikely to delay union rather than to hasten it. Hence this treatment should be reserved for those cases in which the primary reaction is unduly prolonged or the joints are threatened.

When employed, massage should be given daily and very gently. Elastic pressure by a light rubber bandage is often equally useful. It is usually better to apply the bandage only by day.

Hot Air.—Treatment of recent fractures by dry air at a temperature between 300° and 400° F. has been advocated. The indications for its use are the same as those for massage. I have tried it only twice and in both cases it failed, though massage subsequently succeeded.

Ambulatory Treatment.—The vogue of the so-called "ambulatory treatment" is already waning. The idea is an extension of Lucas Championnière's theory that exercise is good for fractures and rest bad. Hence, it was urged, all persons suffering from fracture should be up and about at the earliest possible moment, and this may be accomplished for persons with broken legs by so strengthening the splint that the limb may be used in walking, the weight of the body being transmitted by the splint instead of by the broken bones.

It is a matter of common experience that a Pott's fracture is sometimes no more disabling than a sprained ankle, and that after the permanent splint has been applied, it may be possible to force the patient to walk with the aid of crutches, so little inconvenience does the injured ankle cause him. In such cases ambulatory treatment is quite appropriate, but the application of this theory to fractures of the femur or the tibia and fibula is entirely unwarranted and extremely dangerous. If there is danger of faulty or delayed union from gentle massage at the hands of a competent operator, this danger is multiplied a hundredfold for a patient thus turned out to take care of himself. Moreover, the alleged advantages of rapid union and ability to work are not proven. The safest form of ambulatory splint is a hip splint such as is employed for tuberculous disease, with a plaster encasement for the fracture. For fracture of the leg a very heavy plaster encasement is sometimes employed in which two stout lateral rods of iron or wood are incorporated, bearing above upon a band of plaster under the tuberosities of the tibia and terminating below in a cross-piece two inches below the sole of the foot. This splint transmits the body weight from the tuberosities through the splint to the ground. Though clumsy it is safe for a Pott's fracture but dangerous for a fracture of the leg.

Ambulatory splints should never be applied until after the subsidence of the primary swelling.

Direct Fixation.—Like the other accessory measures, direct fixation has been paraded as the only treatment for fractures. Yet though incision and manual reposition of the displaced bones would give theoretically perfect results, and lessen the primary œdema by allowing evacuation of the clots, the eminently satisfactory results obtained by the ordinary treatment as well as the danger of infection leave but few supporters to this theory.

The accepted indications for direct fixation are:

1. When incision is necessary for reduction, to remove comminuted fragments, or in certain special fractures (patella) to maintain apposition.
2. For most compound fractures.
3. For delayed union after milder means have failed.

The methods of applying direct fixation are two:

1. Periosteal suture.
2. Fixation of the bones themselves.

Suture of the periosteum and adjacent soft tissues gives but an indirect support to the bone. It can prevent only separation of the ends. Angular deviation and overriding must be prevented by splints.

Fixation of the bone is commonly accomplished by silver wire, nails, bone pegs, or special clamps riveted about the bone. These methods effect admirable apposition, but they have a common defect, viz., the liability of these wires, pegs, or clamps to act as irritating foreign bodies, causing bone softening either immediately about them or extending through the whole width of the bone ends and resulting in a fibrous union. This unfortunate result attends a large proportion of cases treated in this manner.

If, therefore, direct fixation is employed, periosteal suture is to be preferred, and if this does not effect sufficiently firm apposition, the bones should be united by a removable suture of silver or silk or some such apparatus as the Parkhill clamp * to be detached at the end of ten days or as soon as the provisional callus has been thrown out.

III. *Compound and Gunshot Fractures.*—The treatment of compound fractures may be broadly classified thus:

1. Treatment of "primary" or "direct" compound fractures in which the wound is gaping, contused, and infected.
2. Treatment of "secondary" or "indirect" compound fractures in which the wound is small, clean, and negligible.

The basis for this distinction has been noted above.

1. The treatment of direct compound fractures comprises extensive incision, copious irrigation with mild solutions, the trimming away and removal of all contused and befouled tissue, and all loose chips that are not firmly attached to the periosteum.

The periosteum and fascia are loosely sutured and gauze or gutta-percha tissue drains are inserted down to the bone, and antiseptic dressings applied.

The splint should be applied to the limb before the patient leaves the operating table. If the wound is expected to run a clean course a fenestrated plaster encasement is the best, reinforced if necessary by iron bands. If, however, suppuration is feared and daily dressings are expected, such a splint soon becomes soiled and soaked with the discharge from the wound in spite of every precaution. Removable splints, such as moulded splints, Volkmann's splint, the double inclined plane (Fig. 2214),

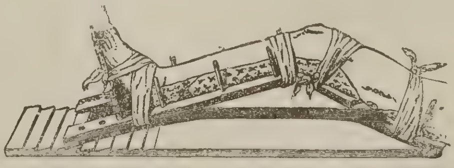

FIG. 2214.—Esmarch's Double-inclined Plane.

---

* Annals of Surgery, 1898, xxvii., 553.

Hodgen's (Fig. 2221) or Smith's splints (Fig. 2215) are then to be preferred. The latter splints afford elevation as well as immobilization.

The treatment of the wound is of the greatest importance. While the primary irrigation and antisepsis are chiefly to be depended upon to prevent infection, the irritation as well as the danger of infection from frequent change of dressings is a common cause of late suppuration. If the wound is but loosely sutured and lightly packed in the first place, it may sometimes be left undisturbed until the fourth day. If at the first dressing the wound is clean it should be disturbed as little as possible. Some of the drainage may be removed. The wound should not be irrigated. After this the drainage is renewed at intervals of from forty-eight to seventy-two hours until the wound is healed. If active suppuration occurs it must be combated by the usual antiseptic methods.

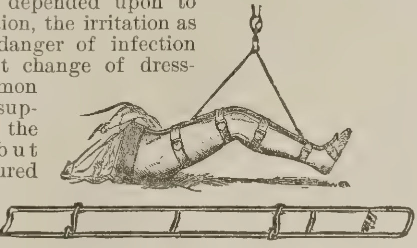

Fig. 2215.—Nathan R. Smith's Anterior Splint.

Amputation is rarely indicated at the time of accident. However crushed the limb may be, every attempt should be made to save it. If, however, the lower segment of the limb remains pulseless and incision into it produces only a stagnant venous ooze, it may be wiser to amputate rather than to subject the patient to a second operation. The rule in amputating is to save as much tissue as possible, and to this end it may even be wise, in case the surgeon feels confident of his asepsis, to allow the line of amputation to coincide in great part with that of the laceration.

2. When the wound is small and clean it may be treated by a superficial cleansing and precautionary drainage, or it may require operation as described above, at the surgeon's discretion.

Gunshot Fractures.—Fractures caused by bullets may be widely compounded or practically simple fractures. The special indications for treatment are dealt with elsewhere (see *Gunshot wounds*).

IV. *Articular Fractures.*—Most of the classical fractures involving joints, such as fractures of the anatomical neck of the humerus, fractures of the patella, Pott's fracture, etc., are to be treated by certain well-defined, special methods. But there are many unusual fractures involving joints, often caused by a direct crushing injury. They have few common features, and each must be dealt with individually. For the treatment of such fractures a few general rules may be laid down.

1. If the fracture is compounded, the joint should be fully cleansed of all foreign matter, fragments of bone, blood clots, etc., and copiously irrigated. Then, if there is a chance of avoiding infection, the joint should be sealed by suturing the soft tissues closely about it. If suppuration is anticipated continuous irrigation should be established and maintained for forty-eight hours. If suppuration appears in a case in which it had not been looked for, the joint must be opened and irrigated continuously until the infection is conquered.

2. Simple articular fractures usually require no special treatment except early passive motion to prevent ankylosis. Exceptionally operation may be undertaken to reconstruct a thoroughly disorganized joint, or to extract a fragment that defies reduction and threatens the future efficiency of the joint.

V. *Treatment of Complications.*—The early complications that require special treatment are (1) gangrene, (2) injury to a nerve, and (3) suppuration and sepsis. Among the later ones (1) persistent pain or paralysis, (2) joint stiffness, (3) delayed union, and (4) mal-union deserve mention.

Gangrene: Gangrene of the limb may often be averted by multiple longitudinal incisions through the skin and fascia (made under primary anæsthesia) followed by elevation and hot wet dressings. If these means fail (as they may do unexpectedly, since under an unbroken skin the deeper tissues may be reduced to a pulp by a crushing force) amputation should be resorted to at once. The line of amputation may be estimated by producing artificial ischæmia with the Esmarch bandage (to be used only if there is no infection). Whatever tissue reassumes a pink hue after the pressure is removed may be saved. If, however, the gangrene is progressive and septic, rapid amputation well above the gangrenous region should be performed immediately.

Injury to a Nerve: It should never be too hastily assumed that a nerve has been ruptured. The injury is a rare one, while traumatic paralysis, hysterical in nature or because the nerve has been bruised, is common and transitory. Moreover, no harm can come from waiting. Operation should therefore be delayed at least a week or two, at the end of which time, if there is no diminution of paralysis or anæsthesia, the rupture of a nerve may be considered probable and the nerve cut down upon and sutured. (See under Fractures of the Lower Extremity of the Humerus.)

Severe and persistent neuralgia may indicate pressure by a fragment or by the callus. To relieve it an incision is necessary, and if no such physical cause for the neuralgia is found, stretching the nerve may relieve the pain.

Suppuration and Sepsis: These complications are confined to compound fractures. To treat them judiciously may tax the keenest surgical instinct, for in many cases the suppuration is at first slight and the constitutional disturbance insignificant. To leave the wound unirrigated is to invite extension of the infection throughout the lacerated tissues, while to irrigate freely is to break down fibrinous adhesions, to bruise granulations, and to irritate the whole area to such an extent as enormously to encourage infection. To steer between the two is less a matter of intelligence than of instinct derived from experience. If the infection promises to be slight, and occurs later than the fourth or fifth day when healing has already progressed so far as to afford a barrier to the spread of suppuration, the pus may simply be mopped away and the cavity swabbed out with peroxide of hydrogen and packed with bichloride gauze (1 to 2,000) or one of the newer organic silver salts. If, however, the infection occurs early or presents other grave features, there is nothing for it but to irrigate the wound copiously (one to two quarts of bichloride solution 1 to 10,000) once and thereafter to change the dressings frequently in the hope that the infection may thus be repressed or at least confined to one spot.

The milder infections may be conquered by these local measures. The more virulent processes require wet dressings, antiseptic baths, multiple incisions, continuous irrigation or even amputations. As already stated, the union of the bone is delayed by the infection as well as by the manipulations, but I have known union to take place in the femur in two cases after a year of hospital treatment. Such a result could not be expected in an old man. He would not survive the prolonged suppuration.

Persistent Pain or Paralysis: There is always a good deal of stiffness and weakness for the first weeks after the patient gets about, but as long as his symptoms are lessening they require no treatment. Progress may be encouraged by any form of muscular or circulatory stimulation such as massage, exercise, passive motion, hot air, electricity, strychnine and other tonics. The salicylic-acid derivatives and colchicine may help.

Pains amounting in severity to an actual neuralgia and persistent paralysis are often best treated by operative investigation of the nerves.

Joint Stiffness: If this does not react to the treatment mentioned above, operation is the only resource.

Fingers that have remained immobile in the extended position for more than two months are practically beyond hope.

Delayed Union: This condition may be treated systemically by tonics, locally by irritants, or by operation. If the delayed union is due to systemic disease, such as syphilis, malaria, etc., this etiological condition must be combated. Over and above this it is customary to administer phosphorus or phosphate of lime. Thyroid extract has been recently employed. It has proved useful at the hands of some and has failed with others.

The local irritative measures may be employed in connection with the drugs or after they have failed. Painting with iodine or guaiacol and cauterization are of little benefit. Exercise is especially useful to encourage union of the tibia, when there is not too much separation. The leg is encased in plaster and the patient is instructed to walk upon it daily. Massage may help. If these measures fail congestion may be produced by bandaging the limb tightly above the fracture. The bandage is applied for two or three hours at a time, on alternate days, for a week. A more efficient and more painful treatment is the injection of a few drops of chloride of zinc (ten per cent.), tincture of iodine or alcohol into the band of union. This sets up an acute reaction which may be followed by ossification. Electrolysis is said to have the same effect. Still greater irritation may be produced by violently wrenching the limb about while the patient is anæsthetized.

Schaffer has obtained union in old fractures of the neck of the femur by special braces exerting direct pressure over the trochanter.

Operation is necessary when the above means fail, or when union is mechanically impossible on account of separation of the bone ends by the interposition of other tissues, or when they (tibia, ulna) are held apart by a parallel bone.

There are various methods of operating. The bone may be cut down upon, the band of union cut away, and the bone ends approximated by periosteal suture or bone pegs or wire. Parkhill's clamp seems especially fitted for this sort of work, and it has given good results after other methods have failed. Permanent wiring, pegging, or clamping is dangerous, for the reasons already stated (p. 256).

The presence of an actual new joint makes no material difference in the operative technique.

The prospect of success from any of these methods is none too glowing. The causes of failure of union may continue in force, and the difficulty in obtaining and maintaining the necessary approximation of the two fragments is great. All else failing amputation may be resorted to.

VII. *Mal-Union.*—When once a bone has united with deformity, the disfigurement can be remedied only by osteoclasis or osteotomy. Before suggesting such treatment, however, the surgeon will do well to consider whether with the material at hand, viz., the existing bony tissue, he can obtain a material improvement from any operation.

Fractures of the lower extremity of the humerus and Pott's fracture often call for relief, in the one case to overcome the restricted mobility of the elbow joint, in the other to remedy the deformity. In either case the best plan of treatment is to chisel through the bones along the old lines of fracture, to remove superfluous callus and then to reduce and splint the fracture as though it were a fresh one. This is done in the foot through curved internal and external incisions. In the elbow it may be impossible to ascertain the nature of the fracture or to be sure of what is callus and what is fragment. If such be the case the surgeon should rest satisfied with the removal of such bony protuberances as interfere with motion and the breaking up of adhesions. Passive motion should be begun at the end of a week and practised daily in order to prevent recurrence of the ankylosis.

SPECIAL FRACTURES.

Fractures of the Skull—See *Head, Injuries of.*

Fractures of the Spine—See *Spine, Surgery of the.*

Fractures of the Bones of the Face—See *Jaws, Injuries of;* and *Nose, Injuries of.*

Fractures of the Laryngeal Cartilages—See *Larynx, Fractures and Dislocations of.*

Fractures of the Clavicle.—Excepting the bones of the forearm and leg, the clavicle is broken more often than any bone in the body.

For clinical purposes the bone is divided arbitrarily into three equal portions. To the inner third are attached the strong ligaments binding the clavicle to the sternum and the first rib; the outer third is protected by the trapezius and the deltoid muscles and the coraco-clavicular ligament; the middle third is unprotected and it suffers by far the greatest number of fractures.

Varieties.—But five compound fractures of the clavicle are recorded. Multiple and comminuted fractures are rare. I have obtained an excellent result by removing a small fragment.

Incomplete fractures are insisted upon by Hamilton and Platt. The former reports 34 incomplete fractures in a series of 157 cases; the latter 25 in 115. The injury is unimportant. It is caused by a fall upon the shoulder in a young person. Within a few days after the fall a swelling appears about the middle third of the bone. False motion and crepitus may sometimes be elicited. No treatment is necessary, except perhaps a broad sling to elevate the elbow.

Simple fracture of the middle third may be transverse (children) or oblique (adults); the shoulder, losing its support, sinks downward and inward. The inner fragment lies above or in front of the outer. When the line of fracture is transverse there may be angular displacement or none at all.

Fracture of the outer third is rare. It is usually caused by direct violence. There may be no displacement and the fracture may pass unrecognized (Lane). Displacement when present is usually angular. If the fracture is within the outer inch of the bone the apex of the angle is upward, otherwise it is usually backward. Fracture of the inner third is very rare. Displacement is slight or absent.

Fracture of both clavicles is unusual. It has been known to cause considerable dyspnœa on account of the weight of the upper extremities upon the chest.

Etiology.—While fracture of the clavicle is usually caused by a fall upon the shoulder or the outstretched arm, it may be due to direct violence or even to such muscular efforts as striking a blow or lifting a heavy weight.

Symptoms and Course.—In fracture of the middle third crepitus cannot always be obtained, but the drooping shoulder and the shortening and deformity of the bone as compared with its fellow are characteristic. Flexion and extension of the arm may be but little impaired, yet abduction is quite impossible.

Fractures of the inner and outer thirds and all incomplete fractures can be diagnosed only by palpation along the bone.

The course of the injury is usually simple, though such complications as puncture of the subclavian vein, aneurism from injury to the artery, rupture of the brachial plexus, and emphysema from puncture of the lung, have been reported. Union may be expected at the end of the fourth week. As a rule, some displacement and shortening persist.

Treatment.—The method of reduction and immobilization is the same for all the varieties, except certain fractures of the outer third which require direct pressure by means of a strip of adhesive plaster passed over the point of fracture and the point of the elbow and back over the fracture (Stimson's dressing for dislocation of the outer end of the clavicle), and a simple sling. In all other cases the object aimed at is to remove the weight of the upper extremity, which drags the outer fragment downward, forward, and inward. To effect reduction, the simplest method is to lay the patient upon his back, manipulating the shoulder until the bone resumes its normal direction. This is simple: but to retain the bone in place is a far more difficult matter; witness the infinite number of methods employed.

The treatment employed depends upon the result desired, whether a useful limb merely or a beautiful neck. To attain the former result a simple sling often suffices, while the latter may perhaps not be reached by the surgeon's most ingenious devices. In general, if a perfect result is desired, the patient must be kept on *her* back for three weeks in the most suitable of the dressings to be described below.

The dressings usually employed are Mayor's scarf, Velpeau's bandage, Sayre's dressing, and Moore's bandage. In applying these several thicknesses of towel or non-absorbent cotton (carded lamb's wool is better) should be padded into the axilla and between the limb and the side.

Mayor's scarf is made of a square of stuff, the diagonal of which is long enough to reach around the body. It is applied like an ordinary sling, but the lower ends are passed around the body and knotted in the back. This is a very satisfactory appliance for dispensary practice.

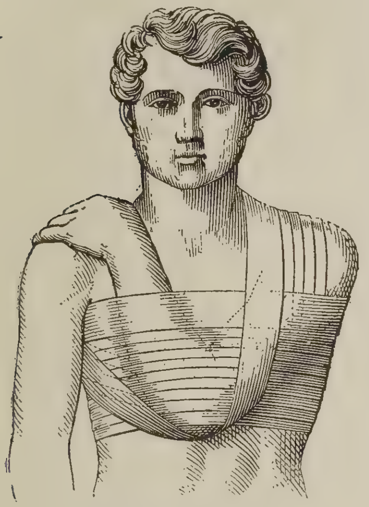

FIG. 2216.—Velpeau's Bandage.

Velpeau's bandage (Fig. 2216) is applied with the hand of the injured side placed on the opposite shoulder, "and the limb is drawn snugly up toward the neck by successive turns of the roller, which, beginning at the opposite axilla, pass obliquely across the back, over the shoulder, in front of the arm, under the elbow, and back to the axilla; after three or four such turns have been placed the bandage is carried circularly around the body, covering in the arm from below upward. The turns should be secured by stitching or by soaking in plaster."

Sayre's Dressing (Figs. 2217 and 2218) consists of "two strips of adhesive plaster, each about three inches wide, and long enough to go once and a half around the body; one end of the first strap is stitched loosely about the arm just below the axilla, and the other end carried around the back and the opposite side to the chest in front. The second strap is then carried from the top of the shoulder on the uninjured side across the back, under the elbow, and along the forearm to the shoulder again. The elbow should be drawn back while the first strap is applied, and well forward while the second is."

Of the latter two dressings Sayre's is the more efficient and lasting but the less comfortable. In each the hand should be left exposed.

Moore's bandage is made of a wide muslin bandage or scarf about two yards long. "Its centre is placed under the olecranon, the forearm being flexed at a right angle, the end that is next the body is carried up between the arm and the side, in front of and over the shoulder across the back and under the opposite axilla, the other end is carried around the outer side and front of the elbow, then between it and the side to the back and across the back to the opposite shoulder, where it is made fast to the first end. The elbow is drawn backward and pressed upward." The wrist is supported by a sling.

Various other splints are employed, too numerous to mention.

FRACTURES OF THE SCAPULA.—Fractures of the scapula are classified as: (1) fractures of the body; (2) of the inferior angle; (3) of the upper angle and supraspinous fossa; (4) of the spine; (5) of the acromion; (6) of the coracoid process; (7) through the surgical neck; (8) of the glenoid cavity.

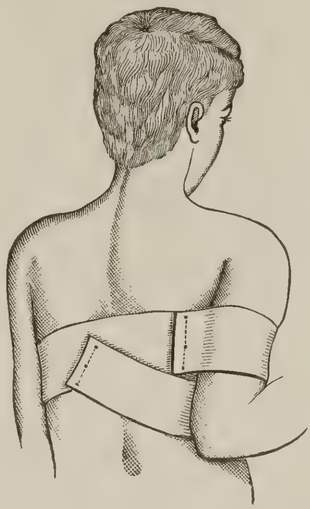

FIG. 2217.—Sayre's Dressing for Fractured Clavicle. First strap.

Fractures of the Body, Lower Angle and Upper Angle.—These fractures are caused by direct violence or muscular action. The lower angle may be displaced forward and upward. Otherwise the displacement is insignificant. There are localized tenderness and swelling, and false motion and crepitus may perhaps be obtained. Fracture of either angle is extremely rare.

The arm may be put in a sling and the scapula immobilized by broad bands of adhesive plaster encircling the chest.

The Spine of the Scapula is fractured by direct violence. False motion and crepitus may be elicited. The arm should be kept in a sling.

Fracture of the Acromion is usually caused by a fall on the shoulder. Either the whole process or merely its tip is broken off. Epiphyseal separation is not uncommon. The contusion often obscures the signs of fracture during the first days, but later the displacement outward and downward may be felt. If the whole process is broken off the shoulder droops. Crepitus may sometimes be obtained by elevation or abduction of the arm. Spontaneous motions of the arm, especially abduction, are restricted. Bony union is not to be expected.

The treatment is that of fracture of the outer third of the clavicle.

Fracture of the Coracoid Process is a pathological curiosity. It usually occurs in connection with dislocation of the shoulder or other fractures. The symptoms are obscure, the diagnosis is difficult, reduction impossible, and the prognosis good.

Fractures of the Neck of the Scapula (including all those that separate the glenoid cavity from the body of the bone) are caused in the same way as dislocation of the shoulder, which they resemble closely. The glenoid process slips downward with the humerus and the long head of the triceps attached. The displacement is limited by the spino-glenoid and coraco-clavicular ligaments and the tension of the soft parts over the shoulder.

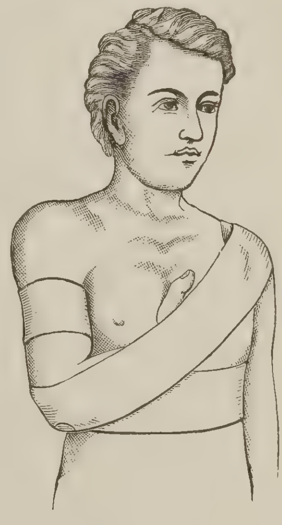

FIG. 2218.—Sayre's Dressing. First and second straps.

The symptoms are those of dislocation of the shoulder, from which the fracture is differentiated by the fact that elevation of the arm produces crepitus and obliterates the deformity, which recurs as soon as the pressure is removed. The treatment is by Stimson's dressing for dislocation of the outer end of the clavicle (*q. v.*). Bony union with some displacement may be expected.

The Rim of the Glenoid Cavity is sometimes broken by dislocation of the shoulder.

FRACTURES OF THE HUMERUS.—Fractures of the humerus are classified as fractures of the upper extremity, fractures of the shaft, and fractures of the lower extremity.

Fractures of the Upper Extremity.—This title includes fissures of the head of the bone, a condition with no clinical significance, and avulsion of the greater or lesser tuberosity, usually a complication of dislocation, recognized by localized tenderness and crepitus, and treated by immobilization (after reducing the dislocation) in outward or inward rotation, according to the tuberosity involved. More important fractures are (1) fracture of the anatomical neck, (2) fracture of the surgical neck, (3) separation of the epiphysis, and (4) fracture dislocation.

True Fracture of the Anatomical Neck is extremely uncommon. The line of fracture usually runs along the anatomical neck and partly through one or both tuberosities. Unless a tuberosity is separated from the shaft, or the head dislocated, the diagnosis is usually impossible, and when a tuberosity is separated the fracture is often a high one of the surgical neck. Strict accuracy of diagnosis, however, may be aided by the *x*-rays in the future. The subjective symptoms vary from slight pain to complete disability. The periosteum is usually in greater part untorn and the displacement slight, though it may simulate dislocation. Crepitus may usually be obtained and the tuberosity may not partake in rotation imparted to the shaft of the bone. Exuberant callus with ossification of the capsule of the joint may result, or there may be non-union.

The treatment is simple immobilization with traction if there is a tendency to shortening. If suppuration should complicate failure of union, incision, removal of the fragment, and free drainage would be necessary.

Fracture of the Surgical Neck is the commonest fracture of the upper end of the humerus. This includes all fractures below the epiphyseal line. The lesion is usually caused by a fall on the shoulder or elbow causing a compression or torsion. Hence the line of fracture is irregular and comminution is not rare. There may be impaction. The upper fragment is usually flexed, abducted, and rotated outward, the lower one slightly displaced inward.

Function is completely lost; there is much local swelling and the elbow is usually abducted simulating dislocation; but the head is in place, and there is local tenderness along the line of fracture and tenderness when the elbow is pressed upward. Unless there is impaction rotation of the arm is not communicated to the trochanter.

If displacement and shortening are present reduction may be accomplished by traction in the line of the upper fragment, namely, abduction and slight flexion. The best retention dressing is a plaster band running along the inner side of the arm from axilla to elbow and with two tails at each end encircling the shoulder and forearm (Hennequin's splint), or an external moulded splint as for fracture of the shaft (Fig. 2210). The elbow is flexed and left unsupported. A narrow band slings the wrist. If displacement or shortening recurs it is overcome by splinting the arm in abduction over a triangular pad reaching from elbow to axilla, made by cracking a piece of cardboard, holding the two sides at an angle of some 30° to 40°, filling in with soft cloths or cotton, and sewing a cover over all. The pad is placed with its sharp angle in the axilla, its base at the elbow (*conf.* Scudder, "Fractures"). Counter-traction is obtained by suspending a five-pound weight at the elbow. If the patient is confined to his bed the weight is attached as for fractures of the thigh (*q. v.*). The tendency to displacement is overcome at the end of two weeks and union is firm at the end of five or six weeks.

Separation of the Epiphysis.—This lesion replaces high fractures of the surgical neck in the young. The epiphyseal line runs through the lower edge of the tuberosities and the epiphysis is hollowed out in its centre, capping the shaft, as it were. The periosteum is usually little torn, the shaft displaced forward and its posterior edge fitted into the cup of the epiphysis which is tilted back. The upper edge of the shaft can, therefore, usually be felt below and in front of the acromion. The head is in place. Function is lost. Upward pressure on the elbow is painful. There is tenderness at the point of fracture.

Reduction is accomplished by abduction and direct pressure upon the ends of the fragments. The subsequent treatment is that of fracture of the surgical neck. Union is prompt, yet premature ossification of the cartilage may lead to shortening of the arm. Surgery is called for if the untorn periosteum prevents reduction, or later if union has taken place with deformity and the range of motion is much impeded.

Fracture-Dislocation.—Dislocation of the head of the humerus is sometimes complicated by fracture of the anatomical or surgical neck of the bone (see *Dislocations*). The proper treatment is to endeavor to replace the bone by traction and manipulations with the patient anæsthetized and prepared for operation. If this fails the head of the bone should be cut down upon and replaced with the aid of McBurney's hook, or removed if replacement is impossible. The older methods of awaiting union before reduction or trying to obtain a false joint have proved eminently unsatisfactory.

Fractures of the Shaft.—Every variety of fracture of a long bone is met with in the humerus. Muscular effort not infrequently causes the fracture. The most notable complications are injury to the brachial vessels and the musculo-spiral nerve.

Reduction is effected by traction. Very high fractures may have to be treated as fractures of the surgical neck, low fractures as supracondylar fractures, contused or compound fractures by rest in bed with the arm supported on cushions until all danger of inflammatory complications has passed. The dressing I prefer is a moulded plaster-of-Paris splint from the side of the neck over the shoulder, down the outer and posterior aspect of the arm, under the elbow and forearm to just above the wrist or a similar gutta-percha splint (Fig. 2210). When this is applied the elbow must be padded an inch deep in cotton. On the second or third day the splint is removed, the greater part of the cotton extracted, and the splint replaced and held in place by adhesive plaster, over the shoulder, around the arm just above and below the point of fracture (thus leaving it open for inspection), on the arm and forearm close to the elbow, and lower down the forearm. The dressing is completed by a shoulder spica and a sling about the wrist, and an axillary triangle if necessary (see above). With the limb in this splint there should be enough traction to prevent overlapping or angular deformity. This traction is allowed by the removal of the cotton from under the elbow and maintained by the adhesive strips on the upper forearm. The patient should be seen twice a week for the first three weeks, and if at any time deformity has recurred it must be promptly overcome by suspending a five-pound weight from the elbow, by coaptation splints of basswood, or by renewing the splint with a greater allowance for elbow traction. The sling at the wrist must not support the splint lest it elevate the elbow. Union is firm at the end of six weeks.

Fractures of the Lower End.—These may be classified as supracondylar fracture, fracture of the internal epicondyle (there are only two recorded cases of fracture of the external epicondyle), fracture of the internal condyle, of the external condyle, intercondylar fractures, hypocondylar fractures, and epiphyseal separation. This confusing array is much simplified by a few general considerations of diagnosis and treatment.

Diagnosis.—To differentiate sprain, dislocation, and fracture about the elbow is a matter of physical examination. Evidence of abnormality in the bones themselves indicates fracture. Evidence of abnormality in the relation of the bones to one another indicates dislocation. Entire absence of these abnormalities indicates simple sprain.

Evidence of abnormality in the relation of the bones to one another is obtained by locating the tips of the two epicondyles, the olecranon, and the head of the radius. When the elbow is fully extended the three former should be in the same horizontal plane, and the head of the radius be recognized as a projection just below the external condyle. It is identified by the motion imparted to it by rotation of the forearm. If the relations of olecranon and radius with the epicondyles are not the same as in the normal elbow of the opposite side (with which comparison should always be made) there is dislocation, which may often be verified by an estimation of the abnormal axes of the bones.

Evidence of abnormality in the bone (*i.e.*, the humerus) is obtained in several ways: by eliciting false motion or crepitus between the condyles and the shaft or small fragments; by mapping out the general deformity of the arm as well as the local deformities about the elbow, the displacement of one or both condyles, and the irregularities along the supracondylar ridges; and finally by eliciting pain. If there is transverse fracture there will be pain on pressing the flexed elbow upward. A local point of pain can often be identified along one or both supracondyloid ridges where the fracture nears the surface, and if there is a line of fracture between the condyles, pressing the two condyles toward each other is painful.

Dislocation and fracture often coexist.

Thus the examination is begun by inspection to note any manifest deformity. An effort is then made to locate and determine the relations of the bony points mentioned above, and the range of motion, active and passive, tested with an eye to abnormal mobility, especially lateral mobility, and crepitus. The supracondylar ridges are searched for points of irregularity and tenderness, and pressure is made under the elbow and upon the two condyles to elicit tenderness. Suspected parts of the joint are then reviewed for false motion or crepitus.

The contusion is, however, often so excessive as to frustrate the surgeon's best efforts. Even an examination under ether may fail to elucidate the diagnosis. The x rays may then be appealed to. The evidence which they furnish should be definite.

Treatment.—Once the diagnosis is established reduction is not difficult. Rarely the fragment is so rotated as to make reduction impossible. Such fragments must be cut down upon and replaced or excised. Fragments of the epicondyles cannot often be retained in place. Their displacement is unimportant, however. Larger fragments acting rebelliously may be excised or sutured in place or nailed to the adjoining bone by a spike driven through the soft tissues and protruding through the dressings, to be removed within ten days.

With these exceptions reduction and retention are easily managed. The best position for the forearm is in all cases one of semiflexion with the natural pronation. The apparent security of complete flexion or extension does not compensate for the displacement which so often occurs with the elbow in these positions. For compound fractures, however, vertical suspension with the elbow extended is a convenient position during the first days, after which the limb may be brought down to the usual semiflexion.

The most convenient splint is a posterior moulded plaster band or wire gutter running the whole length of the arm and forearm and bent to a right angle at the elbow. If adhesive straps are used to retain the splint they should not cover the fragment (the position of which must be frequently verified). A five-pound weight hung from the elbow will overcome the tendency to displacement. The elbow is never to be supported. A sling about the wrist is sufficient.

If perfect reduction is not maintained, a cubitus varus or valgus may result which can be remedied only by osteotomy.

When union is firm and the arm is freed from its splint (at the end of five weeks) the elbow will be found sore and stiff. Motion and massage will help loosen up the joint, but an excessive zeal will only succeed in encouraging the growth of exuberant callus and so permanently restricting the range of motion. Such exuberant callus may also occur through no fault of the surgeon, but it is difficult to estimate its importance within six months. At the end of that time the joint will have gained its maximum of freedom, and the remaining restrictions caused by displaced fragments, ossified ligaments, callus projecting into the olecranon or coronoid fossæ or elsewhere into the joint can be removed only by the chisel. Yet it is well to be conservative in such operations. A mobility of from forty to fifty degrees at the elbow is about all that is needed as far as utility is concerned, and unless there is some definite projection of bone or callus the removal of which will clearly liberate the joint, an operation may well result in nothing more than disabling the patient for a few weeks, during which time new callus replaces that which was excised and after which the patient returns to his duties no better off than before. No general rules for operation can therefore be laid down. Each case must be decided on its own merits.

Of the numerous vessels and nerves in close relation to the joint, the ulnar nerve is the only one likely to be injured. Ulnar paralysis and anæsthesia have been known to disappear spontaneously as late as three months after injury, but in doubtful cases an early operation should do no harm and might do much good.

In *supracondylar fracture*, the lower fragment consists of both condyles and the whole lower extremity of the humerus. The line of fracture is oblique and the fragment slips upward and backward or upward and forward. The condition usually resembles a dislocation, but the relation of olecranon to condyle is unchanged and lateral mobility can be obtained with crepitus. Moreover the fracture when reduced has often a tendency to slip out of place again, with crepitus.

Fracture of an epicondyle is recognized by the abnormal mobility, displacement, and crepitation. Persistent displacement is unimportant since the line of fracture is entirely outside the joint.

In *fracture of the internal condyle* the line of fracture runs obliquely downward and outward from some point in the epicondylar ridge to the region between the trochlea and capitellum. The fragment with the ulna attached is usually displaced backward and the radius may be dislocated in the same direction. Abnormal adduction and antero-posterior sliding are possible. The ulnar nerve may be injured. There is a marked tendency to recurrence of the displacement with the production of cubitus varus. This may be overcome by immobilization with extension, with special care to preserve the normal outward angle at the elbow, by immobilization in flexion aided by a weight supported from the elbow, or by operative fixation.

Fracture of the external condyle is somewhat more frequent than the last mentioned. Its features are similar to those of fracture of the internal condyle, *mutatis mutandis*, but there is less liability to displacement. Indeed there may be a tendency to displacement downward, which would only be encouraged by suspending a weight from the elbow.

Intercondyloid fractures are caused by direct violence. The fracture is often compound or comminuted, its general lines being T- or Y-shaped, with the condyles separated from the shaft and from each other. The ulna may be jammed between the fragments. Reduction is important and may be difficult on account of the number and displacements of fragments. If reduction cannot be performed thoroughly under an anæsthetic, the bones had best be cut down upon and fastened in place or excised according to the judgment of the surgeon.

Separation of the epiphysis is rare. (Consult Plate XXVIII., Fig. 6.) The condition simulates backward dislocation, but the epicondyles retain their relation to the olecranon and the whole may be reduced (and recurs) with cartilaginous crepitus. The usual treatment is required.

Hypocondylar fractures, i.e., fractures of the articular processes, either one or both together, are extremely rare. They are caused by a severe crushing force applied beneath the elbow or transmitted up the forearm. When not associated with other injuries about the joint, they are to be recognized only by crepitus, the *x*-rays, or the displacement of a fragment to a place where it can be left.

Fractures of the Bones of the Forearm.—It is convenient to group the fractures of both bones of the forearm under three headings: fracture of the upper ends, fracture of the shafts, and fracture of the lower ends.

Fractures of the upper ends include fractures of the olecranon, of the coronoid, and of the head of the radius.

Fracture of the Olecranon (see Plate XXVIII., Fig. 8), though usually due to a fall on the elbow, is apparently caused by the violent contraction of the triceps (Stimson). The position and direction of the line of fracture vary widely. The displacement may be so slight that the chief evidences of fracture are independent mobility and crepitus, or so great that the gap between the olecranon and the shaft is readily felt. Yet practically the displacement is found to be slight in most cases. The tendency of the triceps tendon to carry the fragment upward is counterbalanced by the strain on the lateral fibrous attachments of that tendon.

Hence in a surprisingly large proportion of cases immobilization of the elbow in a position of slight flexion is quite compatible with good position of the fragments. The best splint is an anterior moulded one since it allows inspection of the fragment. Careful watching is necessary to forestall late displacement by the continued action of the triceps. To prevent displacement early or late it may be necessary to keep the elbow fully extended, to draw down the fragment by means of adhesive plaster strips, by Malgaigne's hooks, or by operation as for fracture of the patella, the suture being passed from side to side through the tendon and the ulna. If ankylosis, a rare complication, is feared, on account of the intensity of the inflammatory reaction, early passive motion (third week) may be employed. This treatment should, however, be conducted with extreme gentleness since it has been known to cause refracture.

Union is usually fibrous, sometimes bony, and may fail entirely. Unless motion is interfered with by adhesions within the joint, a satisfactory power of extension may be anticipated even though the separation of the fragments amounts to half an inch.

For non-union or undue separation of the fragments the bone may be cut down upon, the fibrous tissues excised, and the fragments sutured together.

Fracture of the Coronoid Process is usually a complication of backward dislocation of the elbow. It is rarely recognized and is unimportant. The separation is slight, for the fragment is held in place by the tendon of the brachialis anticus attached about and below it. This fracture may allow recurrence of the associated dislocation. The elbow must be immobilized in flexion for three weeks.

Fracture of the Head of the Radius is recognized by the localized tenderness, the discovery of a displaced fragment, pain in abduction of the forearm, and pain and crepitus on rotation. The absence of pain on adduction or on pressure of the two bones toward each other excludes fracture of the neck of the bone. The treatment is immobilization, removal of displaced fragments, or, if these fail, resection of the head of the bone.

Fractures of the Shaft of One or Both Bones.—These fractures are usually caused by direct violence. Green-stick fractures are commoner here than anywhere else in the body. Platt records 199 fractures of the shaft. Of these 122 were complete; 66 affected both bones; 42 the radius alone, and 14 the ulna alone. Of the 77 green-stick fractures, in 63 both bones were broken, the radius alone in 9, the ulna alone in 5. Instead of both bones breaking, the ulna alone may give way while the head of the radius is dislocated. When both bones are fractured the radial fracture is commonly nearer the elbow than the ulnar one. The usual displacements depend on the actions of the pronator and supinator muscles. The former tend to draw the fragments toward each other, and this is especially marked in short lower fragments acted upon solely by the pronator quadratus; the latter put the upper fragment of the radius (especially if the break is above the insertion of the pronator teres in the middle third of the bone) in supination (Plate XXVIII. Fig. 1). Overlapping also usually exists.

It is scarcely possible to mistake a fracture of both bones. When the ulna is broken the seat of fracture may be located by palpation. This is impossible along the radius, which lies surrounded by muscles for the greater part of its length; but when the radius is fractured forced pronation cannot be resisted and independent mobility and crepitus may be obtained by grasping the head of the bone firmly while the hand is gently rotated.

Reduction is of prime importance. It is accomplished by local manipulation and traction, direct when both bones are broken, toward the sound bone if only one has given way. It is especially important that the bones be crowded apart lest they unite to each other and thus effectually prevent rotation (Plate XXVIII. Fig. 7). This is accomplished by crowding the muscles between them and by the subsequent splinting. In the immobilization two important facts are to be borne in mind:

1. No circular dressing, bandage, nor splint may be applied close about the forearm. Such a dressing will force the fragments toward each other, or, worse still, it may cause gangrene or "ischæmic contracture" of the muscles of the forearm from which they may never recover.

2. Whenever the radius is broken, unless in its lower third, it is safe to immobilize the forearm in supination. The routine attitude of semipronation usually leaves some rotary displacement between the radial fragments (as explained above) which, while it may not be enough to interfere materially with the function of the limb, still prevents complete supination. Moreover, the shafts of the bones are most widely separated in the position of supination and hence least likely to unite to each other.

The routine practice, therefore, of employing heavy wooden anterior and posterior splints (Figs. 2208, 2209) is most commendable. The splints run from the elbow to the knuckles. They are well padded and bound to the limb with strips of adhesive plaster, the boards being wide enough to prevent constriction. A small roller bandage elevates the palm of the hand from the anterior splint and the whole is encased in a roller bandage and supported by a sling with the hand supinated. A broad sling is employed reaching from elbow to hand. If the hand is not supinated care must be taken lest the sling, by supporting one end of the limb more than the other, cause an angular displacement or an approximation of the bones to each other.

If the limb is extensively contused or becomes markedly œdematous, it should be treated for a few days by elevation, hot wet dressings, and perhaps multiple incisions to prevent gangrene. This precaution may not be lightly disregarded since the muscles of the forearm may be reduced to a pulp, although the skin shows scarcely a sign of injury.

Fractures of the Lower Ends.—Platt tabulates 88 simple Colles' fractures, 7 with additional fracture of the lower end of the ulna, and but 2 fractures of the ulna only. Besides these he reports 6 cases of epiphyseal separation of both bones, 36 of the radius only, and 1 of the ulna alone. All of these varieties are clinically reducible to Colles' fracture. One other variety there is of fracture in this region, the so-called Barton and reversed Barton fractures. This condition is a splintering of the posterior or anterior edges of the under surface of the lower end of the radius by partial dislocation of the wrist backward or forward. The fracture is an insignificant complication of the dislocation and is rare.

Colles' Fracture.—"Every dislocation of the wrist is a Colles' fracture." As a statement this is false, but as

FRACTURES.

IMPORTANT ANATOMICAL AND PATHOLOGICAL FEATURES.—*(From Helferich's Atlas of Fractures and Dislocations.)*

LIBRARY
OF THE
UNIVERSITY of ILLINOIS

a point of view it will save the surgeon from many an error. No fracture of any single bone is so frequent. The cause of the fracture is usually a fall upon the palm of the hand. The lower end of the radius is broken more or less directly across within three-fourths of an inch of its articular surface. In the young the line of fracture often runs through the epiphyseal cartilage (Fig. 2219). The lower fragment may be displaced backward, but is commonly only tilted in that direction (Plate XXVIII. Fig. 9). It is comminuted as a rule and firmly impacted against the upper fragment. The styloid process or lower end of the ulna is rarely broken simultaneously.* The lateral ligaments of the joint are sometimes torn. The periosteum is stripped up from the posterior surface of the radius and the excessive callus produced under it in old unreduced cases produces the excessive protuberance seen in pathological specimens (Plate XXVIII., Figs. 2 and 3).

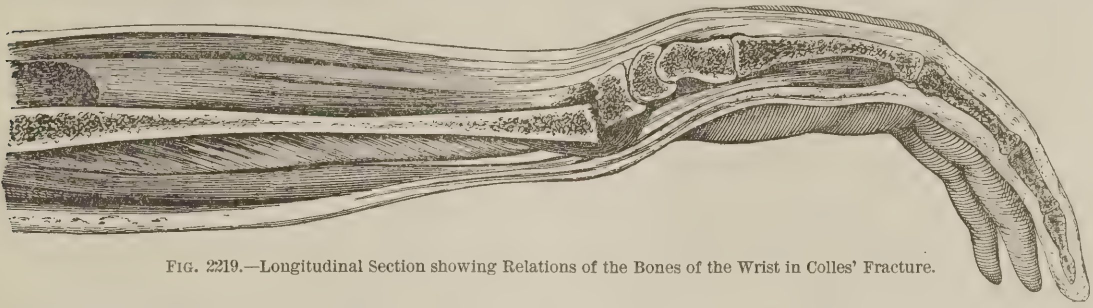

FIG. 2219.—Longitudinal Section showing Relations of the Bones of the Wrist in Colles' Fracture.

The bones of the carpus are carried backward by the tilting of the lower fragment, thus causing the characteristic "silver-fork" deformity, a projection of the back of the wrist with a corresponding depression anteriorly, very aptly compared to the curve of a fork (Fig. 2220). The hand is usually somewhat abducted through the shortening of its radial attachments (Plate XXVIII., Figs. 4 and 5). A more reliable sign of Colles' fracture and one which is never obscured (the above-mentioned deformity is often obscured by excessive swelling) is the elevation of the styloid process of the radius as compared with that of the opposite side. The styloid process of the radius, instead of being a quarter of an inch or so below the tip of the ulnar styloid, has risen to the same level or above it. The ulnar styloid is usually prominent (Plate XXVIII., Fig. 4). There is a line of tenderness over the back of the radius. Crepitus and abnormal mobility cannot commonly be elicited until after the fracture has been reduced.

The treatment of Colles' fracture is simple. Reduction is all important. It is accomplished by grasping the hand firmly as though to "shake hands." At the same time the surgeon grasps the patient's forearm just above the wrist, placing his thumb over the displaced fragment. The patient's hand is then drawn gently backward until he complains of pain. Immediately it is forced sharply backward before he has time to resist and then drawn downward and sharply flexed while the fragment is simultaneously pushed downward by the thumb upon it. These motions performed rapidly and forcibly will usually dislodge the fragment, a result announced by the diminution of the deformity and the appearance of abnormal mobility (and crepitus) where before the mobility was restricted. This method failing, the forearm may be placed on a table, the hand rapidly forced to and fro while the wrist is held firmly at the edge of the table and the fragment is pressed upon. Primary anæsthesia may be employed in rebellious cases.

The fracture once reduced is easily held in place. The usual dressing is a thin padded board along the back of the forearm to the knuckles and another along the anterior surface as for fractures of the shaft (Fig. 2208). This may be reinforced by a cuff made of several turns of adhesive plaster about the wrist. The fingers are liberated at the end of a week,* and all splints except the adhesive plaster cuff removed within three weeks. An anterior or posterior moulded plaster splint is a convenient dressing after the first week.

If this method of treatment is followed the bad results will be minimized. Shortening on the radial side is bound to persist in some cases of epiphyseolysis and in others in which the compression of the bone has been such as materially to reduce the size of the fragments. As a result of this, the ulnar styloid remains unduly prominent. In the middle-aged, rheumatic complications may be looked for. The best way to avert them is to employ daily massage from the start and passive motion as soon as possible. Yet the most intelligent treatment often fails in this regard; though it is almost impossible to persuade the patient that the surgeon's efforts are not to blame for the long months of suffering following so slight a fracture.

Reversed Colles' fracture is extremely rare. The impaction and displacement are directed toward the palmar instead of toward the dorsal surface.

Fractures of the Carpus.—In compound fractures the fragments are to be reduced or removed. Simple fractures are most unusual and a diagnosis can scarcely be made without the help of x-rays.

Metacarpal Fractures.—The displacement is usually angular backward, and slight. The fracture is readily recognized. The fist may be bound over a roller bandage for three weeks and after that a simple dorsal pad and spica employed. Beck's splint I have found serviceable. It is made of short pieces of rubber tubing pressed into the spaces between the metacarpal bones and held in place by two adhesive plaster straps, one just above the knuckles, the other near the mist. The hand is then bound over a roller bandage.

"Bennet's fracture" is the splitting off of a small fragment from the palmar surface of the base of the first metacarpal bone. The backward displacement of the remainder of the bone simulates subluxation. The thumb cannot be apposed to the index finger. It is to be immobilized in full abduction. Similar fractures occur in the other metacarpal bones; they are discovered by pressure upon the end of the bone eliciting tenderness at the point of fracture.

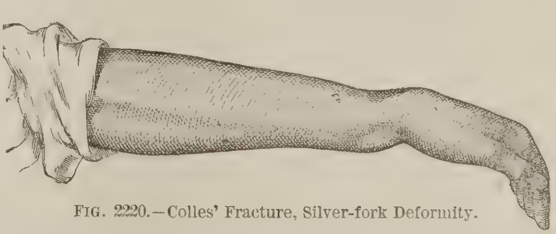

FIG. 2220.—Colles' Fracture, Silver-fork Deformity.

---

* Fluoroscopy shows that the ulnar styloid is broken more often than is usually considered to be the case. Dr. E. A. Codman claims that the ulnar styloid is broken in at least sixty-two per cent. of cases.

* It is essential to liberate the fingers at the earliest possible moment, for they are very quick to become stiffened, especially if immobilized in extension, and slow to regain their full range of motion.

Phalangeal Fractures are often compound. Simple fractures may be immobilized by basswood splints or a plaster encasement, preferably in a position of flexion. After the first two weeks several thicknesses of adhesive plaster suffice. Compound fractures are, however, specially liable to suppuration and necrosis and the prolonged splinting usually results in one or more stiff joints. In such cases, therefore, it is often well to amputate in the first place.

FRACTURES OF THE FEMUR.—Indentations of the head of the femur by impact with the rim of the acetabulum during dislocations have no clinical significance.

Fractures of the Neck of the Femur.—These fractures occur at all ages by direct violence or by a fall upon the knee or foot, but they are specially common in old age when they may result from the slightest muscular action, such as the effort to avoid a fall or even a mere sudden turn. In fact so marked is this liability in the aged that every injury to the hip of an old person should be considered a fracture until this diagnosis has been disproved. This frequency of fracture in old age is due rather to the senile rarefaction of the bones than to the increased obliquity of the angle between neck and shaft.

Pathology: These fractures are classified as fractures through the narrow part of the neck (fracture through the neck, intracapsular fractures, fractura subcapitalis) and fracture at the base of the neck (extracapsular fracture, fractura intertrochanterica). In the former class the bone is broken close to the head. The vitality of the fragment may be completely lost, but more frequently it is maintained by the vessels in some untorn fragment of the periosteum (the vascular importance of the ligamentum teres is doubtful). In the latter class, the chief line of fracture follows the intertrochanteric lines. There is usually considerable comminution. The great trochanter may be split and the cancellous tissue of the neck is more or less crushed. These fractures, though usually spoken of as extracapsular, are often as much within the capsule as outside of it. They are also said to be impacted, but this impaction consists of a crushing of the neck of the bone which is wedged among the fragments about the trochanters, while true impaction in the sense of fixation is not common. The impaction occurs chiefly in the posterior part of the neck (exceptionally the reverse is true), and consequently the head rotates downward and backward as though hinged upon its anterior border. Hence the shortening and eversion of the thigh.

Symptoms and Diagnosis: The subjective symptoms are usually quite characteristic. There is almost entire loss of function. The patient can bear no weight on the limb, and when lying can move it but slowly and cannot lift the foot from the bed. The limb lies everted, abducted, and slightly flexed. Sometimes the eversion is so slight that it can be determined only as a resistance to inversion. This eversion is not entirely due to the fracture, for it is the position commonly noted in simple contusions. About the hip there is more or less swelling, ecchymosis, and pain. There may be an especially tender spot in front of the trochanter over the point of fracture. As a rule, the pain is elicited only by motion.

Exceptionally the limb is inverted and very rarely the patient can move it with a fair amount of freedom and even walk upon it.

The chief objective sign of fracture is shortening. This symptom is practically constant, although it may not be marked until some days have elapsed. The method of determining the shortening has already been described (p. 250), as well as the minute precautions to be observed in measuring the limbs at the same angle of flexion and abduction. The possibility of a congenital difference in the length of the two limbs is the only thing that renders this test fallacious. If, however, the limb can be proven to be distinctly shorter on the second or third day than it was immediately after the receipt of injury, the evidence is conclusive.

Shortening is also measured by Nelaton's line or Bryant's method (which estimate the elevation of the trochanter), or by measurement from the anterior superior spine of the ilium to the internal malleolus. Nelaton's line is drawn from the anterior superior spine to the tip of the ischial tuberosity on the same side. It should cross the tip of the trochanter when the limb is uninjured and slightly abducted. Bryant measures the distance of the tips of the trochanter from a perpendicular dropped from the anterior superior spine to the plane on which the patient lies. The estimation in either case is made by comparison with the opposite limb. Shortening may be inferred when the fascia above the trochanter is more depressible than on the sound side.

A relative fulness and tenderness in Scarpa's triangle is another fairly constant sign of fracture of the neck. If the trochanter is split, its increased antero-posterior diameter may perhaps be made out. The determination of a shorter radius of rotation in the trochanter is in the last degree impracticable.

Crepitus should never be sought for, though it may be elicited incidentally.

Diagnosis: The differentiation of fractures through the small part of the neck of the femur from those at the base is rarely practicable and never important. The chief differential point is comminution of the trochanter which so often accompanies fractures at the base of the femoral neck.

When the femur is broken below the neck there is a local spot of pain and deformity, the depressibility of Scarpa's triangle is unaffected, the trochanter is not elevated (though the limb is shortened) and does not partake of rotation imparted to the limb. When the head of the femur is dislocated it is readily felt if the dislocation is forward; and the limb is inverted, when it is dislocated backward. Those rare instances of inward rotation with fracture are usually mistaken for dislocation until the anæsthetic is administered for reduction when the position of the head is made out.

As to the positive diagnosis of fracture of the neck of the femur, it is based upon the signs and symptoms already enumerated. Doubtful cases, especially in the aged, must always be treated as fracture until the lapse of time has proven them mere contusions. The prognosis is good as regards life, though the shock of such a severe injury upon an aged person may prove fatal, through pneumonia, uræmia, fat embolism, or even simple "shock." Stimson says: "I have come to regard the third week as the time when the condition is most likely to change for the worse; that passed, cases usually do well."

On account of the impaction union is obtained with shortening and some loss of abduction and rotation. When the patient is aged the stiffness, pain, and weakness may never entirely wear away, even though union be perfect.

Firm union may be expected except in the aged. Yet even in the unsatisfactory cases, the fibrous union, the interlocking of the fragments, or surrounding tissues (it is usually impossible to tell which) hold the bone well enough in place for the limb to be used with the aid of a cane or stick. Such results follow fracture of the narrow part of the neck far more often than fracture at the base. The possibility of obtaining union several months after the injury by direct pressure over the trochanter (Schaffer) should not be lost sight of.

Treatment: If the patient is aged and infirm he must be put to bed and every care taken for his comfort and nutrition while but little attention is paid to the limb, which is slung in a Hodgen's splint, with as much traction as the patient will bear.

In younger subjects there is no danger to life, and the limb demands more care. Reduction must not be attempted. The patient is kept in bed and some form of traction apparatus is applied. The choice lies between Hodgen's splint and Buck's extension apparatus. The former is the more comfortable, the latter capable of exerting a greater pull.

For a Hodgen's splint (Fig. 2221) a piece of adhesive plaster three inches wide and long enough to reach from the upper part of the thigh, loosely around the foot and back to a corresponding point on the opposite side of the thigh, is selected. The middle two-fourths of this strip is folded twice upon itself (making a triple thickness), and nicked so as to allow the remainder to lie unfolded. A perforation is made at the centre of the strip and against it is fitted a stout perforated piece of wood two inches wide by five inches long (Fig. 2222). A strong cord knotted at one end is passed through the two perforations. A flannel bandage is then applied to the leg and foot, and the ends of the adhesive strip attached over one-half of the inner and outer aspects of the thigh, the middle folded portion lying below and about two inches away from the sole of the foot. Another bandage over the thigh and knee strengthens the grip of the plaster. The frame of the splint, upholstered with compresses pinned tightly from side to side, is then slid under the limb, and the metal half hoop (*O*) fitted over the ends to prevent them from collapsing. The cords (*DE* and *D′ E′*) are attached as shown in the figure and caught by a rope (*C*) which is attached to a crane at the foot of the bed. The cord of the adhesive plaster is then made fast at *F* bringing the piece of wood close against the bottom piece of the frame. The compresses are tightened and loosened to fit the inequalities of the limb. The end (*C*) is drawn tight enough to elevate the limb from the bed, its line of traction being at an angle of 50° to 70° with the horizon.

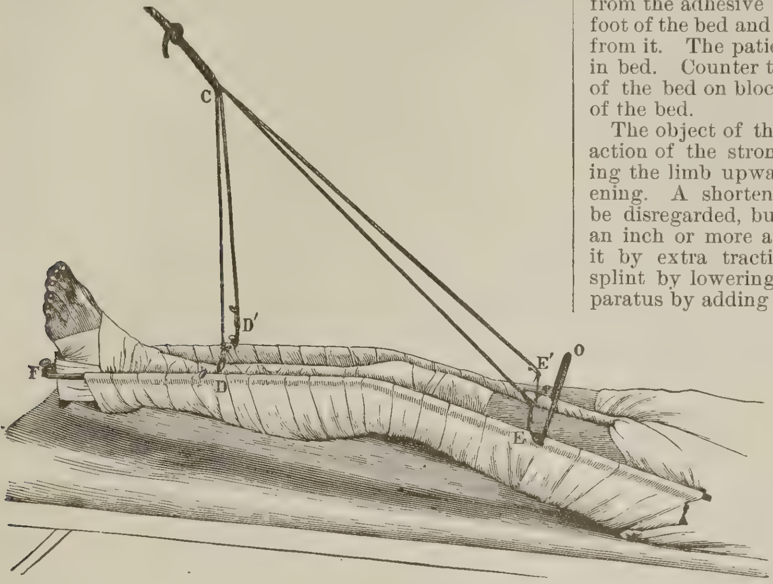

FIG. 2221.—Hodgen's Splint. (From Stimson's work of "Fractures," Lea Bros. & Co.)

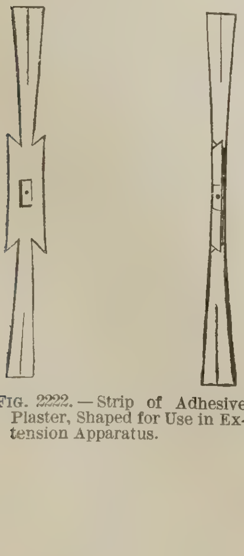

FIG. 2222.—Strip of Adhesive Plaster, Shaped for Use in Extension Apparatus.

For Buck's apparatus (Fig. 2223) the adhesive plaster and bandages are applied in the same manner, the outer bandage being made to include the footpiece of a Volkmann's sliding foot rest (Fig. 2224), which rests upon a frame in the bed, thus giving more play to the foot, and holding it upright. The cord from the adhesive plaster is then let over a pulley at the foot of the bed and a five- or ten-pound weight suspended from it. The patient must not be allowed to slide down in bed. Counter traction is made by elevating the foot of the bed on blocks or by tying the patient to the head of the bed.

The object of these traction splints is to overcome the action of the strong muscles which are constantly pulling the limb upward and tending to increase the shortening. A shortening of one-quarter of an inch may be disregarded, but if the shortening amounts to half an inch or more an effort should be made to overcome it by extra traction. This is done in the Hodgen's splint by lowering the line of traction, in Buck's apparatus by adding more weights.

Old and feeble patients should be gotten up in a chair within three weeks. Others may be in bed for the full six weeks, or may get up at the end of four weeks and walk about in a traction hip splint of the kind used for hip disease. Pressure made by a band over the trochanter may be beneficial at this stage.

Operative fixation and plaster encasement have been tried and rejected. The so-called ambulatory treatment has but a fictitious value. Those who can use it (the vigorous) do not need it. Those who would benefit by it (the aged) are too feeble and tottering to use it.

Fractures through the trochanter are treated like the above. *Fractures of the greater and lesser trochanters* are extremely rare.

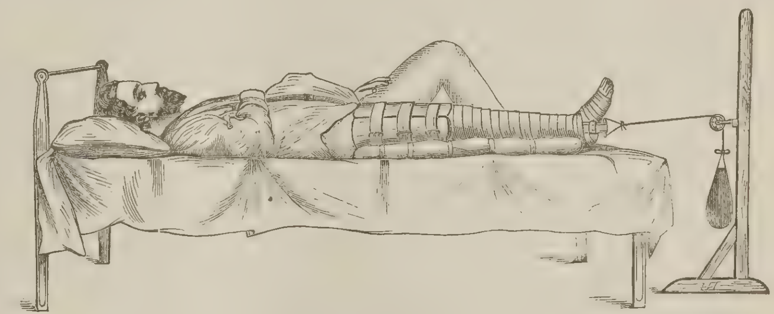

FIG. 2223.—Buck's Extension Apparatus.

Fractures of the Shaft.—These are usually caused by direct violence. The line of fracture may be extremely oblique and comminution is common. There may be considerable displacement. The lower fragment rides up behind or to the inner side of the upper one, producing both shortening and deformity. Subsequently outward rotation of either fragment will occur if the trochanter or the foot is not properly supported. Injury to vessels and nerves is rare. An annoying complication is the projection of the pointed end of the upper fragment, when the fracture occurs in the lower third of the shaft, into or even through the quadriceps extensor muscles. An acute serous synovitis of the knee is not uncommon.

The shortening is determined by measurement from the anterior superior spine of the ilium to the internal malleolus. The differential diagnosis between fracture of the shaft and fracture of the neck of the femur has been noted above. Abnormal motility and crepitus may be elicited by gentle manipulation. The less the limb is disturbed the better.

The *prognosis* is grave. According to Martin's recent statistics of one hundred cases, as a rule children do well. They are usually completely sound five months after injury and the shortening should be less than a half inch. With adults, however, it is different. The disability usually lasts eight months, and an ultimate shortening of an inch and a half may result even if the most skilful treatment is employed. This is in part due to an increased shortening after the patient leaves the hospital. Finally, Martin claims that "not more than one man in five who has sustained a simple fracture of the thigh will ever again be able-bodied."

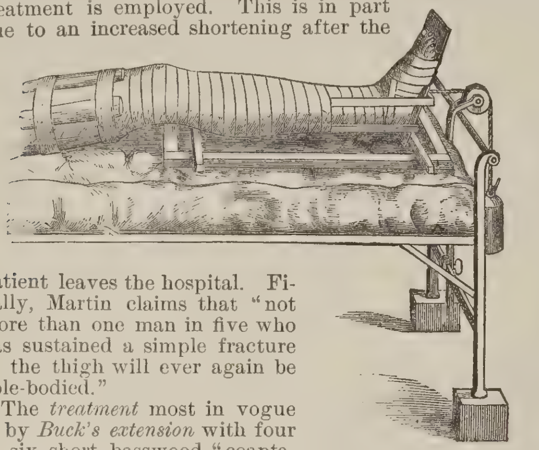

FIG. 2224.—Volkmann's Sliding-rest.

The *treatment* most in vogue is by *Buck's extension* with four to six short basswood "coaptation" splints (Fig. 2225) bound to the limb with adhesive plaster. Outward rotation of the upper fragment is prevented by a small hard pillow under the trochanter, while the lower one is held up by the *Volkmann sliding foot rest.* A weight is used sufficient to prevent shortening.

Hodgen's splint seems preferable for very high or low fractures, in the former case for the purpose of allowing slight flexion of the hip, and slight outward rotation of the foot to neutralize the unavoidable outward rotation of the short upper fragment; in the latter case to allow slight flexion of the knee without which good apposition cannot be maintained.

Compound fractures may be treated by the double inclined plane or an anterior suspended splint, or Hodgen's splint.

For infants the best treatment is vertical suspension of both limbs by adhesive plaster, etc., as for Buck's apparatus, in such a manner that the hips rest but lightly on the bed. The position is not uncomfortable, the child can be kept clean, and satisfactory immobilization can be maintained. *Children* do well under Buck's extension with a long side splint added (Fig. 2226) running from the chest to the ankle of the broken limb. A common oversight is the omission of a thick pad between the femur and the splint. When the broken limb is bandaged to the splint without such a pad it is bowed outward to such an extent as to produce from half an inch to an inch of shortening.

Plaster-of-Paris encasement is not reliable in the first weeks. Some of the above-mentioned traction splints must be kept on for five or six weeks, after which the patient may go about on crutches for three weeks longer with the limb in a plaster jacket or an orthopædic splint. A perfect limb without shortening is very rarely obtained.

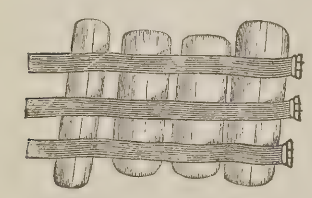

FIG. 2225.—Coaptation Splints used in the Treatment of Fracture of the Thigh by Buck's Extension.

Difficulty of reduction when a muscle is pierced by one of the fragments is met by traction with knee and hip flexed, or, if this fail, by the knife.

Fractures of the Lower End.—The fractures that occur in the lower end of the femur are separation of the epiphysis, intercondylar fracture, and separation of a single condyle. The last is very uncommon.

These fractures are caused by severe local violence or torsion or hyperextension of the knee. The common complications that render the injury serious are hæmarthrosis, going on to suppuration, compound fracture with the likelihood of a similar result, and laceration of the popliteal vessels and nerves.

The fracture may be obscured by effusion into the knee joint, but the diagnosis is readily reached by inspection and palpation.

If only one condyle is fractured the knee must be immobilized in extension, preferably on a posterior moulded splint. When there is intercondylar fracture or epiphyseolysis, the knee must be immobilized in partial flexion over a Hodgen's splint or a double inclined plane. The former apparatus is the more comfortable. Very little traction is needed.

The complications must be treated vigorously. When the knee joint is laid open by a compound fracture it should be treated by continuous irrigation with decinormal salt solution for at least twenty-four hours. The popliteal vessels may be so lacerated as to require amputation lest gangrene set in. A hæmatoma of the knee joint is best treated by elastic pressure, and if this prove useless, by evacuation of the blood clots through a small incision. This should never be undertaken without the most minute antiseptic precautions, for infection of the joint from this or any other cause threatens at least a stiff joint, at most amputation or death.

FRACTURE OF THE PATELLA.—Fracture of the patella occurs commonly in young adult males. It is caused by the muscular action of the quadriceps extensor, in stumbling, jumping, etc. The line of fracture is generally transverse and near the middle of the bone, though it may be but an avulsion of either tip. Less frequently the bone is broken by direct violence.

A sharp pain in the knee and an immediate complete loss of function call attention to the injury. If the joint is examined immediately the upper fragment is found drawn upward a half inch or so by the quadriceps, leaving a manifest gap between the fragments. The joint rapidly fills with blood and this adds to the displacement, which is, however, limited by the lateral attachments of the quadriceps tendon. If the displacement is not remedied, the slow contraction of the muscle, and in a less degree that of the ligamentum patellæ, draw the fragments farther and farther apart until they are separated by several inches. There may be fibrous union even in such a case, yet in spite of this the power of extension is very greatly impaired or lost entirely. Lateral and rotary displacement are unusual, but may occur as late results of contraction in the tissues.

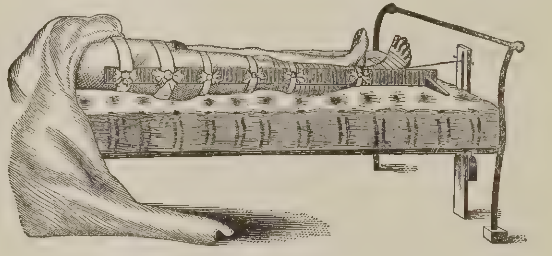

FIG. 2226.—Long Side Splint, with Traction.

The only accessory lesions are the transverse tears in each side of the capsule. The periosteum in front of the bone is torn irregularly so that its fringes drop between the fragments. Compound fracture is very rare.

The symptoms are pain and loss of extension. The diagnosis is made by palpating the broken bone and appreciating the gap between the fragments.

The *treatment* of this fracture by the usual mechanical methods has necessitated so prolonged a convalescence and exposed the patient to such unfortunate results (refracture, permanent stiffening, and loss of the power of extension) that operative measures have been welcomed by many surgeons of large experience. It does not appear, however, that operative success lessens the liability to refracture, and although it shortens convalescence materially, insures a full power of extension, and minimizes the prospect of stiffening, yet operative failure, which is infection, exposes the patient to the loss of limb or life, or at least to an absolutely stiff joint. For the knee joint succumbs to infection more readily than, or at least as readily as, any other region in the body. It is far more susceptible than the peritoneum, and the infection once begun rapidly involves the whole joint and imperils life.

While it is impracticable to detail here the operative successes and failures, or to substantiate an opinion upon which sound surgical judgments are still so much at variance, a moderate series of conclusions may be set down.

1. In the absence of a wide surgical experience and all the aseptic surroundings, assistants and implements, the general practitioner or the occasional surgeon must accept mechanical treatment with all its inconvenience.

2. The surgeon who feels himself sufficiently well equipped to venture operation should bear in mind the highest rule of asepsis, "Be sure your hands are thoroughly clean, and act as though they were absolutely dirty," which is to say, "Keep them from all contact with the wound." Rubber gloves should be permitted to lend no false sense of security.

3. Such compromising measures as the subcutaneous suture, or the use of Malgaigne's hooks, may well be more risky than a clean surgical wound made with no false sense of security, while they do not afford the three chief advantages of an open operation, viz.: the removal of all impediments to union, the evacuation of clots from the joint, and accurate apposition of the fragments.

Mechanical treatment is usually applied somewhat as follows: the limb is immobilized on a posterior moulded splint passing from the toes to the gluteal fold and maintaining the foot at a right angle and the knee extended (if a board splint is used the foot must not be allowed to droop). Hiding the fragments in a plaster encasement is a risky procedure. The limb is firmly bound to this with a roller bandage, after which the fragments are approximated as well as may be by direct pressure and held in place by several strips of adhesive plaster, encircling the limb and splint obliquely. Over all a light (Martin) rubber bandage is applied to hasten the absorption of the blood distending the joint. The rubber bandage does its work within a week (daily massage may aid), after which it is dispensed with. As the patient lies in bed the rectus muscle is relaxed by keeping the foot elevated and thus flexing the hip. This splint is retained for five or six weeks, splint, plaster, and bandages being renewed as often as necessary. An interval of more than a quarter of an inch between the fragments should be considered unsatisfactory. For the second month a hip splint and daily massage are employed (or a plaster encasement for less opulent patients), the patient being up and about. After this the patient is allowed to go free, but is warned to begin exercising gradually and to be especially careful about stooping, going up and down stairs, and such other motions as involve bending the knee. This period of convalescence requires from one to four months longer.

Operative Treatment.—For the reasons already given I shall describe only one operation. A vertical or U-shaped incision is used, according to the fancy of the operator. The fracture is laid bare and while the fragments are retracted the joint is copiously flushed with warm salt solution until all clots have been washed away. The ragged fringe of periosteum is clipped from the edges of the fragments, after which they are approximated and held together by a periosteal suture of catgut or kangaroo tendon. The rents in the lateral expansions may be similarly caught up and the whole reinforced by a circular catgut suture uniting the quadriceps tendon to the ligamentum patellæ, the strands to lie at each side or in front of the patella. This last suture is rarely necessary. During all these manipulations no finger should touch the tissues. The skin is sutured with silk and the limb is bound to a posterior splint. A week later the silk sutures are removed and a plaster encasement is applied. A week after this the patient goes about on crutches and so continues until the end of the fifth week. After this the splint, preferably a hip splint, is worn only by day and as soon as free flexion is obtainable, during the third month, the splint is discarded altogether; by that time convalescence is complete.

Bony union is expected after operative treatment, fibrous union with an ultimate separation varying from a quarter of an inch to an inch after mechanical union. Yet even in the former case there is usually separation of the anterior edges of the fragments, and bony union may fail after all. In either case restricted motility is rarely due to loss of power. Indeed the quadriceps extensor adapts itself to very wide separations. When some stiffness persists in the joint, as is often the case after mechanical treatment and less frequently after the operative methods, it is due either to organized blood clot within the joint, to prolonged immobilization, or to such a lengthening of the patella as to prevent its slipping smoothly over the condyles. Chopart, who advanced the last theory, excised the upper fragment in one case with marked benefit to the patient. The frequent practical failure of secondary operations which seek to remedy disability by approximating the fragments makes a field for this operation. Slight disability, however, had best be borne as a necessary evil. Refracture may be treated by suture or by splint. Fractures by direct violence are usually associated with little or no laceration of the capsule. Hence there is no displacement and no operation is needed.

FRACTURES OF THE TIBIA AND FIBULA.—*Fractures of the Upper Ends.*—These fractures are rare. They may involve the joint causing hæmarthrosis, may rupture the vessels, and are not infrequently comminuted. Avulsion of the spine of the tibia is a complication of dislocation. Avulsion of the tubercle is an extremely rare result of the muscular action of the quadriceps extensor. Epiphyseal separation at this site has no peculiar features.

Fractures of the Shafts.—These occur commonly at the junction of the lower and middle thirds. The fibula is usually broken at a higher level than the tibia. The fracture of the tibia is often V-shaped and from the point of the V a fissure may descend to the ankle joint. Moreover, muscular contraction usually displaces the lower fragment backward and the sharp point of the upper fragment is likely to pierce the skin either at the time of accident or subsequently.

The fracture of the tibia is readily determined by palpation. The fibular fracture may be neglected unless it occurs alone (by direct violence), in which case pressure along the bone elicits a point of tenderness, and this same tender spot is disturbed by pressure over the shaft of the bone some distance away.

Treatment: Reduction is readily accomplished with the knee flexed to a right angle to relax the muscles. If the tendency to displacement is slight the leg is placed in a Volkmann splint (Fig. 2212) or fracture box (Fig. 2211) for a few days until the primary reaction has subsided, and then later is put up in a plaster encasement, or the advantages of the two splints may be combined in a posterior moulded splint running from the knee to the toes or terminating below in two broad flaps, which overlap over the dorsum of the foot. The Cabot wire frame employed by Scudder also commends itself. Union may be expected at the end of six weeks in simple cases, but if there is much comminution it may be considerably delayed. Such cases as well as all others in which the circulation of the limb is poor are benefited by elevation and daily massage of the injured member, though as routine practice it is best to get the patient out of bed during the first week. Otherwise several extra weeks will be required to overcome the œdema and stiffness felt on first using the limb.

A marked tendency to displacement may be overcome fairly well by traction applied to the ankle. Operative fixation is, however, more generally employed. Ambulatory treatment has been considered elsewhere. A compound comminuted fracture often takes months to heal.

Fractures of the Lower Ends.—Separation of the tibial epiphysis is caused by eversion or inversion of the foot. The line of fracture runs well above the articular surface. The foot is to be immobilized in such a position as to retain the fragment in place. Union may be followed by cessation of growth in the tibia and inversion of the foot from overgrowth of the fibula.

Supramalleolar fractures usually show the same features as epiphyseal separation, but if there is extensive comminution there is the added danger of a stiff ankle.

The fibular epiphysis is often separated in Pott's fracture.

Pott's Fracture.—This is by far the commonest fracture of this region. It is *the* injury of the ankle quite as Colles fracture is *the* injury of the wrist, and yet the rational principles upon which the treatment of this fracture must be based are commonly misunderstood, and Pott's fracture is casually spoken of as an injury from which a perfect recovery is not to be expected. On the contrary, it has been my experience that a good result may and should be expected, and will be obtained by appropriate treatment.

Pott's fracture is caused by indirect violence, a twist of the foot. The twist is outward, causing a "fracture by eversion and abduction." Inversion and adduction cause a simple "malleolar fracture" (see below).

The lesions of Pott's fracture (Plate XXVIII., Figs. 10 and 11) are: (1) fracture of the internal malleolus or rupture of the internal lateral ligament; (2) diastasis of the tibio-fibular joint caused by the rupture of the tibio-fibular ligament with perhaps avulsion of the adjoining bone; (3) fracture or epiphyseal separation of the external malleolus; and (4) an outward and backward displacement of the foot. This displacement is due to the tibio-fibular diastasis, which allows the powerful tendo Achillis to draw the foot backward while the lack of support on each side allows the peroneal muscles to hold the foot in the position of eversion and outward displacement into which it has been forced. Compound fracture, which is rare, is usually the result of excessive or prolonged violence, which forces the internal malleolus through the tense skin of the inner side of the ankle while the foot is held abducted. The fragment of the internal malleolus may be so rotated as to require operative reposition.

The symptoms of Pott's fracture vary between the limits of acute continuous pain with entire disability and a mere aching and soreness without any great loss of function during the first hours after injury. The physical signs are, however, constant and definite. There is more or less contusion about the ankle, and in many cases the outward (Plate XXVIII., Fig. 10) and backward displacement of the foot is so marked that the nature of the injury is manifest. There are, moreover, several pathognomonic signs. Three points of tenderness are always present: one over the line of fracture of the internal malleolus, usually near the tip; a second over the fracture of the fibula, usually at the junction of the shaft and malleolus; and a third in front of the ankle between the bones of the leg marking the site of the ruptured tibio-fibular ligament. Another characteristic sign is lateral mobility in the ankle joint. This is elicited by grasping the foot firmly with one hand (the palm of the hand beneath the sole, the thumb under one malleolus, and the fingers under the other) and moving it bodily from side to side, while the leg is steadied by the surgeon's other hand. If there is lateral mobility the astragalus may be felt to glide smoothly from side to side, and may usually be brought up against one or other malleolus with a distinct click. Abnormal forward and backward mobility may also be elicited. It may be impossible to produce crepitus. Extension and flexion of the ankle is painful, but upward pressure on the heel is not.

Treatment.—The backward displacement and eversion are overcome by drawing the foot forward and inverting it sharply. Comparison with the sound limb will readily determine whether the backward displacement has been corrected; the eversion should, however, be overcorrected, for while there is no danger of the foot becoming fixed in abnormal inversion, hyperinversion pulls the fibular fragment downward and inward into place and at the same time leaves no possibility of any permanent eversion. The foot must be kept at a right angle with the leg.

In splinting care must be taken to maintain the reduction inward and forward and at the same time to prevent a drooping of the foot from traction by the tendo Achillis. Stimson's posterior and lateral plaster splints are admirably suited to this purpose. The posterior splint runs from just below and behind the knee down over calf, ankle, heel and sole, to the toes. The lateral "stirrup" splint begins just below the head of the fibula, and runs down the outer side of the leg, over the sole of the foot (and the posterior splint) and around to the outer side of the dorsum of the foot. The foot is held in proper position while the splints are applied. This apparatus is more secure than wooden splints and allows inspection and correction of the deformity better than the familiar plaster encasement. The patient should be kept in bed a few days with the leg elevated on pillows. He may be allowed about as soon as the primary reaction has subsided (at which time a new splint is usually required). If the splints are not sufficiently strong or are loosely applied, the foot will sag. This is not likely to occur before the second week, when the splints have begun to wear out. The tendency is overcome by applying a new moulded splint, or an orthopædic splint made with a movable foot-piece on two lateral braces of metal, or even a plaster encasement or by dividing the tendo Achillis.

Union is firm at the end of six weeks, but six weeks more are usually required to limber up the ankle joint and to overcome passive œdema. When reduction is properly maintained, a perfect ultimate result may be predicted, if due allowance be made for extreme old age, rheumatism, gout, etc.

Old unreduced or imperfectly reduced fractures are very disabling. The eversion causes a constant drag on the ligaments of the inner side of the ankle, while the backward displacement limits dorsal flexion and makes the gait stilted. The eversion may be corrected by supramalleolar osteotomy, but the backward displacement can be corrected only by opening up the old lines of fracture in the tibia and fibula, chiselling away any exuberant callus, and reducing the fracture as though it were a recent one.

Malleolar Fracture.—The malleoli may be broken by direct violence; but the fracture is commonly caused by inversion of the foot. Only the external malleolus may be broken, usually near its tip, or the internal malleolus as well may be fractured. There is no tibio-fibular diastasis, nor any dislocation of the astragalus, as in Pott's fracture.

The symptoms of disability, pain, and ecchymosis, point to some injury about the ankle joint. Examination reveals one or two points of local tenderness over the external or both malleoli; but there is no tender spot in front of the ankle and the lateral mobility characteristic of Pott's fracture can rarely be demonstrated. Independent mobility of the fragments may sometimes be elicited. In a few cases the fracture of the tibia has been so high as to carry away a large part of the articular surface with the fragment. In such cases lateral mobility and backward displacement of the foot are possible; but the condition may still be differentiated from Pott's fracture by the absence of the anterior tender point, and by recognition of the large tibial fragment, which is displaced upward and inward.

The foot usually requires only fixation at a right angle for five weeks while the fragments unite. When there is any tendency to displacement the foot must be well drawn forward and immobilized in a position of natural right-angled flexion. Hyperinversion would be liable to cause mal-union of the tibial fragment.

The prognosis is generally good, though when the tibial fragment is large the usefulness of the joint may be imperilled by exuberant callus.

Fracture of the Bones of the Foot.—Tarsal Fractures: The bones of the tarsus are rarely broken. The only fractures of any clinical importance are those of the astragalus and os calcis. A compound fracture of either or both is readily diagnosed and is treated according to the surgical and mechanical requirements of the case by antisepsis and excision or reposition of fragments. When the fracture is a simple one, the diagnosis may be impossible without the aid of the *x*-rays. Such cases do well under simple immobilization and massage until the foot will again bear the weight of the body. If a fragment is irreducible it may be excised or replaced by operation. Avulsion of the tendo Achillis does well under expectant treatment. Even when there is marked separation satisfactory union may be anticipated within six or eight weeks.

Metatarsal and Phalangeal Fractures.—These present the same features as the homologous fractures of the hand.

Fracture of the Ribs and Sternum.—*Fracture of the Ribs:* This is one of the commonest of all fractures. It is usually caused by a crushing force, such as a fall upon the chest or a heavy blow. The ribs give and then break. Fractures by direct violence are not uncommon. Multiple fractures are frequent, although the two upper and lower ribs almost always escape. Green-stick fractures occur but usually pass unrecognized. The rib is usually broken between the mammary and mid-axillary lines. Displacement is unusual unless the whole side is caved in. There is localized pain at the point of fracture, which may be elicited by compressing the chest sharply from before backward. Crepitus may be elicited by gentle manipulation of the fragments, and by deep inspiration. It may be inaudible unless a stethoscope is used.

The fracture of a rib is not a matter of great importance. There is usually severe persistent pain for several weeks; yet a contusion may cause as much. There may be puncture of the lung, mediastinum, or heart, resulting in any one of the many conditions due to wounds and contusions of these viscera (*q. v.*); but these internal injuries can and do occur as a result of simple contusion without any fracture, and hence when they occur in connection with fracture it is by no means proved that they are caused by the broken bone. They are not necessarily complications of the fracture, and their symptoms and treatment are not modified by the presence of a broken rib.

Treatment: A strip of adhesive plaster five inches wide and eighteen inches long having been prepared, the patient is instructed to take a deep inspiration followed by a deep expiration. At the depth of expiration the adhesive strap is rapidly applied, beginning at a point close to the spine, on the sound side, and following the curve of the broken bone around nearly to the opposite nipple. This strap, applied as tightly as possible, splints the side and minimizes the movements of respiration which constitute one of the chief causes of pain. Several overlapping straps increase the support. Rest in bed adds to the patient's comfort but is by no means necessary. Union is firm in four weeks.

Fracture of the Sternum: These fractures are rare at best. They are most often breaks at or near the junction of the manubrium and the body of the bone. The lower fragment is displaced forward as a rule. The fracture has been caused by muscular effort. The prognosis depends upon the shock and the internal injuries. Uncomplicated cases do well.

Reduction is accomplished by direct pressure on the displaced fragment aided by hyperextension of the spine, the patient lying over a block or box, and breathing deeply. When manipulative efforts fail, operative reduction may be attempted by such means as drawing the depressed fragment forward with a small corkscrew, or removing the overlapping portion of the anterior fragment. Such operations only may be undertaken with due respect for the vital organs lying directly beneath the bone. *Edward L. Keyes, Jr.*

FRAMBŒSIA. See *Yaws.*

FRANGULA. See *Buckthorn.*

FRANKLIN SPRING.—Franklin County, Georgia.

Post-Office.—Royston.

Access.—Viâ Elberton Air-line Railroad to Royston, thence two miles by hack line to springs. This spring has had considerable reputation as a resort for invalids as far back as the oldest citizen can remember. Qualitative analysis: Iron carbonate, calcium sulphate, magnesium sulphate, sodium chloride, aluminum sulphate, potassium sulphate, iron protosulphate, sulphuretted hydrogen gas.

This water contains sufficient aluminum to render it valuable in chronic diarrhœa and dysentery and useful as a local application in ulcerative skin diseases. The deposit of iron in the spring was used to some extent during the late war to supply the place of copperas. The temperature of the water is 60° F. and the flow two and one-half gallons per minute. The climate is good and near by is some very fine mountain scenery. There are facilities for bathing and the neighborhood offers numerous features of interest. *James K. Crook.*

FRANZENSBAD.—An Austrian village on the frontier of Bohemia, 1,300 feet above sea-level, renowned for its mineral springs and baths, ranking next in popularity to Marienbad, and at present resorted to chiefly by women. The climate is mild, but is subject to sudden change.

The springs are eleven in number, namely: (1) Wiesenquelle; (2) Kalter Sprudel; (3) Franzensquelle; (4) Louisenquelle; (5) Neuquelle; (6) Loimannsquelle; (7) Stahlquelle; (8) Mineral Sprudel; (9) Salzquelle; (10) Oestliche, and (11) Westliche. Of the numerous gas springs in the vicinity, several are used for charging mineral water and to supply the gas baths. The chemical composition of the principal springs varies so little as to hardly justify the usual division of them into four classes.

The Wiesenquelle, Kalter Sprudel, and Franzensquelle are considered therapeutically most important, resembling in composition the springs of Carlsbad and Marienbad. The Franzquelle, "the mineral spring of Egra," is enclosed in a temple-like building. The fount contains 20,000 cubic inches of clear, sparkling water, of about 50° F. the year round, which is, with slight variation, the temperature of the other springs. Exposed for several hours to the atmosphere, the water becomes turbid from precipitation of carbonate of iron. Its taste is agreeable, though slightly ferruginous. The other springs are provided with equally elegant surroundings. The Kalter Sprudel produces 3,648 cubic inches of water a minute, accompanied by an escape of free carbonic acid so abundant as to produce the sound of a boiling caldron. The Louisenquelle is the largest in water supply. Its fount contains 6,861,738 cubic inches, flowing 27,000 cubic inches a minute, and the escape of free carbonic acid is tumultuous.

Composition.—Sodium sulphate predominates in all the springs, varying from 10.897 grains in a pint of the Mineral Sprudel to 26.926 grains in the Kalter Sprudel; the Wiesenquelle containing 25.643 grains. The other ingredients are the carbonates of iron, manganese, sodium, calcium, magnesium and lithium, sodium chloride, calcium phosphate, and traces of silicates.

Indications.—The Franzensbad waters, especially those of the Salzquelle, Wiesenquelle, and Kalter Sprudel, are recommended for: (1) Chronic catarrhs, especially chronic gastritis, constipation and cystitis; (2) hyperæmia and moderate hypertrophy of the liver and spleen; (3) disorders of the uterine system; (4) scrofulous affections and gout; and (5) as an after-treatment to Carlsbad and Marienbad.

The Franzensbad and Stahlquelle have been recommended chiefly for: (1) anæmia after hemorrhage, notably that following repeated miscarriages, and exhausting diseases in scrofulous, rachitic, or scorbutic constitutions; (2) diseases of the abdominal or sexual organs with anæmia; (3) slow development of puberty, chronic uterine or vaginal catarrhs, abnormal menstruation, and (4) nervous diseases, especially the neuroses.

Peat Baths.—These are among the most noted in Europe. The fresh peat has a gray or yellowish-gray color, acid reaction, and an odor of sulphurous acid. It is dug up in the autumn and placed in heaps, where chemical changes occur, forming a large number of sulphates, and the mass becomes jet-black, smooth, and homogeneous. In the bath-house, it is diluted with water from the Louisenquelle and heated by steam to 70° or 80° F. The bath is said to be invigorating to the system as well as stimulating to the skin.

The peat baths are recommended for: (1) anæmia and chlorosis, chronic rheumatism, gout, scrofula, and rickets; (2) various neuroses, paralyses not of cerebral origin, the early stages of progressive muscular atrophy, concussion of the spine; (3) sexual disturbances, a tendency to abortion, prolapsus uteri, loss of virility; (4) to aid the absorption of exudates and the infiltrations of intermuscular connective tissue, synovial sacs, ligamentous structures and glands.

Gas baths are also administered, the entire body, except the head, being enclosed in a chamber resembling the ordinary vapor-bath cabinet. *James M. French.*

These are very good examples of sulphuretted saline waters, and are useful in those diseases to which that class of water is applicable. They are used commercially at the present time. *James K. Crook.*

FRONTAL SINUSES, DISEASES AND INJURIES OF.—Anatomy.—The frontal sinuses are two irregular-shaped cavities, which extend upward and outward a variable distance between the two tables of the frontal bone, upon the vertical portion of its internal surface. They are situated one upon either side of the base of the nasal spine, between the latter and the orbital plate. They are separated from each other by a thin, bony partition. In size they vary in different individuals, and are, as a rule, larger in the male than in the female sex. The frontal sinus of the left side is commonly the larger of the two. They are sometimes subdivided by incomplete bony laminæ. They open into the middle meatus of the nose through the infundibula, and occasionally communicate with each other by apertures in the septum. They are absent at birth, but appear during the first year of childhood, and remain of small size up to puberty, at which time they undergo considerable enlargement from the recession of the brain. In advanced life they increase in size by absorption of the cancellated tissue in their vicinity. In their development they are practically formed from the diploë. Large frontal sinuses do not necessarily imply large external prominences over the glabella and superciliary eminences. They are lined by mucous membrane, this being continuous with that lining the middle meatus of the nose through the infundibula. This mucous membrane, like that which lines the antrum of Highmore, is notably thin and pale. Its blood supply is derived chiefly from the internal maxillary and ophthalmic arteries, and by anastomosis of these with the lateralis nasi branch of the facial artery. Its nerve supply is principally from the first and second divisions of the fifth cranial nerve. In the middle meatus of the nose the communication through the infundibulum of either side with the frontal sinus is partially hidden, and sometimes practically closed by a projecting fold of mucous membrane.

Diseases and Injuries.—Owing to the continuity of tissue and similarity of anatomical structure, the affections of this sinus, like those of the other accessory cavities of the nose, resemble to a greater or less degree those of the nasal fossæ proper. They may be conveniently grouped, for purposes of study, under the general headings of inflammations, acute and chronic (frontal sinusitis), and their sequelæ; tumors, the only primary forms described by modern authorities being osteoma and sarcoma; trauma of the sinus wall, which comprises fissure, fracture, impressions, etc., usually associated with hæmatoma of the sinus; and foreign bodies, which are nearly always projectile, but which also comprise insects and their larvæ. Generally speaking, the diseases of these sinuses occur with great infrequency, although trauma is of somewhat common occurrence, by reason of the exposed situation of the anterior sinus wall.

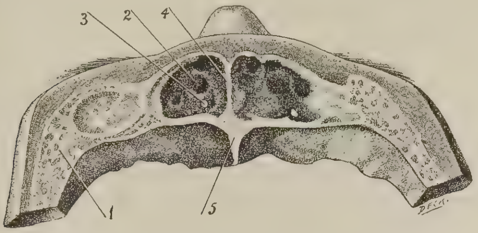

FIG. 2228.—Horizontal Section through the Frontal Sinus. (One-half actual size.) 1, Frontal bone; 2, frontal sinus; 3, aperture of the frontal sinus; 4, septum between the frontal sinuses; 5, frontal crest. (After von Mihalkovicz, in Heymann's "Handbuch der Laryngologie," etc.)

Sinusitis Frontalis.—The acute form of this disease generally results from the extension, by continuity, of a coryza, especially when the latter accompanies influenza. Acute sinusitis is frequently found in autopsies upon those who have died of acute infectious diseases. In this affection the mucosa becomes congested and œdematous, often to the extent of obliteration of the cavity. The exudate is usually purulent, but may be mucous or even serous. A fibrinous exudate is not known to occur.

Of the symptoms headache is the most constant. Constitutional reaction is indicated at times by the presence of fever, vertigo, vomiting, etc. Ocular reflexes are often seen, consisting of lachrymation, photophobia, colored vision, spectra, sense of pressure, etc. Œdema of the upper eyelid and exophthalmus are now known to occur at times.

The secretions, while they may escape to a greater or less extent into the nose, tend to accumulate, by reason of œdematous obstruction of the sinus outlet.

The disease supervenes suddenly in the majority of cases. Its course is brief and usually terminates at the end of the first week in the evacuation of the sinus and the subsidence of the inflammatory œdema which has produced more or less retention of the effusion within the cavity. In a certain proportion of cases, however, this favorable termination does not transpire and the disease then becomes chronic.

Acute sinusitis is often complicated by serious affections due to direct extension of the original malady. Periostitis is common, the orbital wall of the sinus being the principal sufferer in this respect. While this process may terminate in ulceration or necrosis of the bone, with resulting infection of the orbit, the fact is now well attested that the latter cavity may become inflamed without previous organic disease of the bony wall. This extension through osseous tissue without the serious participation of the latter is also seen in the endocranial lesions which occasionally follow acute frontal sinusitis. This mode of termination of the latter affection is attributable in most cases to phlebitis and thrombosis of the veins which traverse the walls of the sinus. In this manner the brain may be imperilled long before sufficient time has elapsed for organic perforation of the bone. Endocranial infection having once occurred, a variety of pathological processes may be set up, including extra- and intradural abscess, meningitis, encephalitis and cerebral abscess, thrombosis of the superior longitudinal sinus, etc.

Chronic frontal sinusitis, while a sequela, as a rule, of the acute affection, may be due exceptionally to one form or there may be several causes. It may undoubtedly result from the extension of an ozæna; or it may be due to a trauma affecting the sinus or its immediate vicinity. Syphilis, tuberculosis, and carcinomata which develop near the sinus may readily implicate the latter, although the present state of our knowledge enables us to state that these serious affections seldom or never originate in this cavity.

There is evidently some special principle involved in virtue of which an acute sinusitis may become chronic. When the sinus first becomes inflamed the anterior ethmoidal cells are usually implicated. When the sinusitis proper undergoes resolution, these accessory cavities may remain inflamed; and from this focus the chronic œdema and polypoid hypertrophy which characterize chronic sinusitis may readily develop. The irregularities which occur in the anatomy of these accessory cells should be reckoned with as factors in individual cases. Finally, one frontal sinus may infect its fellow through perforation of the septum, or this may occur even without any previous solution of continuity in the latter.

The constant pathological features of chronic sinusitis consist of œdema with a certain amount of polypoid hypertrophy. Fibrinous exudation, non-existent in acute sinusitis, may develop in time in the course of the evolution of the chronic type of inflammation.

From the clinical point of view, chronic frontal sinusitis presents two phases, according as the inflammation terminates in dilatation or in destruction of the bony walls and abscess. In the earlier stages of the process symptoms may fail entirely or they may be of the same character as those of the acute type (headache and numerous ocular disturbances of a reflex character).

In regard to chronic sinusitis with termination in dilatation, Killian [1] has collected and analyzed the entire recorded material (some sixty-four cases), with the following results: Dilatation of the sinus may develop at any time from the first to the twentieth year of the disease. The resulting cavity usually attains the size of a pigeon's egg, although it may exceptionally have the capacity of half a pint or more. The orbital wall is the one most disposed to yield to the pressure from within, although the entire bony capsule may suffer. The osseous structures may come to assume the thinness of parchment.

The secretions, the accumulation of which distends the sinus, are usually mucous or muco-purulent, while in rare instances they are serous in quality. The mucous variety is of especial interest, as it represents the condition often described under the name of *mucocele*. The idea of a separate disease with the latter designation appears to have originated in the peculiar qualities of the fluid, which is very tenacious and gelatinous and of variable color. Cholesterin crystals are sometimes obtainable from these collections. "Mucocele" has been held to be of cystic nature, and its inflammatory origin has been unsuspected by many writers. In about three-fourths of the cases of mucocele examined, the outlet of the sinus was accurately closed. Dilatation can occur in sinusitis

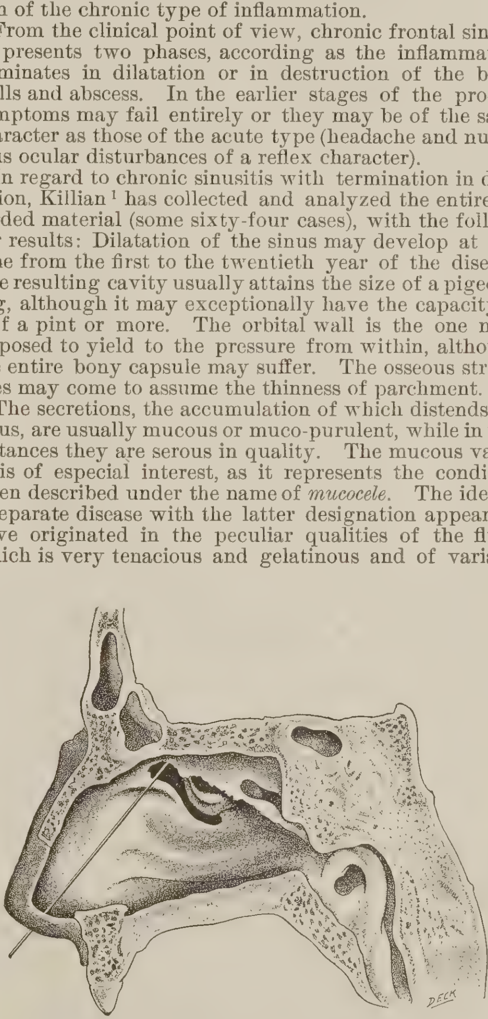

FIG. 2229.—Sagittal Section through the Frontal Sinus, Showing Probe Passed into the Sinus from the Middle Meatus. (After Lichtwitz.)

only in connection with the molecular absorption of bone.

The other mode of termination of chronic sinusitis, viz., in abscess and destruction of the sinus wall, appears to be nearly twice as common as that which is characterized by dilatation. Our knowledge of this destructive type is largely derived from Killian's analysis of the one hundred or more recorded cases. This aspect of sinusitis is eminently chronic, and in not more than a sixth of the cases did the destructive process manifest itself within the first year of the disease. We know that in these cases the sinus must have become infected in connection with an acute sinusitis; and thus the old "retention" hypothesis is rendered untenable.

The first organic change which takes place is ulceration of the lining membrane of the sinus. The denuded bone either becomes carious or secondary periostitis leads to necrosis, with expulsion of sequestra. In the majority of cases these organic changes affect the orbital wall of the sinus. Killian gives the localization as follows: Orbital wall, 66⅔ per cent.; cranial wall, 16⅔ per cent.; frontal wall, 16⅔ per cent.

As in acute sinusitis, a considerable percentage of cases of infection of the orbit and encephalon occur without demonstrable lesion of the bony wall. Of twenty cases of endocranial infection, the bone was perforated in seventeen. The lesion most commonly produced in these cases was cerebral abscess.

The symptoms of the destructive and purulent form of chronic sinusitis vary greatly. Pyorrhœa nasalis may be abundant and fœtid. Pain is often a conspicuous feature. Infection of the orbit, with or without perforation of the orbital wall, tends to the formation of an abscess. Swelling of the lids results, and displacement of the bulbus oculi produces diplopia. Rupture of the abscess produces a fistulous opening, the pus tending to accumulate in the conjunctival sac. The fistula causes shortening of the upper lid. Optic neuritis is occasionally seen as a complication.

The symptoms of endocranial infection closely resemble those which supervene in disease of the middle ear.

In the diagnosis of suspected dilating sinusitis—equivalent to the "latent" sinusitis of some authors—the practitioner should first cocainize the middle turbinate. A nasal speculum with blades adapted for inspection of the middle meatus will render good service in the hands of an expert. But the middle meatus may itself be the seat of inflammation and polypoid hypertrophy; and, furthermore, anatomical anomalies are very common, affecting the turbinates, septum, ethmoid cells, etc.; finally, the operator may not possess the requisite skill to obtain a view of the outlet of the sinus, so that as a routine procedure it is often advisable to resect a portion of the middle turbinate and then make use of the probe or cannula. In employing the probe we must bear in mind that there are at least two fatalities upon record, due to the perforation of the cranial floor by the instrument in question. Experienced operators advise practice upon the cadaver or upon an anatomical preparation, the instrument, a flexible silver probe, being bent at every possible angle to facilitate its introduction.

The old test for the presence of the probe in the sinus was one of mensuration, viz., as soon as the bent end of the instrument is an inch above the anterior process of the middle turbinate, it should be within the sinus. Within the past few years the employment of the Roentgen rays has assisted in the localization of the probe under these circumstances.

If a gush of pus follows the penetration of the probe into the outlet of the sinus, this occurrence might be regarded as *prima facie* evidence of latent empyema, were it not for the fact that certain anomalies of the ethmoid cells are known to occur, in consequence of which we may have to distinguish between frontal sinusitis and anterior ethmoiditis, which affections, more frequently than not, coexist.

If an escape of pus does not take place from probing, the fluid may sometimes be flushed out by substituting a fine cannula for the probe, and forcing air into the sinus.

Second only to the foregoing as a diagnostic resource is the presence of induced tenderness over the sinus. Headache, being a symptom of such common occurrence, is of little value in diagnosis. Tenderness may be elicited at the external and orbital walls of the sinus by percussion and palpation; but simple hypersensitiveness is not pathognomonic, because it has been encountered in hysteria. When tenderness of the orbital wall is associated with thickening due to periostitis, and when orbital cellulitis has already set in, the diagnosis is placed beyond doubt.

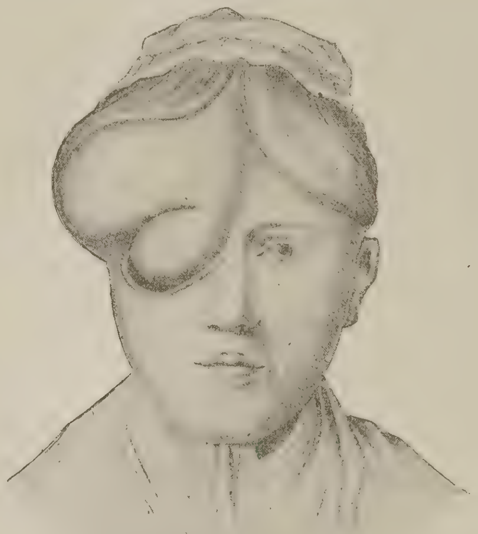

FIG. 2230.—Mucocele of the Right Frontal Sinus. Case of a girl seventeen years of age. (From Gerber's "Atlas der Krankheiten der Nase," Berlin, 1901.)

Chronic empyema of the frontal sinus may lurk beneath the picture of trigeminal neuralgia. Hajek[2] has especially noted this source of confusion in connection with influenza.

In dilatation of the sinus with resulting attenuation of its walls, a yielding and peculiar crackling sound have occasionally been elicited on pressure; these effects resembling those which result from compressing the lid of a tin box.

If the sinus cannot be probed through its outlet, the question of exploratory puncture of the sinus wall must be considered. Opening the floor of the sinus through the nose with an electric drill controlled by lateral illumination of the forehead with Roentgen rays (as advocated by Spiess) appears to be too hazardous a procedure. It is sometimes possible to open an infundibular cell which communicates with the sinus, and an exploratory puncture for this purpose may be safely essayed just in front of the middle turbinate. The method of transillumination of the sinus, while not trustworthy, has exceptionally proved of great diagnostic value. The establishment of an opening from without, for diagnostic purposes, is sometimes justifiable, especially if there is a prospect that the radical operation will be required.

Killian's diagnostic summary is as follows: Simple dilatation is recognized by the local deformity and displacement of the eye, the absence of pain, slow evolution, and parchment-like crackling or fluctuation. Exploratory puncture may be required to differentiate between dilatation and osteoma.

Ulceration is usually announced by circumscribed periostitis, abscess, perforation, fistula, or caries. Pressure over the sinus is often followed by an escape of pus into the nose. Liquids may be forced into the sinus through its intranasal outlet, and they may then escape by the fistulous opening.

Cerebral implication should be easy of recognition; but if this secondary disease pursues a latent course, diagnosis is impossible without laying open and inspecting the sinus cavity. Since the encephalon may be infected without the existence of a perforation, it is often necessary to expose the dura before coming to a definite conclusion. If the dura is healthly, it is extremely likely that the parts beneath are quite intact. If the dura is not in a healthy condition it must be laid open, unless spontaneous improvement follows its exposure. The presence of intrameningeal pus may then be discovered, and a fistula may show that the pus proceeds from a cerebral abscess. In any case the cerebral cortex should be carefully studied, and it may be advisable to puncture the brain for supposed abscess.

Treatment.—Acute sinusitis requires, as a rule, only expectant treatment, consisting of rest in bed; diaphoresis; warm applications to the brow; inhalation of steam; and the administration of such remedies as phenacetin, salol, etc. To the preceding may be added Politzerization and cocainization of the nose.

If these measures do not give relief, the middle turbinate should be resected and the sinus irrigated with warm saline solution. In those rare cases in which the acute formation of pus threatens the encephalon, the sinus should be laid open through its outer wall. It may also be necessary to enter the cranial cavity through the posterior wall of the sinus, split the dura, and give vent to an abscess in the frontal lobe of the brain; or even to extirpate a portion of the cortex. After intervention of this sort, thorough external drainage is all-important.

In chronic frontal sinusitis Hajek is a firm believer in the routine resection of the middle turbinate. He recommends this resource in any case of sinusitis, without regard to the degree or stage of the inflammation. Surgeons and ophthalmologists (and even many rhinologists) do not countenance such a radical procedure, save in special cases. Hajek believes that timely intervention through the nose would often prevent the occurrence of orbital and endocranial complications.

After suppurative complications have occurred, nothing of course is to be gained by resecting the turbinate.

In the majority of cases the operation of turbinectomy is tantamount to a radically curative procedure. Exceptions occur in those cases in which a high degree of destruction has transpired in the mucous lining or bony walls of the sinus.

The immediate results of extirpation of the middle turbinate is an increased amount of secretion. Not until one or two weeks have elapsed do we find a change in the character of the discharge, which then tends to consist of mucus alone. Some secretion remains in evidence for a longer or shorter interval, but in many cases it ceases by the end of the second month.

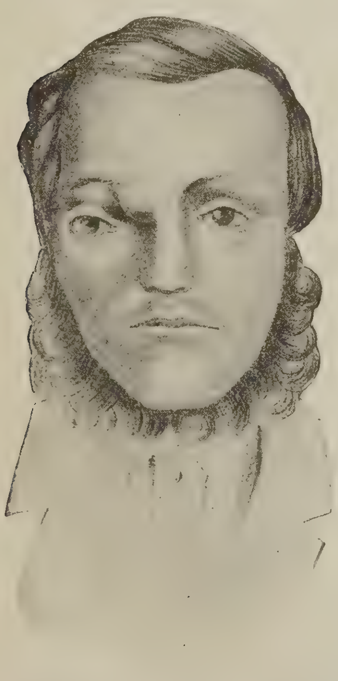

FIG. 2231.—Abscess of the Right Frontal Sinus. Case of a man, forty years of age. (From Gerber's "Atlas der Krankheiten der Nase," Berlin, 1901.)

Hajek has treated 27 cases of chronic empyema according to the principles just enunciated, and has been able to follow up his material indefinitely. In 9 cases the discharge ceased absolutely, while in 11 others it persisted in a mild form. The remaining 7 cases continued to discharge pus, but 4 of these were materially benefited. Hajek regards these figures as equal to the results of complete surgical destruction of the sinus. The patients naturally prefer the conservative form of intervention. Hajek uses the cold snare for the removal of the turbinate, and takes away about one-third of the bone.

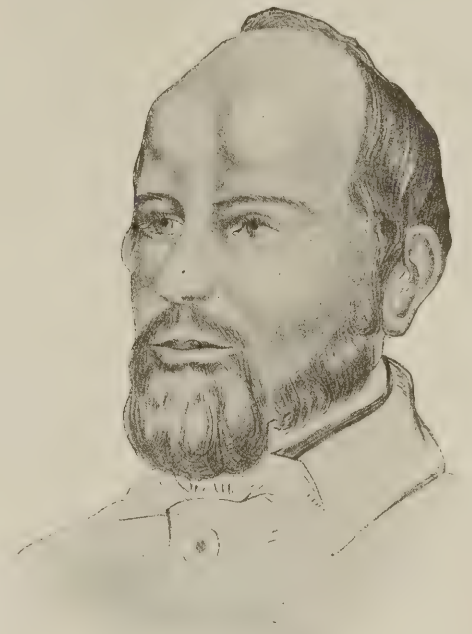

FIG. 2232.—Empyema of Both Frontal Sinuses, with the Formation of a Large Sequestrum of the Outer Plate of the Frontal Bone and of a Tumor Containing Air Beneath the Frontalis Muscle. (From Gerber's "Atlas der Krankheiten der Nase," Berlin, 1901.)

But the intranasal method, which requires special apparatus and skill in its use, has a limited range of applicability; and many surgeons are naturally disposed to regard it as inadequate to answer the indications. Certainly a great variety of procedures have been devised for entering the sinus from without. Originally surgeons had a natural repugnance to opening this cavity, and the earliest form of intervention consisted in following up a fistulous tract. Limited exposure, with application of the actual cautery, was the next step. To-day, the radical procedure of opening directly into the sinus is generally advocated.

Operative procedures have heretofore been divided into simple trephining and the radical operation. Kuhnt combines these two resources into two stages of one operation. For simple trephining, otherwise known as the preliminary or exploratory opening, for the sake of cosmetic effect, the preliminary incision should run from the naso-frontal suture for 3 or 4 cm. along the supraorbital margin, and should reach to the bone. The periosteum should then be pushed upward (often a very difficult procedure), and the sinus wall perforated with the aid of an electric drill and chisel. If the bone is healthy and the mucosa free from polypoid hypertrophy, it is sufficient to irrigate the sinus daily with antiseptics and dust it with iodoform until the opening has healed.
